Infants with meconium ileus are at increased risk for cholestasis, particularly if they have had, or are receiving TPN. Alkaline phosphatase, alanine aminotransferase, aspartate aminotransferase, and bilirubin should be monitored weekly. The fluid and nutritional status of infants who have had significant bowel resection (greater than one third) may be difficult to manage. In addition, the presence of an ileostomy may lead to excessive losses of fluid and sodium. Again, stomas should be closed as soon as possible. In the interim, if access to the distal, defunctionalized bowel is feasible, drip feeds of glutamine-enriched formula or instillation of the effluent from the proximal stoma may be tried at low volumes to enhance bowel growth and help prevent bacterial translocation.

Gastric acid hypersecretion is seen in patients who have short bowel syndrome.<sup>118</sup> An acidic intestinal environment inactivates pancreatic enzymes and prevents dissolution of enteric-coated microcapsules.

Histamine-2 (H<sub>2</sub>)-receptor antagonists or proton pump inhibitors may be used as an adjunct to pancreatic enzyme therapy in patients who have had significant bowel resections. Patients with excessive sweat and intestinal sodium losses may develop a total body sodium deficit. Urine sodium should be measured in infants with ileostomies, especially when there is failure to grow, even if serum sodium levels are normal. Those with urine sodium less than 10 mEq/L will need sodium (and possibly bicarbonate) supplementation.<sup>119</sup>

### Pulmonary Management

Although clinical lung disease does not usually develop early, mucus plugging and atelectasis can be seen. Prophylactic pulmonary care with chest physiotherapy is initiated immediately postoperatively. The head-down position should not be used because this increases the risk of gastroesophageal reflux and aspiration. Infants should receive nebulized albuterol (2.5 mg) twice a day followed by chest physiotherapy. Prophylactic antibiotics are not necessary, and antibiotic therapy is directed by respiratory tract cultures if needed.

### Prognosis

Prior to the mid 1900s, the prognosis for infants with meconium ileus was uniformly poor despite surgical treatment. Early reports showed mortality rates of 50% to 67%.<sup>70,71,105,106</sup> Improved survival in infants with meconium ileus can be attributed to many factors. Because of advances in prenatal diagnosis, pulmonary and neonatal intensive care, nutrition, antibiotics, anesthesia, operative management, and an improved understanding of the pathophysiology and treatment of the complications of CF, the prognosis for infants with both complicated and simple meconium ileus has improved dramatically.<sup>25,120</sup> Survival rates of 85% to 100% have been reported in uncomplicated meconium ileus<sup>4,86</sup> and up to 93% in complicated cases.<sup>4,70</sup>

Some argue that long-term follow-up of patients with meconium ileus shows pulmonary function at age 13 years to be no different between those born with meconium ileus and those without meconium ileus.<sup>25</sup> However, a recent prospective study found CF children with meconium ileus have worse lung function and more obstructive lung disease than those without meconium ileus.<sup>121</sup> Furthermore, comparison of the nutritional status of a similar population of patients with CF suggests that those who presented with meconium ileus suffer long-term nutritional complications as well as other problems.<sup>122</sup>

## MECONIUM PLUG SYNDROME

Meconium plug syndrome, a cause of newborn colonic obstruction, was first described in 1956.<sup>123</sup> It was hypothesized that either colonic motility or the character of the meconium was altered, thereby preventing normal passage and decompression of the colon in the newborn period. Under normal conditions, the

terminal 2 cm of neonatal meconium is firm in texture, forming a whitish cap. Most newborns pass this cap of meconium before, during, or shortly after delivery. One in 500 newborns will have a longer, more tenacious obstructive plug. Failure to pass this plug results in meconium plug syndrome and the term *plugged-up babies* was coined.<sup>123</sup>

The presentation of meconium plug syndrome is similar to that of meconium ileus. Signs include failure to pass meconium, bilious vomiting, and abdominal distention with an obstructive pattern on plain abdominal radiographs. Often, the meconium plug may become dislodged after digital stimulation of the anus and rectum. Fortunately, colon function is generally preserved and returns to normal after passage of the plug. Ultimately, most of these infants are found to be healthy.

Pathologic causes of meconium plug syndrome include CF, small left colon syndrome, and Hirschsprung's disease.<sup>118,124,125</sup> Less common causes include congenital hypothyroidism, maternal narcotic addiction, and neuronal intestinal dysplasia. Affected newborns should undergo contrast enemas, which may be therapeutic as well as diagnostic. After resolution, a sweat test should be performed to evaluate for CF and a thyroid-stimulating hormone level should be checked. All patients with slow passage of meconium require close observation of their stool pattern. Historically, a rectal biopsy has been recommended to rule out Hirschsprung's disease.<sup>77,118</sup> A recent report documents a 13% incidence of Hirschsprung's disease in a neonate with meconium plug syndrome. Therefore, a suction biopsy could be reserved for those neonates with an abnormal stooling pattern.<sup>126</sup>

## COMPLICATIONS OF MECONIUM ILEUS AND CYSTIC FIBROSIS

### Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) occurs with increased prevalence in patients with CF. Moreover, aspiration in children with CF may aggravate failure to thrive, may adversely affect pulmonary function, and may account for the predilection of CF lung disease for the right upper lobe.<sup>127,128</sup> Pathologic reflux with endoscopic and histologic esophagitis is present in over 50% of CF patients, and the incidence of GERD in patients with CF is approximately 81% in patients younger than 60 months.<sup>129</sup> Many children with CF lung disease are managed with theophylline, which causes a decrease in lower esophageal sphincter pressure and may contribute to the development of GERD.<sup>127</sup> It is clear that early diagnosis and treatment of this condition is of prime importance if the complications of pathologic reflux are to be curtailed and respiratory function maximized because reflux may also worsen the respiratory status of the CF patient.

Antireflux medications, modification of chest physiotherapy, and eliminating the 30-degree head-down tilt may all decrease the incidence of GERD in

this population.<sup>130</sup> Children unresponsive to medical management may benefit from a surgical evaluation for an antireflux procedure.<sup>129,130</sup> Our antireflux procedure of choice is a laparoscopic Nissen fundoplication. Recent data suggest that a fundoplication may improve respiratory function (improved FEV<sub>1</sub> slope) in CF children with mild versus moderate disease.<sup>131</sup> Patients with symptomatic reflux requiring an antireflux procedure may benefit from concurrent placement of a gastrostomy tube if inadequate caloric intake is a problem. Barrett's esophagus, a rare finding in children, has been reported in older children with CF.<sup>4,132</sup> Although an antireflux procedure may halt the advancement of metaplasia, if dysplasia is present the malignant potential remains.<sup>128</sup> Frequent endoscopic monitoring is the same for patients with CF as those without.<sup>133</sup> In adults, if high-grade dysplasia is confirmed by two pathologists and aggressive medical therapy fails to eliminate the dysplasia, esophagectomy is recommended. With so little data available in children with CF, it is reasonable to suggest that those patients with CF who have dysplastic esophageal changes should be evaluated for an antireflux procedure.<sup>128</sup>

### Biliary Tract Disease

Multiple macroscopic cysts may replace the pancreas in CF.<sup>30</sup> Although it was classically thought that hepatic and pancreatic dysfunction occurred together, hepatic dysfunction may occur in patients with maintained pancreatic function.<sup>128</sup> The most common hepatic complications of CF are steatosis, fibrosis, biliary cirrhosis, atretic gallbladder, cholelithiasis, sclerosing cholangitis, and biliary dyskinesia. Obstruction of intrahepatic biliary ductules by abnormal mucoid secretions or inspissated bile, resulting from absence of functional CFTR in bile duct epithelial cells, leads to cirrhosis in patients with CF.<sup>134</sup> The classic liver histology in CF is focal biliary fibrosis with progression to multilobular, biliary cirrhosis.<sup>134</sup> Prolonged cholestatic liver disease in CF patients may lead to cirrhosis, portal hypertension, and, ultimately, liver failure and death without liver transplantation.

Although more common in older patients with CF, intrahepatic cholestasis can be seen in the neonate. In extreme neonatal forms with early profound intrahepatic cholestasis, this process can be associated with a marked decrease in ductal diameter, varying from hypoplasia to atresia. Additionally, these neonates are at increased risk for cholestatic jaundice when they are not being fed enterally. This condition is suggested by prolonged jaundice unresponsive to choleretics, non-dilated bile ducts and gallbladder on ultrasonography, absent biliary excretion on nuclear scan, and characteristic liver biopsy.<sup>135-137</sup>

End-stage liver disease (ESLD) is manifest by loss of synthetic function, growth failure, or portal hypertension presenting as variceal hemorrhage.<sup>128</sup> Although abnormal results of liver function tests have been noted in 12.9% of CF patients, only 4.2% manifest overt liver disease.<sup>138</sup> However, the prevalence is reported as high as 37% depending on the definition of liver

disease.<sup>139</sup> Surgical portosystemic shunts, transjugular intrahepatic portosystemic shunts (TIPS), partial splenectomy, and endoscopic injection sclerotherapy have been advocated in treating CF patients with portal hypertension.<sup>140</sup> Other surgical options for these patients are direct ligation of the varices, esophageal transection, or the Sugiura procedure (gastric devascularization).<sup>141,142</sup> These procedures are all palliative. The only curative treatment for portal hypertension and ESLD is orthotopic liver transplantation.

Liver transplantation has been successfully carried out in CF patients with ESLD who did not have respiratory failure.<sup>128,140</sup> Successful reports exist of combined liver and intestinal transplantation, combined liver and pancreas transplant, kidney transplant after combined heart and lung transplants, and triple-organ transplant (pancreas, liver, and kidney) in patients with exocrine pancreatic insufficiency and insulin-dependent diabetes related to CF.<sup>4,143,144</sup> Liver, pancreas, kidney, intestine, and multiple-viscera transplantation are valid options for children with CF.

Gallbladder disease is prevalent in the CF population and includes cholelithiasis in up to 24%<sup>139,145</sup>; microgallbladder, atretic cystic duct,<sup>139</sup> abnormal cholecystograms in 46%<sup>146</sup>; and hyperviscous mucus.<sup>147</sup> Many CF patients with gallstones are asymptomatic,<sup>128</sup> with symptomatic gallbladder disease encountered in only approximately 4% of patients.<sup>148</sup> Ultrasonography (not computed tomography) is recommended in patients with CF<sup>139,149</sup> because the stones are radiolucent.<sup>148</sup> Bile in patients with CF is not cholesterol supersaturated, and the stones are composed of protein and calcium bilirubinate.<sup>145</sup>

Patients with symptomatic gallbladder disease (symptomatic cholelithiasis and acute cholecystitis) should undergo prompt cholecystectomy.<sup>149,150</sup> Experience with laparoscopic cholecystectomy is positive, and it is the recommended approach.<sup>4,151</sup> The incidence of common bile duct stones in CF is very low,<sup>149-151</sup> and routine intraoperative cholangiograms or preoperative endoscopic retrograde cholangiopancreatography is not usually needed.<sup>128</sup> In fact, the biliary tract abnormalities often encountered in patients with CF make penetration of radiocontrast dye into the biliary tract during endoscopic retrograde cholangiopancreatography difficult.<sup>139</sup> Intraoperative cholangiography is recommended if jaundice, pancreatitis, cholangitis, dilated common bile duct, or palpable stones in the common bile duct are present.<sup>128</sup>

## Distal Intestinal Obstruction Syndrome

Distal intestinal obstruction syndrome (DIOS, formerly called meconium ileus equivalent) is a recurrent, partial or complete intestinal obstruction unique to teenage and young adult patients with CF that occurs secondary to abnormally viscid mucofeculent material in the distal ileum and right colon.<sup>152-156</sup> The etiology of DIOS is unclear, but these patients are more likely to have a history of steatorrhea from pancreatic exocrine insufficiency, despite adequate enzyme therapy.

A number of aspects particular to gastrointestinal function of the CF patient may help to explain this syndrome. In addition to inherently slow intestinal motility, other contributing factors may include thickening of chyme secondary to the presence of undigested protein and fat,<sup>157</sup> precipitation of undigested protein and bile acids in duodenal fluid with reduced pH,<sup>157-159</sup> lower water content of pancreatic and duodenal secretions, hyperviscosity of mucus resulting from abnormal ion and water transport,<sup>158,159</sup> abnormal regulation of mucin secretion,<sup>160</sup> and altered biochemical properties of mucus glycoprotein.<sup>157-160</sup> Precipitating factors include sudden withdrawal of, or noncompliance with, adequate enzyme supplementation, immobilization, dehydration, respiratory tract infections, and recovery from surgery. However, in the majority of cases, no identifiable cause will be found.<sup>4</sup>

DIOS occurs in 15% to 37% of patients with CF, particularly those with associated pancreatic insufficiency with malabsorption and severe pulmonary limitation.<sup>124,161-168</sup> One study noted a 12% incidence in children with CF, but the majority (63%) had meconium ileus as an infant.<sup>4</sup> Children with normal fat absorption are rarely affected.

Patients with DIOS present with crampy abdominal pain often localized to the right lower quadrant and a decreased frequency of defecation. They may complain of an insidious, debilitating abdominal pain. Physical examination in uncomplicated DIOS usually reveals abdominal distention and a tender mass in the right lower quadrant with no evidence of peritonitis. Typically, there is no fecal impaction on rectal examination and the stool is Hemoccult negative. Different degrees of obstruction will be present, from partial, which is most common, to complete, with vomiting, abdominal distention, and obstipation.

A supine and erect abdominal radiograph is the most helpful initial investigation when DIOS is suspected (Fig. 33-9). This will show distended small bowel with scattered air-fluid levels and a granular, bubbly pattern of intestinal gas representing the mixing of air and inspissated meconium in the right lower quadrant similar to infants with meconium ileus.

Inspissated material in the right colon and distal ileum can be demonstrated with a water-soluble contrast enema. In doing so, ileocolic intussusception, which is also seen in CF patients, can be excluded and the investigation itself may prove therapeutic in some cases.

The diagnosis of DIOS must take into consideration other potential causes of abdominal pain and intestinal obstruction in CF patients. This constellation of signs and symptoms has historically been a diagnostic dilemma in patients with CF. Intussusception, mechanical small bowel obstruction due to adhesions, appendicitis, Crohn's disease, and biliary tract disease may present similarly.

In the absence of mechanical small bowel obstruction due to adhesions, intussusception, or appendiceal disease, a trial of medical management aimed at relieving the inspissated distal bowel obstruction is recommended. After adequate volume resuscitation

**Figure 33-9.** This 18-year-old with cystic fibrosis presented with crampy abdominal pain that was localized to the right lower abdomen. In addition, he also had a decreased frequency of defecation. **A**, The ground-glass appearance in the loops of bowel on the right side are typical findings in a patient with distal intestinal obstruction syndrome. **B**, The upright abdominal film shows air-fluid levels. This patient responded nicely to a contrast enema with relief of his symptoms.

and colonic enema washout, a balanced polyethylene glycol-electrolyte solution can be given orally or by nasogastric tube. The dose is 20 to 40 mL/kg/hr with a maximum of 1200 mL/hr. Alternatively, ingestion of a nonabsorbable intestinal lavage solution such as a hyperosmolar solution may produce the most striking results.<sup>169</sup> A single oral dose is successful in the majority of patients. Careful attention to the fluid status is vital. Oral administration of the hyperosmolar solution should be withheld in patients with preexisting dehydration, obstruction, or peritoneal signs. Younger patients will usually require nasogastric tube placement, whereas older children are able to ingest sufficient volumes of lavage solution to relieve the impacted material.

The passage of stool, resolution of symptoms, and the disappearance of a previously palpable right iliac fossa mass implies successful treatment. Sequential abdominal radiographs will help to document the resolution of DIOS, but if symptoms persist then the differential diagnoses already outlined must be considered. Some authors have recommended prophylaxis with the use of scheduled laxatives and high dietary roughage.<sup>124,161</sup>

When there is complete obstruction or evidence of peritonitis, surgical intervention is necessary and all oral or rectal therapies are contraindicated. A nasogastric tube should be placed to help with decompression and adequate resuscitative measures initiated. At laparotomy, the bowel wall will feel thickened and filled with tenacious material. It can be decompressed and irrigated with hyperosmolar solution through a small catheter placed through the appendiceal stump, as previously described for uncomplicated meconium ileus. It is also possible to leave an irrigating tube in situ to irrigate the bowel postoperatively. Some children may require lysis of adhesions and/or bowel resections with either a primary anastomosis or creation of an ostomy.<sup>4</sup>

## Appendicitis

Abdominal pain is a common complaint of patients with CF. Because they are often already being treated with antibiotics and corticosteroids, the classic clinical signs and symptoms of appendicitis are often masked and the diagnosis missed. This results in a high incidence of perforation and substantial morbidity in this patient group. Despite the blunting of clinical signs, there may still be evidence of fever and leukocytosis. Depending on the location of the appendix, a contrast enema may show deformity of the cecum with an associated mass effect and not the typical inspissated material features of DIOS. Abdominal ultrasonography or computed tomography will show free fluid or an abscess collection in the region of the cecum. In such cases of perforated appendicitis, treatment should then proceed with percutaneous drainage of the abscess and interval appendectomy. Appendectomy is required in acute nonperforated appendicitis. If the diagnosis is still in doubt, diagnostic laparoscopy may be indicated. Many surgeons perform incidental appendectomy during other abdominal operations.

## Intussusception

Intussusception occurs in approximately 1% of children with CF with the average age at onset being 9.5 years.<sup>170</sup> In contrast, the average age at onset in children with idiopathic intussusception in the general pediatric population is 6 to 18 months.<sup>126</sup> Toddlers and older children presenting with intussusception and a history of recurrent pulmonary infections should be tested for CF.<sup>127</sup> The most common site for intussusception is ileocolic, but it may be ileoileal, cecocolic, or colocolic.<sup>128</sup> The abnormally thick stools adhering to the bowel wall or the appendix may act as a lead point.<sup>170,171</sup> Controversy exists over conservative management of intussusception in CF patients, with

some reporting high rates of successful hydrostatic reduction<sup>172</sup> in the majority of patients. However, others report poor results.<sup>170</sup> If the intussusception is unable to be reduced operatively, bowel resection with anastomosis is necessary. Regardless, the appendix should be removed at operation in cases of intussusception.<sup>170</sup>

## Fibrosing Colonopathy

Fibrosing colonopathy is a result of colonic strictures, and these children present with the signs and symptoms of DIOS.<sup>112,113,153,173-175</sup> Findings include colonic strictures with histopathologic changes of post-ischemic ulcer repair, an erythematous cobblestone appearance to the mucosa, mucosal and submucosal fibrosis, and destruction of the muscularis mucosa. In some patients, a change from conventional enteric-coated pancreatic enzymes to high-strength products 12 to 15 months earlier has been described. In the largest case-control study reported, the absolute dose of pancreatic enzymes, rather than the type of enzyme, was the strongest predictor of fibrosing colonopathy.<sup>176</sup>

The diagnosis of fibrosing colonopathy should be considered in CF patients who have been exposed to high doses of pancreatic enzymes and present with symptoms of abdominal pain, distention, chylous ascites, change in bowel habit, or failure to thrive. Continued diarrhea may also be a prominent feature, which unfortunately may prompt the family to increase supplemental enzymes further. On occasion, the diarrhea may be bloody. A barium enema may reveal mucosal irregularity, loss of haustral markings with a foreshortened colon, and varying degrees of stricture formation. In some cases the whole colon is involved. Colonoscopy may show an erythematous mucosa and areas of narrowing, from which it is advisable to take multiple biopsy samples.<sup>173</sup>

Initial management should include reduction of the enzyme dosage to the recommended levels of 500 to 2500 lipase units/kg per meal. This should be accompanied with adequate nutritional supplementation, which may be enteral elemental feeding or even TPN for a time. Those patients who show signs of unrelenting failure to thrive, obstruction, uncontrollable diarrhea, or chylous ascites will need surgical intervention.

When surgery is planned electively for patients with intractable symptoms, a gentle bowel preparation can be given preoperatively. The aim of surgical

intervention is to resect the affected bowel and perform a primary anastomosis. Unfortunately, this is not possible in the event of total colonic or rectal involvement. As a result the patient may require an ileostomy or colostomy. It is also not clear if this condition completely resolves with a reduction in enzyme dosage and surgical resection. Therefore, the operated group also requires regular follow-up for any signs of deterioration or recurrence.

## CONCLUSION

The operative mortality in patients with CF has decreased considerably in the past 3 decades. The average mortality rate for meconium ileus and peritonitis was 55% in the 1960s and 1970s.<sup>177</sup> During this time there was a significant decrease in survival in the first year of life compared with those patients with CF who did not have meconium ileus.<sup>178</sup> After the first year, survival among infants with meconium ileus approached that of other infants with CF. Over the past few years, these statistics have improved dramatically. There are now reports stating a 100% early survival and 86% late survival in 42 patients with meconium ileus<sup>127</sup> and a 91.6% survival for uncomplicated meconium ileus and 85% for complicated cases at 1 year.<sup>70</sup> Most recently, survival for patients with simple meconium ileus was reported at 93% (early 100%, late 93%) and that for those with complicated meconium ileus at 89% (early 96%, late 93%).<sup>4</sup>

Discussing the long-term needs of the patient with meconium ileus means discussing the long-term needs of a patient with CF. A multidisciplinary approach to the management of the surgical patient with CF, including respiratory care, nutrition support, and pancreatic enzyme therapy, allows for a low operative morbidity and mortality. Children with meconium ileus need long-term follow-up because they are prone to develop DIOS and fibrosing colonopathy. Furthermore, patients may be more prone to develop mechanical bowel obstructions later in life if operated on as an infant for meconium ileus.<sup>4</sup> Other late complications of meconium ileus, including gallstones, cirrhosis of the liver, and male sterility, may also be viewed as late complications of CF in general.<sup>4</sup> Many patients with CF are now surviving into the third and even fourth decades of life, and many of the surgical complications of CF occur later in life.

# NECROTIZING ENTEROCOLITIS

Marion C. W. Henry, MD, MPH • R. Lawrence Moss, MD

The earliest reports of necrotizing enterocolitis (NEC) in the United States originated in the early 1960s.<sup>1,2</sup> Santulli and his colleagues published the first significant surgical experience with NEC when they described a disease of low birth weight infants with high mortality rates that required early, aggressive surgical management.<sup>1</sup> In the half-century since these early reports, many investigators have devoted careers to helping better define this challenging disease and improve our strategies of treatment and prevention. Despite these efforts, NEC remains a difficult and elusive disease. We continue to struggle to best delineate which premature infants are most at risk, to maximize our prevention strategies, to determine the optimal treatment strategies, and to understand and treat the long-term sequelae faced by survivors of this disease.

## EPIDEMIOLOGY

Several large population-based studies have found incidence rates of 0.7 to 1.1 cases of NEC per 1000 live births and occurrence rates of 3% to 7% in selected populations (Table 34-1). An 8-year population-based study in the state of New York found an average annual incidence of 0.72 case per 1000 live births. The highest incidence was in those infants weighing 750 to 1000 g, and this incidence decreased with increasing birth weight.<sup>3</sup> A database query of 98 neonatal intensive care units (NICUs) in 24 states across the United States found an NEC rate of 3% among infants of 23 to 34 weeks' gestational age. In this group, low birth weight was the most significant risk factor for NEC.<sup>4</sup> The Vermont Oxford network reported rates of 6% to 7% between 1991 and 1999.<sup>5</sup> A study of 17 tertiary NICUs in Canada found an incidence of 6.6% stage 2 NEC among very low birth weight (VLBW) infants, defined as weight less than 1500 g, and 0.7% among those weighing more than 1500 g. NEC was associated with lower gestational age and birth weight, with the highest incidence in the group weighing less than 1000 g.<sup>6</sup>

Rates have remained stable for VLBW infants cared for at centers of the National Institute of Child

Health and Human Development (NICHD) Neonatal Research Network. Between 1999 and 2001, 7% of VLBW infants developed proven NEC. Half of these infants required surgery.<sup>7</sup> A database of neonatal hospitalizations in 2000 found a rate of 1.1 cases of NEC per 1000 live births.<sup>8</sup> These studies all showed that the incidence of NEC and its fatality rates increase with decreasing birth weight and gestational age.<sup>3,6-9</sup>

Mortality from NEC remains high, with rates ranging from 15% to 30%.<sup>3,4,7-10</sup> Higher fatality rates are associated with lower birth weight and younger gestational age.<sup>9,10</sup> In a study summarizing trends for mortality and NEC in the United States between 1979 and 1992, there were 6692 deaths from NEC or an average of 474 deaths per year.<sup>10</sup> This equaled a death rate of 12.4 deaths per 100,000 live births. The highest mortality was in VLBW infants who were black and male.<sup>3,8,10</sup>

Although the majority of cases of NEC are managed medically, 20% to 40% will require surgical intervention.<sup>4,6,9,11</sup> The mortality rate markedly increases when surgical intervention is necessary and has been reported to be as high as 50%. The highest fatality rates in this subgroup are also in the lowest birth weight and youngest gestational age infants.<sup>12</sup>

NEC is primarily a disease of prematurity, with over 90% of cases occurring in preterm infants. However, there are occasional reports of NEC in full-term infants. Although the clinical and pathologic findings are similar in preterm and term infants, the initiating factors are likely different. Term infants who develop NEC are more likely to have predisposing risk factors such as congenital heart disease, respiratory disease, or reported hypoxic events.<sup>13-16</sup> A study from a multi-hospital health care system between 2001 and 2006 found that 0.5% of term infants developed stage II or greater NEC.<sup>14</sup>

## PATHOPHYSIOLOGY

Despite recent insights into the multifactorial pathogenesis of NEC, a complete understanding of its pathophysiology remains elusive. The classic histologic findings of inflammation and coagulation necrosis are present

**TABLE 34-1** Population-Based Epidemiologic Studies on Necrotizing Enterocolitis (NEC)

Author	Year	Population	No. Studied	No. NEC	%	Rate per 1000 Live Births	Fatality Rate
Llanos	2002	New York State	117,892	85		0.72	19%
Guthrie	2003	Pediatrix Medical group	15,072 (23-34 wks gestation)	390	3%		12%
Sankaran	2004	Canadian Neonatal network	18,234 (3628 VLBW)	336	7% VLBW	1.8	
Luig and Lui	2005	New South Wales NICU Study	4649 (24-31 wks gestation)	178	4%		30%
Guillet	2006	NIHCD Neonatal research network	11,936 VLBW	787	7% VLBW		24%
Holman	2006	Hospital discharges in USA: 2000—children inpatient database	Sample of all neonatal hospitalizations (4,058,814 live births)	4464		1.1	15%

VLBW, very low birth weight.

in over 90% of surgical specimens.<sup>17</sup> As patients progress along the clinical spectrum of suspected NEC to advanced stage III disease, radiologic and clinical findings also give hints as to the pathologic processes that are unfolding. The development of pneumatosis intestinalis (air within the intestinal wall) is thought to be due to gas produced by overgrowth of enteric bacteria.<sup>18</sup> The progression to portal venous or lymphatic gas suggests extension of the process along vessels draining the affected intestine. Pneumoperitoneum indicates necrosis with complete disruption of the intestinal wall.

As greater understanding into the pathophysiology of NEC evolves, a unifying concept is emerging that allows for a working model to understand the many factors that play a role in the pathogenesis of this complex disease. This unifying concept is based on the concept that NEC represents an overexuberant or inappropriate inflammatory response to some type of insult. The nature of this insult is not defined. It may be a global ischemic insult from congenital heart disease, an infectious insult from abnormal bacterial colonization, an insult related to formula feeding or the absence of any enteral feeding, or simply the response of translocation of normal bacterial flora in a genetically predisposed host.

This insult leads to a disruption of the intestinal epithelial barrier, with translocation of bacteria, which subsequently results in an exaggerated or inappropriate response, likely owing to the immature nature of the intestine. Stress pathways become activated, and perhaps even overactivated, whereas pathways that normally suppress the immune system are inhibited. The end result is the activation of the host immune system and the release of circulating cytokines, leading to a global and detrimental inflammatory response.

## The Intestinal Barrier

The pathologic features of NEC suggest that failure of the intestinal barrier is crucial in its development. Therefore, an understanding of the critical components

of the normal intestinal barrier, and how these components differ in the immature intestine, may lead to a better understanding of the pathogenesis of NEC. The normal intestinal barrier is composed of both mechanical and nonmechanical factors that contribute to its impermeable nature. The mechanical factors include intestinal peristalsis, the mucous coat, and tight junctions between epithelial cells.

## Intestinal Motility and Digestion

Intestinal motility normally develops during the third trimester of pregnancy but may not be fully mature until the eighth month of gestation.<sup>19-22</sup> The mechanical action of intestinal motility not only aids in digestion but also serves as the first step in epithelial barrier integrity by limiting the amount of time any substance is in contact with the surface of the enterocytes. In premature infants, the immature intestinal motility leads to an increased exposure of the epithelium to potentially noxious substances with poor clearance of bacteria and subsequent bacterial overgrowth. Additionally, the immature intestine has decreased nutrient digestion and absorption, which may lead to direct epithelial injury through a lowered pH level.<sup>23-25</sup>

Other studies suggest that increased ileal bile acid levels may play a role in the pathogenesis of NEC. The accumulation of bile acids in the intestinal lumen and in enterocytes may be due to immature levels of the ileal bile acid-binding protein, which is crucial for transporting bile acids through the enterocyte and into the portal circulation,<sup>26</sup> as well as suppression of these bile acid transporters by proinflammatory cytokines such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ).<sup>27-29</sup> Two other risk factors for NEC also may contribute to abnormal bile acid levels. Formula feeding elicits more toxic bile acids than breast feeding,<sup>30</sup> and the formation of secondary bile acids, which have been found in animals with NEC, requires bacterial-induced deconjugation.<sup>31</sup>

### The Mucous Coat

The mucous coat overlying the intestinal epithelium plays a key role in the barrier function of the epithelium. The mucous layer is composed of water, mucin, lipids, and peptides, such as trefoil factor.<sup>32</sup> The glycoprotein mucin, as well as the peptide trefoil factor, is secreted by goblet cells interspersed within the epithelial layer.<sup>33-35</sup> Mucin aids in lubrication, mechanical protection, protection against the acidity of gastric and duodenal secretions,<sup>36</sup> and fixation of pathogenic bacteria, viruses, and parasites.<sup>37</sup> The effectiveness of mucin as a protectant is related to the maturity of the mucin,<sup>36</sup> because mature mucins have a higher viscosity, better pH buffering, and resistance to breakdown by bacteria.<sup>36-38</sup> The amount of mucin production, as well as its composition, also changes with gestational age, bacterial challenges, and colonization by commensal organisms.<sup>39</sup> Immaturity of goblet cells may also lead to a deficiency in the production of mucus.<sup>40,41</sup> Deficits in the production or composition of mucin may contribute to the ability of bacteria to invade the intestinal epithelium and thus contribute to the pathogenesis of NEC.<sup>32,42-44</sup>

### Tight Junctions

Tight junctions create fusion points between epithelial cells, thus forming an intact barrier that maintains the semipermeable properties of these cells. Mature tight junctions are composed of the transmembrane proteins occludin, claudin, and junctional adhesion protein.<sup>45</sup> Immaturity in the composition of tight junctions likely plays a role in some of the increased permeability of the epithelium in the newborn intestine.<sup>46</sup>

Additionally, cytokines that are produced in response to bacteria and their products, such as lipopolysaccharide, may also interfere with tight junctions, promoting the translocation of bacteria.<sup>47</sup> Inflammatory mediators such as TNF, interferon (IFN)- $\gamma$ , and interleukin (IL)-1 $\beta$  further cause epithelial dysfunction by upregulating inducible nitric oxide synthase (iNOS), overproducing nitric oxide (NO), and generating the reactive nitrogen intermediate peroxynitrite (ONOO<sup>-</sup>), which has been associated with increased epithelial cell apoptosis and death.<sup>48</sup> NO has been shown to play a role in mediating the decrease in the localization and expression of tight junction proteins as well as occludin.<sup>49</sup> Disruption of tight junctions by these inflammatory mediators may lead to increased intestinal permeability that gives way to bacterial translocation and the activation of the immune system.

### Immunologic Defenses of the Gastrointestinal Tract

The gastrointestinal tract contains the greatest amount of lymphoid tissue in the body and coordinates the immunologic defense mechanisms of both the adaptive and innate immune systems.<sup>50</sup> The gut-associated lymphoid tissue (GALT) consists of lymphocytes, macrophages, dendritic cells, M cells overlying Peyer's

patches, and Paneth cells in the crypts. Macrophages and dendritic cells act as the antigen-presenting cells while M cells and epithelial cells may also play a role in presenting antigens to resident lymphocytes.<sup>51</sup>

In neonates, the processing and presenting of antigens is less efficient, thus reducing the ability of the immune system to respond to pathogenic organisms. Peyer's patches are also fewer and smaller and lack germinal centers in preterm infants, thus impairing the systemic and intestinal immune system.<sup>32</sup> Paneth cell activation by bacteria or components of bacterial cell walls leads to secretion of a variety of antibacterial substances, primarily  $\alpha$ -defensins, which play an important role in selecting and limiting the growth of both pathologic and commensal bacteria.<sup>52,53</sup> Thus the decreased production of these peptides in premature infants may predispose infants to bacterial overgrowth, allowing NEC to develop.

IgA is normally synthesized by plasma cells of the lamina propria and secreted into the mucin layer where it binds bacteria and viruses so that they cannot attach to the epithelium. Neonates can also obtain IgA through passive transfer from breast milk. The newborn lamina propria is largely devoid of the IgA-secreting plasma cells, which may contribute to the susceptibility of the newborn to mucosal infections.<sup>54,55</sup>

### Regenerating the Intestinal Barrier

The pathologic findings of NEC arise not only from alterations in the integrity of the intestinal barrier but also from an impaired ability to regenerate properly.<sup>56</sup> Premature infants have a reduced capacity for intestinal repair, and this may contribute to the pathogenesis of NEC.

### Lipopolysaccharide

Lipopolysaccharide (LPS) is the endotoxin portion of the gram-negative bacterial cell wall. It is one of the most abundant proinflammatory stimuli in the gastrointestinal tract and has been seen in high levels in clinical NEC.<sup>18</sup> LPS impairs intestinal barrier function by causing inhibition of intestinal restitution and by promoting the release of signaling molecules such as NO and IFN- $\gamma$  from enterocytes.<sup>57</sup> LPS increases the activity of signaling molecule RhoA, which leads to an inhibition in cell movement.<sup>56</sup> LPS also causes an increase in the expression and function of integrins on the cell surface, resulting in an increase in cell adhesion to the basement membrane.<sup>58</sup> LPS stimulates the release of proinflammatory cytokines, including NO, IFN- $\gamma$ , and cyclooxygenase-2 (COX-2), which promote intestinal injury through direct cytopathic effects on the enterocytes.<sup>59,60</sup> LPS also compounds the effects of platelet-activating factor (PAF).<sup>61,62</sup>

### Nitric Oxide

NO is a key mediator of numerous physiologic and pathologic systems. Low levels of NO may be important for maintaining vasodilation, but excessive levels

of NO can lead to the production of toxic nitrogen intermediates. Thus, NO has competing and dose-dependent roles in intestinal physiology.

NO is a highly reactive free radical formed by the conversion of arginine to citrulline by NO synthase (NOS), of which three isoforms exist.<sup>63</sup> These three isoforms include the constitutive neuronal isoform, nNOS, the inducible isoform, iNOS, and the constitutive endothelial isoform, eNOS. The presence of the constitutive forms of NOS in the gastrointestinal tract suggests that NO has a normal physiologic role in gut function. The constitutive calcium-dependent eNOS isoform maintains intestinal homeostasis by enhancing mucosal blood flow and maintaining microvascular tone and will be discussed later.<sup>64</sup>

Whereas low levels of NO may play a homeostatic role in the gastrointestinal tract, when it is produced by iNOS under inflammatory conditions in high concentrations, NO may lead to cellular damage and failure of the intestinal barrier. Excess NO reacts with superoxide anion ( $O_2^-$ ) to produce the highly toxic ONOO-, which causes much of the cytopathic damage that is attributed to NO.<sup>65,66</sup> The activities of NO may be compounded in the presence of high levels of LPS, which leads to increased iNOS expression and function within the intestine.<sup>66,67</sup>

Studies have linked NO with the pathogenesis of NEC. The expression of iNOS has been shown to be upregulated in critically ill patients and in patients with NEC.<sup>48,68</sup> NO may also inhibit intestinal restitution by blocking enterocyte migration.<sup>57,69</sup>

### **Platelet-Activating Factor**

PAF is an endogenous phospholipid mediator of inflammation that is produced by inflammatory, endothelial, and lamina propria cells.<sup>70</sup> PAF has a short half-life and is regulated by the PAF-degrading enzyme acetyl hydrolase (PAF-AH). The cytotoxic effects of PAF are likely due to reactive oxygen radical formation. PAF-induced bowel injury is associated with the production of oxygen-derived free radicals and with neutrophil migration, activation, and capillary leakage.<sup>71</sup>

Various studies have shown the importance of PAF in the pathogenesis of NEC. Higher concentrations of PAF have been found circulating in NEC patients compared with age- and disease-matched controls.<sup>72,73</sup> PAF-AH activity has been shown to be deficient in sick infants with NEC, and the administration of PAF-AH in animal models of NEC reduces the degree of intestinal injury.<sup>72,74</sup>

## **Maintaining Intestinal Barrier Homeostasis**

### **Epidermal Growth Factor**

Epidermal growth factor (EGF) plays an important role in the development, maturation, and maintenance of gut homeostasis.<sup>75-80</sup> Additionally, EGF is important in the prevention and treatment of inflammatory conditions. EGF enemas given to patients with left-sided

colitis have been shown to be effective treatment, resulting in significant improvement in the scoring of disease activity and histologic grading of injury compared with controls treated with a placebo.<sup>81</sup>

Other studies have shown that EGF has a role in adaptive bowel regeneration after intestinal loss. After 50% small bowel resection in mice, salivary EGF levels were increased with increased enterocyte receptor (EGFR) activity, which is the receptor on which EGF acts.<sup>82</sup> Sialoadenectomy before bowel resection resulted in an inhibition of this response, but exogenous EGF administration resulted in rescue.<sup>83</sup> Mice with a dysfunctional EGFR have an impaired adaptation response, whereas those with overexpression of EGFR or stimulation of EGFR have improved adaptation.<sup>84-88</sup>

EGF is believed to play an important role in the pathogenesis of NEC. Decreased levels of EGF have been demonstrated in the saliva and serum of premature infants with NEC.<sup>89</sup> Furthermore, additional studies have shown that salivary levels of EGF in the first 2 weeks of preterm life may have a predictive value for the occurrence of NEC.<sup>90</sup> Mice that are unable to express EGFR either die in utero or shortly after birth from hemorrhagic enteritis that closely resembles NEC in humans.<sup>91</sup> A potentially therapeutic role for EGF was reported on an infant suffering from intestinal necrosis resembling NEC who received a continuous infusion of EGF that resulted in the complete recovery of the damaged intestine.<sup>92</sup> These investigators subsequently treated a small group of neonates with stage II and III NEC in a randomized, double-blind, prospective trial with recombinant EGF and found that repair of the intestinal epithelium was seen at 4, 7, and 14 days, as inferred from rectal biopsy specimens.<sup>93</sup> One limitation of this study, however, is the extrapolation of changes in the distal colon to the upper intestine.

EGF may also have a role as a potential preventive strategy for NEC. In a mouse model of NEC, supplementation with EGF has been shown to decrease the incidence of NEC, downregulate the production of inflammatory cytokines, and decrease apoptosis at the site of injury.<sup>94-96</sup> The enteral administration of EGF appears to decrease the overproduction of the proinflammatory mediator IL-18 and increase production of the anti-inflammatory cytokine IL-10 in the ileum.<sup>48</sup> Therefore, EGF may have a protective effect by altering the balance of these pro- and anti-inflammatory cytokines in the pathogenesis of NEC. EGF may also play a role in decreasing bacterial translocation from the intestine, another key factor in the pathogenesis of NEC.

## **Neonatal Vasculature and the Pathogenesis of NEC**

The newborn intestinal circulation is characterized by a low resting vascular resistance, particularly in comparison with older subjects.<sup>97,98</sup> This results in a relative increase in blood flow and oxygen delivery. The control of this vascular resistance involves both intrinsic and extrinsic control mechanisms.<sup>99</sup> The extrinsic mechanisms are mediated by the autonomic nervous

system. The intrinsic regulation is mediated by two vascular effector mechanisms produced and released within the intestine—one vasoconstrictive and one vasodilatory.<sup>100,101</sup> Endothelin (ET)-1 is the primary vasoconstrictor stimulus in the newborn intestine and is produced by the endothelium.<sup>102,103</sup> Although constitutively produced, it can also be stimulated by decreased flow, hypoxia, and various inflammatory cytokines.<sup>104-106</sup> The production of ET-1 is age specific, being greater in younger subjects.<sup>102</sup>

NO is the primary vasodilator stimulus in the newborn intestinal circulation.<sup>97,98</sup> eNOS is also continuously produced, but like ET-1 the rate of production can be increased in response to a variety of stimuli.<sup>100</sup> In the neonate, the balance of these two products favors vasodilation due to an increased production of NO, thus generating the characteristic low vascular resistance. In pathologic states, however, endothelial dysfunction leads to ET-1–mediated vasoconstriction, which can cause compromised blood flow, intestinal ischemia, and injury (Fig. 34-1). The vasoconstrictor ET-1 has been linked to intestinal tissue injury in several studies.<sup>102,107</sup> Increased expression of ET-1 has been found in intestine removed from infants with NEC, and the amount of ET-1 increased proportionally to the degree of intestinal injury.<sup>101</sup>

In summary, the intestinal circulation of the newborn is unique, with a dynamic balance between constrictor (ET-1) and dilator (NO) stimuli maintaining basal vascular resistance. Disruption of the intestinal

endothelial function can alter the delicate balance, favoring ET-1–dependent vasoconstriction over the normal state of vasodilation, leading to significant intestinal ischemia and tissue injury.

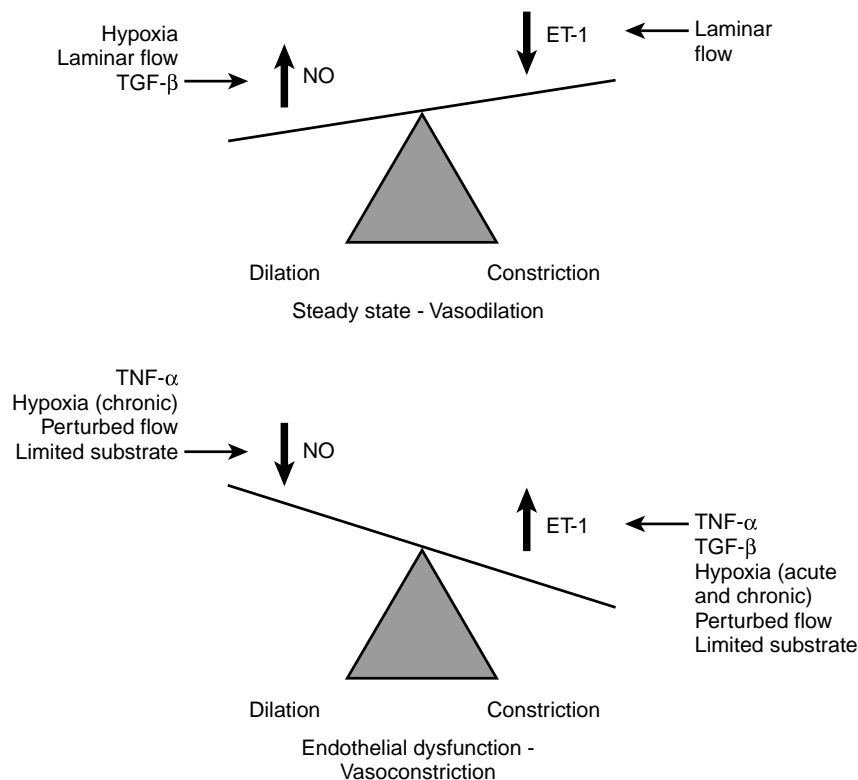

## Bacterial Colonization

NEC most commonly is diagnosed during the second week of life, after intestinal colonization has been established. Therefore, bacteria likely play a role in the pathogenesis of NEC. Not attributable to a single infectious agent, NEC more likely arises from an unfavorable balance between commensal and pathogenic bacteria.

Abnormal colonization may alter the balance of pathogenic and beneficial bacteria, favoring an increase in pathogenic bacteria and resulting in a loss of the beneficial role of commensal bacteria. This could lead to an increase in the inflammatory response due to a loss of the inhibition that commensal bacteria provide. Furthermore, the immature immune system of premature infants may not be able to respond appropriately to normal colonization of bacteria, much less abnormal flora.<sup>108</sup>

## CLINICAL DIAGNOSIS

The diagnosis of NEC is based on clinical findings as well as characteristic radiographic findings. The clinical course can vary from a slow, indolent process to

**Figure 34-1.** Characterization of the dynamic balance between nitric oxide (NO) and endothelin-1 (ET-1) in determining intestinal vascular resistance in the newborn. Many exogenous stimuli play a role in the regulation of NO and ET-1. Under steady-state conditions, the balance heavily favors vasodilation secondary to the copious production of endothelium-derived NO. However, endothelial dysfunction would alter the balance, thus favoring ET-1–mediated vasoconstriction leading to ischemia and tissue injury.

one that progresses rapidly to death in a few hours. Early signs are nonspecific, including apnea, bradycardia, lethargy, and temperature instability. Feeding intolerance, demonstrated by high gastric residuals, and occasionally bilious vomiting, is the most common gastrointestinal symptom of NEC. The most common presenting sign is abdominal distention. Gross or occult blood in the stool may be found.

The gastrointestinal signs progress from initial abdominal distention to tenderness suggestive of peritoneal irritation. Palpable loops of intestine may become evident as the ileus worsens. Localized disease may progress to generalized peritonitis or may worsen in a focal area with evidence of severe disease, including discoloration or ecchymotic changes of the skin and the presence of an abdominal mass

**Figure 34-2.** An infant with NEC. Note the abdominal wall ecchymosis extending from the suprapubic region to above the umbilicus and laterally to the flanks.

(Fig. 34-2). When they are present, the findings of a fixed abdominal mass and erythema of the abdominal wall are strongly predictive of NEC. However, these findings are present in only 10% of patients with NEC.<sup>109</sup> Ascites may also become evident on physical examination as the disease progresses. A sudden need for increased ventilatory support that cannot otherwise be explained may also serve as a harbinger of NEC.<sup>110</sup> This is due to increased metabolic requirements in combination with increased intra-abdominal pressure.

Confirmation of the diagnosis of NEC combines the signs and symptoms described earlier with radiologic findings that are described later. All of the findings have been combined into the clinical staging system proposed by Bell that aids in describing the severity of disease (Table 34-2).<sup>111,112</sup>

### Laboratory Studies

Laboratory studies reveal nonspecific indicators of an inflammatory or infectious process such as leukocytosis with bandemia. Thrombocytopenia and metabolic acidosis are also common. A rapid fall in platelet count is a poor prognostic factor.<sup>113</sup>

Several studies have tried to identify an accurate biochemical marker that might identify neonates who are at risk for NEC, thus avoiding prolonged periods without enteral nutrition as well as the use of unnecessary tests and antibiotics.<sup>114</sup> Serum acute phase proteins and cytokines have been investigated for an association with high levels and the severity of a course of NEC. Increased levels of IL-6, IL-10, and C-reactive protein (CRP) have been documented in premature infants with NEC, with the highest levels of IL-10 in those patients who did not survive.<sup>115</sup> CRP has also been associated with NEC when the levels rose quickly after the diagnosis was suspected. A failure of the levels to return to normal was also associated with complications, including abscesses, strictures, and sepsis.<sup>116</sup> In a prospective study, CRP levels were elevated in infants with stage II and III NEC and might

**Table 34-2** Modified Bell's Staging for NEC

Stage	Clinical Findings	Radiographic Findings	Gastrointestinal Findings
I—Suspected	Apnea, bradycardia, temperature instability	Gas pattern of mild ileus	Increased gastric residuals, occult blood in stool, mild abdominal distention
IIa—Definite	Apnea, bradycardia, temperature instability	Ileus gas pattern with one or more dilated loops, focal pneumatosis	Grossly bloody stools, prominent abdominal distention, absent bowel sounds
IIb	Thrombocytopenia, mild metabolic acidosis	Widespread pneumatosis, ascites, portal venous gas	Abdominal wall edema with palpable loops and tenderness
IIIa—Advanced	Mixed acidosis, oliguria, hypotension, coagulopathy	Prominent bowel loops, worsening ascites, no free air	Worsening wall edema, erythema and induration
IIIb	Shock, deterioration in laboratory values and vital signs	Pneumoperitoneum	Perforated bowel

be useful in discriminating between stage II NEC and other gastrointestinal disorders.<sup>117</sup>

Activation of the Thomson-Friedenreich cryptantigen (TCA), a naturally occurring antigen on red blood cells, occurs when *N*-acetyl neuraminic acid is cleaved from a bacterially produced neuraminidase. Such activation, in the setting of NEC, is diagnostic of the involvement of neuraminidase-producing anaerobic organisms and correlates with the severity of disease.<sup>113</sup>

Multiple other potential markers have been studied—gastrointestinal tonometry, urinary D-lactate levels, exhaled breath hydrogen, endotoxin elevations in stool, plasma intestinal fatty acid binding proteins—but none of these has yielded the sensitivity or specificity required for a diagnostic tool.<sup>58,118-120</sup> Currently, no biochemical markers have been adequately predictive of the patient's clinical course or outcome to be clinically useful.

## Radiographic Findings

### Radiography

The cornerstone of the radiographic diagnosis of NEC relies on standard anteroposterior and cross-table lateral or left lateral decubitus radiographs. The most specific radiographic finding is pneumatosis intestinalis, either cystic or linear, as seen in [Figure 34-3](#). Other radiographic findings that are often found include air-fluid levels, gas-filled loops of bowel, persistently dilated loops of bowel, thickened bowel walls, portal

venous gas, and pneumoperitoneum. Although most commonly seen in NEC, pneumatosis intestinalis has also been reported in cases of Hirschsprung's enterocolitis, severe diarrhea, and carbohydrate intolerance. Portal venous gas ([Fig. 34-4](#)) is a less common radiographic finding but is generally considered a poor prognostic sign. Several studies have noted a high incidence of diffuse or "pan" necrosis associated with portal venous gas and a high associated mortality rate. Nevertheless, many patients with portal venous gas recover fully with medical management.

### Other Imaging Modalities

Although plain radiography is the current standard for diagnosing and evaluating NEC, recent studies have examined ultrasonography as an adjunctive measure for the diagnosis and management of infants with NEC. Abdominal ultrasound evaluation emerged as a potential modality in the treatment of NEC after a report in 2005 that assessed bowel viability using color Doppler imaging in neonates with NEC.<sup>121,122</sup> This publication established critical data for bowel wall thickness, echogenicity, peristalsis, and perfusion in both normal neonates and those with NEC. Additional studies corroborated the usefulness of ultrasonography as a means of diagnosing NEC.<sup>122,123</sup> Ultrasonography offers some potential advantages over radiography in that it can depict bowel wall thickness and echogenicity, free and focal fluid collections, peristalsis, and the presence or absence of bowel wall perfusion by using Doppler imaging.<sup>124-126</sup>

**Figure 34-3.** Pneumatosis intestinalis (arrows) is seen on this abdominal radiograph.

**Figure 34-4.** Portal venous gas (arrow) is seen on this radiograph.

The presence of pneumatosis on plain abdominal radiographs helps clinch the diagnosis in cases of suspected NEC. However, in the setting of nonspecific, possibly mild findings and radiographs without intramural gas, the diagnosis may be more difficult. Abdominal ultrasonography may be a useful adjunct in this population because it may be able to detect small amounts of intramural gas not visible on plain films or changes in bowel wall thickness, peristalsis, or perfusion that could confirm or exclude the diagnosis of NEC.<sup>127</sup> The time frame for when to perform ultrasonography initially or when to use it during follow-up has not been established.

In addition to assisting with the diagnosis in difficult cases as just described, ultrasound evaluation has been suggested as an adjunct modality in two other groups of patients: those in whom the evolution of changes in the radiographs does not match the clinical course and those whose condition is deteriorating without evidence of pneumatosis on plain films.<sup>127</sup> Finally, some have suggested that ultrasonography may be useful in helping to decide the appropriate time to re-initiate and advance feeding.<sup>122</sup> At this time, ultrasonography does not yet have a well-defined or established role in the management of NEC.

Contrast examinations of the gastrointestinal tract in the acute setting, computed tomography, and magnetic resonance imaging have not been found to be clinically useful modalities in clinical practice in treating infants with NEC.<sup>128-132</sup>

## DIFFERENTIAL DIAGNOSIS

The most clinically relevant differential diagnosis in a premature infant with abdominal distention is distinguishing between NEC and sepsis with ileus. In the absence of clinical signs of peritonitis or radiographic signs of NEC, the two conditions may well be clinically indistinguishable and only differentiated after observing the course of the disease. The differential diagnosis also includes other conditions that may cause abdominal distention, including Hirschsprung's disease, ileal atresia, volvulus, meconium ileus, and intussusception.

A subset of premature infants presents with bowel perforation while not exhibiting any other symptomatology of NEC nor pneumatosis on radiographs. Some investigators have defined this as spontaneous, isolated, or focal intestinal perforation (FIP). FIP tends to occur in extremely low birth weight infants, very early in life (usually the first 7-10 days), and sometimes in association with indomethacin treatment.<sup>133-139</sup> Whether these infants have a "limited" form of NEC or a distinct entity is controversial. Some reports contend that FIP is a different disease than NEC, but definitive evidence is lacking.<sup>138-141</sup> As expected, neonates with a bowel perforation have better outcomes in the absence of extensive disease.<sup>137,142,143</sup> Increasing recognition of the differences between these entities may warrant an improved classification of neonatal intestinal diseases and new criteria for their description.<sup>144</sup>

## MEDICAL MANAGEMENT

Medical management of NEC begins with the suspicion of disease. Infants are initially treated with bowel rest, gastric decompression, intravenous fluid resuscitation, and broad-spectrum antibiotic therapy, including anaerobic coverage. Blood, urine, and sputum cultures should be obtained before the initiation of antibiotic therapy. Adjunctive therapy such as cardiovascular support with pressors, pulmonary support with oxygen and ventilation, and hematologic support with the transfusion of blood products may all be necessary. A critical component of medical management is ongoing close observation with serial abdominal examinations and serial radiographs. As long as the clinical situation is stable or improving, expectant management can continue. Clinical deterioration or worsening radiographic features may indicate the need to consider surgical intervention.

### Experimental Medical Treatments—Heparin-Binding EGF

Heparin-binding EGF-like growth factor (HB-EGF) is a member of the EGF family. Endogenous HB-EGF is increased in response to hypoxia, stress, and during wound healing.<sup>145-150</sup> HB-EGF mRNA is induced after intestinal ischemia/reperfusion injury *in vivo*<sup>151</sup> and is involved in epithelial cell repair, proliferation, and regeneration in the early stages after injury.<sup>152</sup> Based on these findings that endogenous HB-EGF is involved in the promotion of healing, it has been theorized that exogenous HB-EGF may also play a role protecting the intestinal mucosa from injury.

Multiple studies have demonstrated that exogenous administration of HB-EGF can protect cells and organs from injury both *in vitro* and *in vivo*. HB-EGF can protect enterocytes from proinflammatory cytokine-induced apoptosis<sup>153</sup> and renal tubule cells from acute oxidant-induced apoptosis.<sup>154</sup> Intestinal epithelial cells pretreated with HB-EGF before hypoxia showed less necrosis with maintenance of the cytoskeletal structure and improved recovery ability.<sup>155</sup> HB-EGF also downregulates the production of NO<sup>156,157</sup> and blocks (NF-κB) activation in intestinal epithelial cells after cytokine stimulation.<sup>157</sup> In a neonatal rat model of NEC, the administration of HB-EGF reduced the severity and incidence of NEC with preservation of gut barrier integrity.<sup>158</sup> These findings were consistent with studies showing EGF reducing the severity and incidence of NEC, decreasing the overproduction of IL-18 and increasing the production of anti-inflammatory IL-10.<sup>159</sup> HB-EGF is the only compound with imminent plans for investigation in humans. A host of other therapeutic agents have shown promise but not yet reached the stage of clinical testing.

## Surgical Management

Although many infants can be managed medically, 20% to 40% will require surgical intervention. In some cases, indication for operation develops during

observation, while in others it is found at presentation. The only absolute indication for surgical intervention is evidence of intestinal perforation either on abdominal radiograph or via paracentesis that is positive for stool or bile.<sup>160</sup> Relative indications for surgical intervention include deterioration of the infant's clinical condition despite maximal medical management. Findings can include oliguria, hypotension, worsening metabolic acidosis, worsening thrombocytopenia, leukopenia or leukocytosis, and ventilatory failure. Radiographic relative indicators for surgical intervention include portal venous gas or persistently abnormal "fixed" loops of bowel on serial radiographs.

Ideally, surgical intervention would occur when intestinal gangrene is imminent but before actual perforation or necrosis occurs. However, this theoretical ideal time for intervention has been difficult to identify; thus, perforation has consistently been considered the only absolute indication for surgery. One study has tried to evaluate the sensitivity and specificity of 12 different findings in an attempt to identify earlier indicators for surgery.<sup>109</sup> Three findings had specificity and a positive predictive value (PPV) close to 100% with prevalence greater than 10%. These were deemed "best" indications and included pneumoperitoneum, portal venous gas, and positive paracentesis (Table 34-3). Three indicators had specificity and PPV close to 100% but prevalence less than 10%. These indicators were, therefore, considered "good" and included a fixed loop on abdominal radiograph, erythema of the abdominal wall, and a palpable abdominal mass. One indicator, severe pneumatosis, was deemed "fair" because it had a specificity and PPV above 90% and 20% prevalence. The five remaining indicators were considered "poor" because the specificities were less than 90% and the PPVs less than 80%. This probability analysis can be used to assist in the complex decision-making process of when surgical intervention is warranted.

NEC can affect any segment of the gastrointestinal tract. Most commonly, both large and small bowel are involved.<sup>17</sup> Isolated small intestinal lesions occur with

the next greatest frequency. It is as common to have a single affected area as to have multiple-segment disease.<sup>17,161,162</sup> A small subgroup of NEC patients may have massive necrosis of the entire intestine, known as "NEC totalis."<sup>161</sup>

Traditional surgical management has consisted either of laparotomy with limited resection of the affected bowel and the creation of stomas or of peritoneal drainage. Much of the attention of surgical investigators of NEC has focused on the relative benefits of these procedures.

Peritoneal drainage was first reported in 1977 as a salvage treatment for perforation in VLBW infants who were believed to be too unstable for laparotomy (Fig. 34-5).<sup>163</sup> Initially, this strategy was intended as a temporizing procedure in the sickest and smallest patients. However, it rapidly evolved into a widely utilized option for primary treatment of perforated NEC. After many years of conflicting results comparing outcomes of the two approaches, a meta-analysis was attempted to synthesize these disparate data into a treatment recommendation. This study found such significant bias in the assignment of patients to one treatment or another that the techniques could not be adequately or effectively compared.<sup>164</sup> A need existed for a prospective randomized controlled trial.

Three prospective studies have recently evaluated laparotomy and peritoneal drainage to determine which surgical procedure is associated with better outcomes. The NICHD Neonatal Research Network conducted a prospective observational cohort study at 16 centers.<sup>165</sup> In this study, 156 infants with either NEC or FIP underwent either laparotomy or drainage. Overall 50% (n = 78) of the patients died and 72% (n = 112) either died or had some element of neurologic impairment at 18 to 22 months. The patients in this study were not randomized to their treatment groups. The treating surgeons and neonatologists chose which therapy to use for each infant. However, unlike other nonrandomized studies, extensive prospective data were collected, allowing for risk-adjusted

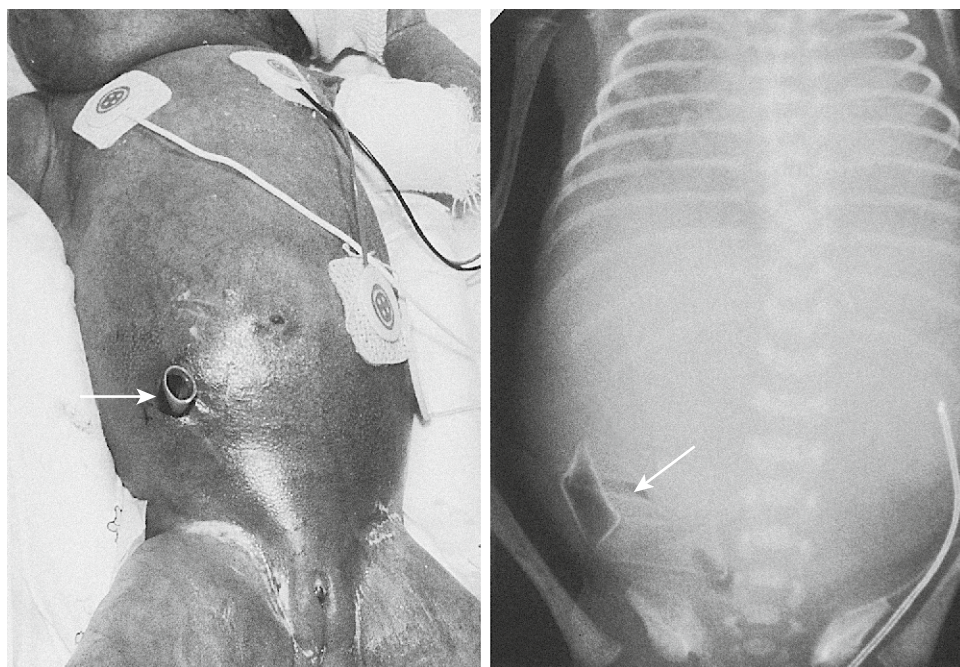

**Table 34-3** Probability Analysis of Various Indications for Operation in NEC (%)

Indication	Sensitivity	Specificity	PPV	NPV	Prevalence
Pneumoperitoneum	48	100	100	52	31
Portal venous gas	24	100	100	43	16
Fixed loop (on radiograph)	12.5	100	100	46	7
Fixed abdominal mass	12.5	100	100	46	7
Erythema of abdomen	8	100	100	45	5
Positive paracentesis*	87	100	97	60	72
Severe pneumatosis	31	94	91	43	20
Clinical deterioration	39	89	78	59	25
Platelet count < 10 <sup>5</sup>	38	83	73	54	28
Severe gastrointestinal hemorrhage	12	83	50	42	14
Abdominal tenderness	29	72	58	43	29
Gasless abdomen/ascites	0	94	0	41	2

PPV, positive predictive value; NPV, negative predictive value.

\*Positive paracentesis was defined as brown fluid and/or bacteria noted on Gram stain.

From Kosloske AM: Indications for operation in necrotizing enterocolitis revisited. *J Pediatr Surg* 29:663-666, 1994.

**Figure 34-5.** A micropremature infant with NEC and perforation is shown with her corresponding abdominal radiograph. A percutaneous drain (arrows) has been placed in the right lower quadrant for drainage of the intestinal perforation. Note that the drain is placed at a position below the level of the umbilicus to avoid injury to the lower edge of the right lobe of the liver.

multivariable regression analyses to be performed. This strategy enabled the investigators to account for the differences between the treatment groups. The odds ratio for death after adjusting for differences in the two treatment groups was 0.97 for laparotomy compared with peritoneal drainage (95% confidence interval [CI]: 0.43-2.20). The odds ratio for the combined outcome of death or neurodevelopmental impairment at 18 to 22 months was 0.44 for laparotomy compared with drainage (95% CI: 0.16-1.2). Although not statistically significant, there is some suggestion in this study that overall outcomes at 18 to 22 months of age may be improved by laparotomy rather than drainage.

The first randomized trial evaluating laparotomy versus peritoneal drainage was the NECSTEPS trial.<sup>166</sup> In this trial, 117 VLBW infants at 15 North American tertiary care centers were randomized to either treatment group. The primary outcome variable was mortality at 90 days. There was no difference in mortality at 90 days between the two treatment groups (34.5% vs. 35.5%) (Fig. 34-6). Secondary outcomes were the need for parenteral nutrition at 90 days and the length of hospitalization and were also similar between the two groups. This study only focused on short-term outcomes. However, within those limits, the results suggest that the method of surgical intervention does not impact the outcome.

A second randomized trial comparing laparotomy and peritoneal drainage in infants with perforated NEC has also been completed.<sup>167</sup> The NET trial was a multinational trial conducted at 31 centers in 13 countries. The primary outcome variable was mortality at 1 and 6 months. Sixty-nine patients weighing less than 1000 g were enrolled and randomized. There was a trend toward better survival in the laparotomy group (65% survival) compared with the drainage group (51%),

with a relative risk of mortality of 0.5 (95% CI: 0.2-1.5). These findings were not statistically significant, with a *P* value of 0.2, but the sample size does limit their power to detect a difference. The authors concluded that there was no evidence from the trial to support the benefit of primary peritoneal drainage in extremely LBW infants with intestinal perforation.

Overall, both of these randomized trials suggest that the method of surgical management does not affect the ultimate outcome of infants with perforated NEC. The impact of choice of operation on the outcome of infants who underwent operation for an indication other than perforation is not known. Most commonly, these infants are treated with laparotomy.

When laparotomy is performed, stomas are usually created. Because of concerns about the high morbidity associated with enterostomies, a few centers have advocated primary anastomosis at the time of initial laparotomy. The data, however, to support such management are nonrandomized and retrospective. In actuality, the majority of stomal complications are easily managed and early closure is well tolerated.<sup>168</sup> One study found that survival was 72% with intestinal diversion but only 48% in those undergoing primary anastomosis.<sup>169</sup>

Diffuse intestinal involvement poses the most difficult situation for the surgeon. Those infants who survive may develop short bowel syndrome and have some level of dependency on total parenteral nutrition given the extensive amount of affected bowel. Surgical strategies focus on trying to preserve as much intestine as possible while still resecting enough bowel to stabilize the patient. Second-look laparotomies have been proposed as a way to minimize the amount of bowel resected.<sup>170</sup> The “clip and drop back” technique is another option with a similar strategy.<sup>171</sup> All nonviable

**Figure 34-6.** Survival outcomes of patients treated by laparotomy and peritoneal drainage in the NECSTEPS trial. There was no difference in mortality at 90 days between the two treatment groups.

intestine is resected initially but no ostomies or anastomoses are created. Blind-ending segments are left in the abdomen, and continuity is restored or ostomies are created on re-exploration in 48 to 72 hours. Proximal diversion alone has also been used to treat “pan” necrosis without reported worsened survival and with recovery of much of the bowel by the time of ostomy closure.<sup>172</sup> However, none of these approaches has been prospectively evaluated. Thus, no single technique can be strongly advocated.

## OUTCOMES

### Recurrence

Recurrence can occur after NEC, although the incidence is low, only occurring about 5% of the time.<sup>173,174</sup> There is no apparent correlation between the site of disease and the site of recurrence. Usually recurrent disease can be managed nonoperatively.<sup>160,174-179</sup>

### Length of Hospitalization

Hospital stays are longer for infants who suffer from NEC when compared with other infants of the same gestational age. Furthermore, those who require surgical intervention tend to have even longer and more expensive hospitalization. Multiple studies have shown hospital stays averaging 2 to 3 months for medically treated NEC and 4 to 5 months for surgically treated NEC.<sup>180-182</sup> There was no difference in length of hospitalization between the two treatment groups in the NECSTEPS trial.<sup>166</sup>

### Mortality

Estimates of mortality from NEC have remained steady over the past 2 decades at 15% to 30% despite the fact that the postsurfactant era has led to a rise in the incidence of disease.<sup>3,4,7-10,180,181,183,184</sup> Surgical mortality has seen improvement though, with a decline from 70% mortality in the 1960s<sup>185</sup> to more recent rates of 20% to 50%.<sup>4,8,10,180,183,186,187</sup> The main predictor of mortality in NEC is gestational age. As

mentioned previously, the highest mortality occurs in the youngest, smallest infants and black male VLBW infants are at greatest risk. Additionally, infants with a greater extent of bowel affected by the disease tend to also have a higher mortality rate.<sup>188,189</sup> Patients who were discharged from their primary hospitalization had more than an 80% chance of long-term survival.<sup>180</sup>

## Gastrointestinal Outcomes

### Short Bowel Syndrome

NEC is the leading disease responsible for short bowel syndrome in children, accounting for half of all pediatric cases. Furthermore, short bowel syndrome develops in a fourth of all patients who suffer from NEC.<sup>190</sup> This condition develops when an infant is left with inadequate intestine to absorb enteral nutrients that are required for growth. Inadequate intestine can result from the extent of the resection at the time of operation or from poor function of the remaining intestine. Traditional teaching based on early reports has suggested that a minimum of 40 cm of small intestine is required for a patient to have a chance of weaning from total parenteral nutrition.<sup>191</sup> Despite these observations, experience has shown that the functional outcome is much more important to this disease rather than the specific length of intestine.

The portion of intestine resected is also important for subsequent gastrointestinal functioning. Patients with ileal or jejunal disease have a higher mortality rate than those with colonic disease.<sup>187,188,192,193</sup> Patients with extensive jejunal resection fare better than those with extensive ileal resection. These outcomes are due to the differing abilities of the intestinal regions to undergo adaptation. The ileum has the greatest capacity to undergo adaptive changes and increase its absorptive capacity. Therefore, infants who undergo jejunal resection but retain their ileum are much better off compared with those who have an ileal resection.

Preservation of the ileocecal valve has been considered important for minimizing the risk of short bowel syndrome.<sup>194</sup> Some studies have suggested that dependence on parenteral nutrition is lessened when

the ileocecal valve was preserved,<sup>195-198</sup> but others have found no difference.<sup>180,199-202</sup> Recent data suggest that the actual length and functional capacity of the remaining ileum is far more important than the presence of the valve itself.

**Stoma Complications**

Creation of a properly constructed stoma can be life-saving in the management of NEC. Stomas are used for both decompression and diversion. However, enterostomies can also be fraught with early and late complications. Thus, a number of strategies have been proposed for optimal stoma creation, including what type of stoma to create as well as how to exteriorize the stoma (Table 34-4). End stomas, double-barrel (Mikulicz) stomas, and a loop enterostomy have all been advocated. However, small studies comparing complication rates between these various strategies have not found differences in complications, including retraction, prolapse, hernias, or wound infections.<sup>203-205</sup> Many surgeons bring the stoma and mucous fistula out through the surgical incision, some at one end, others at opposite ends of the incision. Others advocate a separate incision, citing concerns about increased incidences of wound infection. Another consideration for a separate incision is whether the stoma needs to remain for a prolonged period of time.<sup>203</sup> Most surgeons do not recommend maturing a stoma owing to potential interference with an already tenuous blood supply.<sup>203</sup>

Stomal complications of both the small and large intestine can lead to significant morbidity (Table 34-5). Studies have shown complication rates exceeding 50%.<sup>187,206-209</sup> The most serious complications include prolapse, stricture, and retraction, all of which may require surgical intervention. Proximal jejunostomies can cause significant electrolyte and fluid losses that can lead to problems with fluid balance and weight gain.<sup>194,210</sup> Furthermore, fluid losses from jejunostomies can cause peristomal skin complications. However, with an aggressive approach to fluid and electrolyte replacement and meticulous skin care, proximal jejunostomies can be a viable option for the management of NEC.<sup>194,211</sup>

 Dehydration

The timing of enterostomy closure remains controversial. Recommendations vary from as early as 1 month to as late as 4 months after surgery.<sup>212-215</sup> Most suggest waiting 1 to 2 months after the initial operation, and until a weight of 2000 g is reached, as long as adequate feeding and growth is being maintained.<sup>194,210,213</sup> Earlier closure may be necessary with very proximal stomas due to fluid and electrolyte losses and inability to gain weight. Coexisting medical problems must also be considered in determining the optimal time to closure.

**Intestinal Strictures**

Intestinal strictures are a common occurrence after both medically and surgically managed NEC. The incidence of stricture formation has been reported from 12% to 35%.<sup>130,207,216-221</sup> This incidence does not differ between patients treated by primary anastomosis or enterostomies.<sup>160,186,187,199,206,207,212,215-227</sup> In one series of patients treated for severe NEC by proximal diverting enterostomy, the incidence was 55%.<sup>217</sup> Most post-NEC strictures occur in the colon, specifically the left colon (Fig. 34-7).<sup>161,212,219,226,228</sup>

Resection of strictures is standard management, although not all lesions are symptomatic and spontaneous resolution has been reported.<sup>130,224,229,230</sup> Therefore, other approaches have been proposed, including close radiographic follow-up of asymptomatic patients.<sup>130</sup> Balloon catheter dilatation has also been tried for focal, nonobstructing lesions, although this technique has not been studied in a large number of patients.<sup>230</sup>

Patients who have been treated by laparotomy and stoma creation for NEC should undergo routine imaging of the distal intestine before enterostomy closure to evaluate for a possible stricture. However, patients managed medically, by peritoneal drainage, or with primary anastomosis may also develop strictures. Some patients remain asymptomatic and others present acutely in distress due to perforation.<sup>219</sup> Cautionary tales of these acute incidences presenting after completion of medical treatment have led some surgeons to advocate routine contrast studies in these NEC patients.<sup>130,218,219,221</sup> However, the potential for

**Figure 34-7.** This contrast enema demonstrates a stricture in the left colon (arrow) after medical treatment for NEC.

false-negative results and the invasiveness of the procedure prevent this practice from being common.

Despite a relatively high incidence of stricture formation after NEC, little evidence exists regarding the impact of this complication on long-term outcomes. For those infants requiring ostomy closure, strictures can usually be addressed at that time. For those managed without ostomies initially, stricture resection requires a new operation with subsequent prolongation of recovery and time to full enteral feeding. Resection of additional bowel may also ultimately impact gastrointestinal functional outcomes.

## Growth

Impaired growth rates may be a long-term problem after NEC. Several small observational studies have shown that children treated for NEC fall below the 50th percentile for height and weight even into their grade-school years.<sup>231-233</sup> Although not all studies have had the same findings,<sup>234,235</sup> this growth retardation seems particularly to affect those who suffered from stage III NEC. Additionally, the problem is much more severe in those children who develop short bowel syndrome as a result of NEC. Long-term evaluations of growth are required to evaluate the impact that birth weight, NEC severity, operative strategy, and subsequent outcomes may play in ultimate growth outcomes for these children.

## Neurodevelopmental Outcomes

In infants surviving NEC, adverse neurodevelopmental outcomes remain an important challenge. Concerns were first raised in a groundbreaking study in 1980 that reported that less than half of children surviving NEC were neurodevelopmentally normal at 3-year follow up.<sup>236</sup> Subsequently, multiple observational studies have cited “intellectual delays,”<sup>237</sup> “moderate-to-severe developmental delay with speech and motor impairment,”<sup>183</sup> “developmental delay requiring special educational classes,”<sup>231</sup> and delays in “locomotor,” “hearing and speech,” “intellectual performance” and “personal and social” skills.<sup>234</sup>

A large multicenter cohort study from the NICHD Neonatal Research Network evaluated neurodevelopmental outcomes in 1100 extremely low birth weight survivors.<sup>238</sup> This study confirmed that NEC is associated with increased odds of having a delayed score on psychomotor developmental assessment as well as increased odds of cerebral palsy. This study found that almost all of these abnormalities occurred in patients with surgically treated NEC.<sup>239</sup>

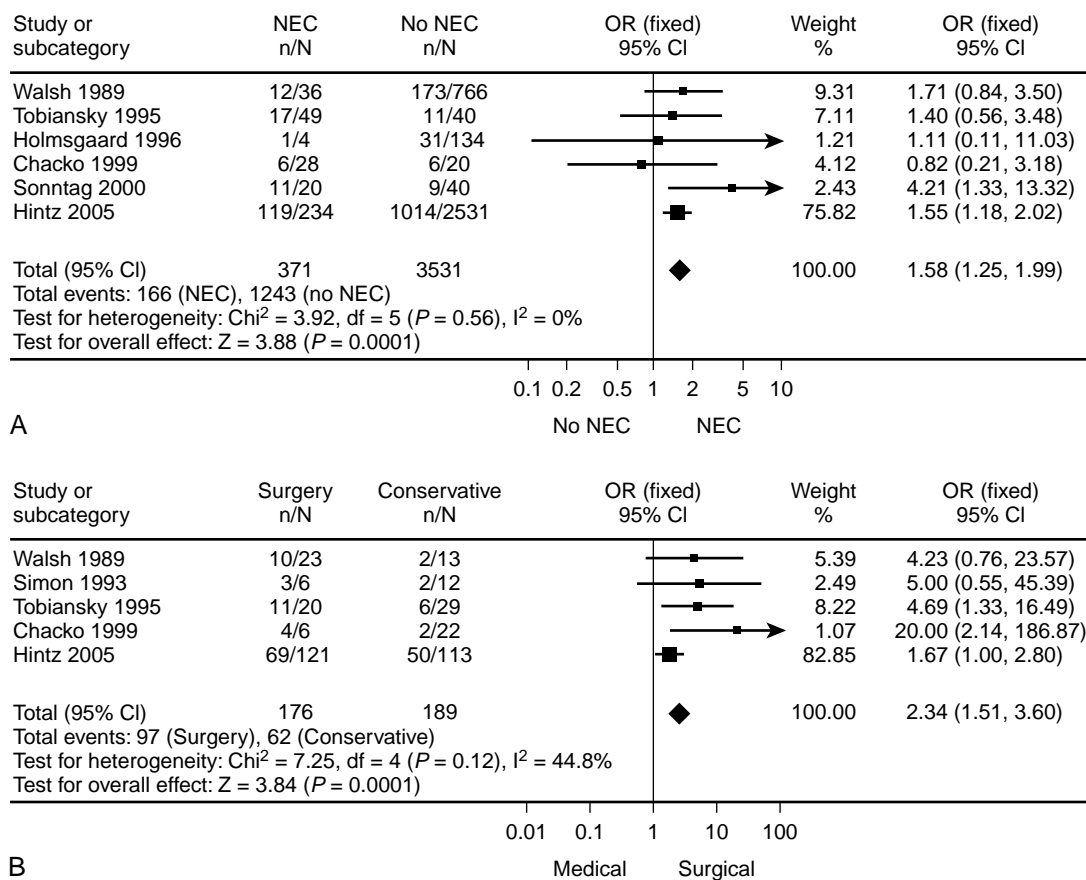

Two systematic reviews have confirmed these findings of an increased risk of neurodevelopmental impairment in VLBW infants who develop NEC.<sup>240,241</sup> Additionally, they found that the risk for those treated surgically is almost twice the risk for those treated medically (Fig. 34-8). Most infants with NEC who are treated medically develop like age-matched premature infants without NEC, whereas those with more severe disease requiring surgical intervention have a significantly increased risk of poor neurodevelopmental outcomes.

## PREVENTION

Prevention of NEC has become a major focus of research because management strategies have had little impact on mortality. Prevention has focused on two main aspects of care: feeding strategies and infectious characteristics of the gastrointestinal tract.

## Human Milk

Human milk has a variety of antimicrobial, anti-inflammatory, and immunomodulating properties that may be protective for the gastrointestinal mucosa. Additionally, it furnishes mucosal antibody via secretory IgA as well as macrophages, lactoferrin, and EGF. Because of these properties, it has been postulated that breast milk is protective against developing NEC. However, there are major challenges in evaluating the efficacy of human milk in preventing this disease. One issue lies in a lack of standardization of what is considered human milk: maternal preterm milk, donor preterm milk, donor term milk, and unfortified or fortified human milk. Another lies in the fact that many infants receive supplementation with formula or donor milk when there is insufficient maternal milk. Thus, determining how much human milk is fed and what

**Figure 34-8.** Summary data from systematic reviews examining the relationship between NEC and neurodevelopmental outcome. **A**, Data comparing infants with NEC with those without NEC. **B**, Data comparing infants with NEC requiring surgical treatment with those with NEC who were treated medically.

constitutes human milk feeding versus formula feeding has not been standardized. Finally, recent practices in the NICU often involve fortifying human milk to increase the caloric and nutritional content.

Four small ( $n = 36$  to  $81$ ) randomized or quasi-randomized studies in the 1980s evaluated the incidence of NEC in infants fed either human milk or formula.<sup>242-245</sup> None of these studies showed a significant difference in NEC between the two groups.

An additional randomized study was done as part of a larger prospective observational study in the United Kingdom.<sup>246</sup> The randomized portion of this study included 159 infants who were fed exclusively either donor breast milk or preterm formula. The incidence of all cases and confirmed cases of NEC was slightly lower in the breast milk group, but the odds ratio did not reach significance. These investigators subsequently looked at all 926 patients who were part of the prospective observational study being conducted. They divided the patients into three groups based on what they had been fed: formula only, formula plus mother's milk, and human milk only. The formula group had a 10% incidence of NEC versus 4% in the human milk only group. When only considering confirmed cases, the formula group had 7% versus 1% in the human milk group. The overall study design entailing two separate studies, with one conducted at two

centers and one at five centers, may have confounded the findings. However, adjustments for the effects of different centers did not affect the overall outcomes.

Two systematic reviews and meta-analyses have subsequently been published, combining the results of the four initial studies as well as the results from 159 randomized patients from the later study.<sup>247,248</sup> Both of these meta-analyses found that combining the evidence from these studies suggests that human milk reduces the risk of NEC with findings of a relative risk of 0.21 (95% CI: 0.06-0.76) in one and 0.25 (95% CI: 0.06-0.98) in the other. However, these findings must be evaluated with some caution. One of the meta-analyses is based on 13 cases of NEC in 268 infants and the other one had 13 cases of NEC in 343 infants. The studies included in the meta-analyses also had significant variation in the incidence of NEC (0-20%), the type of human milk (donor, maternal, term, or preterm) and the timing of feeding. Furthermore, one of the included studies was not truly randomized but used an alternate assignment allocation and none of the studies was blinded to allocation or outcome. The diagnosis of NEC was also not uniform among the studies.

Fortification of human milk is commonly practiced to improve caloric and nutrient content of the human milk received. Fortification has been shown to result

in increases in weight, length, and head circumference.<sup>249</sup> A Cochrane review did not show an increase in NEC in the group fed fortified milk.<sup>249</sup> Additionally, a nonrandomized study evaluated 108 infants fed either fortified human milk or preterm formula. In this study, there was a significantly lower incidence of NEC in those fed human milk compared with those fed formula.<sup>250</sup> Given the apparent association of human milk in decreasing rates of NEC, and the lack of clear data reflective of contemporary neonatal practices, large randomized controlled trials examining the rates of NEC in premature infants fed fortified human milk seem warranted.

## Feeding Strategies

Early initiation of enteral feedings in preterm infants helps to promote growth and decreases the need for parenteral nutrition. However, there have been concerns that early feeding may be associated with an increased risk of NEC. A systematic review found only two small, randomized studies with a total of 82 infants.<sup>251</sup> In these studies, early feeding had no effect on the incidence of NEC. Given the small sample size, important effects of either strategy may have been missed. In one large prospective study, early feeding of human milk appeared protective against NEC while early feeding of formula was linked to an increased incidence.<sup>246</sup> These investigators found that for each day earlier formula feeds were started, the risk of developing NEC increased 20%. Among those infants who received breast milk there was no association between the day of life that feeds were begun and the risk of NEC.

After starting feeds, the rate at which to advance feeds is another concern with regard to NEC. For infants to quickly regain their birth weight and achieve full feeds, rapid advancement is advocated.<sup>252</sup> However, concerns have been raised about the safety of this strategy with regard to increasing the incidence of NEC. In one randomized trial, the study was terminated early due to a higher incidence of NEC in the group that had their feeds rapidly advanced.<sup>253</sup> The results from this study were confounded by a questionable randomization model, an unusually high incidence of NEC, and the early termination of the study itself. Additionally, 4 patients were excluded from the study who died or developed intestinal perforation, which may have introduced bias into the patient population. A systematic review of rapid versus slow advancement of feeds examined 372 patients in three separate trials and did not find any difference in the relative risk of developing NEC.<sup>252</sup>

## Amino Acid Supplementation

Arginine is the sole substrate for nitric oxide synthase. As described earlier, NO plays an important role in the proper functioning of the gastrointestinal tract. Therefore, supplementation with arginine has been considered as a potential preventive measure for avoiding NEC. One randomized controlled trial of 152

preterm infants found a significant reduction in NEC in those infants receiving supplementation.<sup>254</sup> However, because this was a small study that was unable to evaluate stage II and III NEC independently, further research on this possible preventive measure needs to be performed to confirm these results.<sup>255</sup>

A deficiency of serum glutamine has also been correlated with NEC.<sup>256</sup> Glutamine is a key fuel for enterocytes and promotes the growth and integrity of the intestinal epithelium. Therefore, glutamine has also been postulated as having protective effects against NEC. However, two large multicenter randomized trials did not show a benefit for those who received glutamine.<sup>257,258</sup> A Cochrane systematic review of five trials also did not show any benefit to the group receiving glutamine.<sup>259</sup>

## Oral Antibiotics

Given the role of bacteria in the pathogenesis of NEC, enteral antibiotics have been considered as possible NEC prophylaxis. The use of antibiotics, of course, also increases the potential for the development of resistant bacteria. Five randomized trials have examined the effects of prophylactic therapy with enteral antibiotics. The primary outcome variable in each study was the occurrence of NEC. Although no individual study found a significant reduction in NEC, when the five were combined together in a meta-analysis there was a significant reduction in the incidence of NEC in those who received the antibiotics.<sup>260</sup> Unfortunately, these studies did not report on the potential harmful effects of such widespread use of enteral antibiotics. Without sufficient evidence regarding the safety of using enteral antibiotics as prophylaxis, an endorsement of this prophylactic measure cannot be made.

## Probiotics

Probiotics have been proposed as a potential means of promoting the healthy colonization of the premature gut and, therefore, possibly protecting the immature intestine against NEC. Defined as "live microorganisms which when administered in adequate amounts confer a health benefit on the host,"<sup>261</sup> these supplements contain potentially beneficial bacteria or yeasts, most commonly *Lactobacillus*, *Bifidobacterium*, and *Streptococcus* strains.<sup>262</sup> They can enhance the mucosal barrier by reducing permeability, increasing the production of mucus, inhibiting bacterial translocation, and strengthening tight junctions, all problems in the immature intestine.<sup>39,263-268</sup> Furthermore, colonization with these organisms can reduce the ability of pathogenic bacteria to adhere to the intestinal mucosa.<sup>269,270</sup> Probiotics have also been shown to increase the production of mucosal IgA and short-chain fatty acids that help the immature immune system.<sup>271-273</sup> Additionally, they decrease intestinal inflammation through the reduction of proinflammatory cytokines, the increase of anti-inflammatory cytokines, and the increase of cytokine production by T cells.<sup>274-277</sup>

Studies have examined the ability of probiotics to normalize intestinal flora and to prevent NEC. One randomized controlled trial showed that administration of *Bifidobacterium breve* within the first 24 hours and continued for 28 days can change the intestinal colonization rates, with increased levels of *Lactobacillus* and decreased counts of *Enterobacter*.<sup>278</sup> Another study showed that administering *Bifidobacterium* probiotics to preterm infants lowered the levels of pathogenic species such as *Enterobacter* and *Clostridium* in their intestines compared with controls who did not receive the probiotics.<sup>279</sup> In a study that differentiated between infants under 1500 g and those of 1500 to 1999 g, the infants with the lower birth weight had lower stool colonization rates than the higher birth weight group, despite being given *Lactobacillus casei* subspecies for 2 weeks longer.<sup>280</sup> These studies all suggest that the use of probiotic supplementation can influence intestinal colonization, although the success may vary with birth weight and gestational age.

Once it was shown that such changes in intestinal flora could be manipulated, the next step lay in determining what clinical effect this might have on these preterm infants. One large prospective cohort study using historical controls evaluated whether newborns given *Lactobacillus acidophilus* and *Bifidobacterium infantis* would have reduced rates of NEC.<sup>281</sup> They studied 1237 infants over 1 year with a mean gestational age of 35 weeks and mean birth weight of 2040 g. These infants were treated with each probiotic daily until discharge. The results were compared with those in the 1282 infants hospitalized the year before. During the treatment year, they had an incidence of NEC of 3% compared with 6.6% the year before ( $P < .0002$ ). Furthermore, no side effects were noted.

Subsequently, there have been three randomized prospective trials specifically looking at rates of NEC in infants treated with probiotics. In the first study, 585 preterm infants were randomized to receive *Lactobacillus GG* or no probiotics.<sup>282</sup> The three main outcomes for this study were NEC, sepsis, and urinary tract infection. There were no differences between the two groups in any of these three outcomes. However, the study may not have had adequate power to detect any

difference in NEC because the observed baseline incidence was very low (2.8% in the controls).

Another study of 367 infants weighing less than 1500 g randomized those infants who survived beyond 1 week of life and were receiving enteral feeds to either *Lactobacillus acidophilus* and *Bifidobacterium infantis* or no supplementation until discharge.<sup>283</sup> The incidence of NEC in the study group was 1.1% compared with 5.3% in the control group ( $P = .04$ ). Additionally, the study infants had less severe NEC and there were no deaths due to NEC in the study group.

The third randomized study examined the effectiveness of a combination of *Bifidobacterium infantis*, *Streptococcus thermophilus*, and *Bifidobacterium bifidus* in 145 infants weighing less than 1500 g.<sup>284</sup> These infants were entered into the study at the time they started enteral feedings, and the two groups had no difference in the time it took to reach full feedings. The study group received probiotic supplementation until they reached 36 weeks' gestational age. The study group showed a lower incidence of NEC (4% vs. 16.4%,  $P = .03$ ), less severe NEC, and no NEC-related deaths.

These three randomized trials specifically evaluating the incidence of NEC were combined with four other trials that evaluated NEC as a secondary outcome in a systematic review and meta-analysis (Table 34-6).<sup>285</sup> In the combined analysis, there were 690 infants who received no treatment and 703 who received probiotics. After combining the individual study results using meta-analysis, the relative risk for NEC in the group that received probiotics was 0.36 (95% CI: 0.20-0.65). However, these results must be considered with caution because this meta-analysis combined studies that had many significant differences. This heterogeneity normally would preclude the method of meta-analysis.<sup>286</sup> There was considerable variability among the studies in the demographics of the patients, the age at commencement of treatment, and the type, dose, and duration of probiotic treatment. Additionally, although this meta-analysis found no increased risk of sepsis in the treatment group, the issue of side effects of probiotics was not adequately addressed owing to the lack of power to detect serious infections.

\*See references for further information.

Given the high-risk population in which these probiotics might be used, the issue of safety is crucial.

The results of this meta-analysis suggest that probiotic supplements might reduce the risk of NEC. These results are promising and call for additional large well-designed randomized trials to confirm these results before implementing this strategy in the prevention of NEC. However, additional trials must evaluate both short-term and long-term safety considerations.

### Epidermal Growth Factor

As discussed earlier, EGF plays an important role in the pathogenesis of NEC. Furthermore, premature infants in general, and infants with NEC, specifically, have been shown to have decreased salivary concentrations of EGF.<sup>89</sup> Because EGF is known to support the maintenance of the intestinal barrier and down-regulate proinflammatory cytokines,<sup>121</sup> it could help to prevent NEC. A preliminary study of neonates already diagnosed with NEC has shown that administration of EGF will promote the repair of the intestinal epithelium. In animal models, supplementation with EGF has decreased the incidence of NEC.<sup>287</sup> Heparin-binding epidermal growth factor (HB-EGF) has been shown to have similar effects. Trials to test both EGF and HB-EGF as preventive strategies are planned.<sup>288</sup>

### CONCLUSION

Despite many advances in the care of premature infants, NEC remains a challenging disease with a relatively constant incidence rate over the past 4 decades. The only clearly established risk factor is prematurity. Much insight has been gained into the pathophysiology of this disease, with a unifying hypothesis emerging: an excessive and uncontrolled inflammatory response by the neonatal intestine after exposure to some inciting event. Future research efforts will focus on further elucidating the underlying causes and the molecular mechanisms that occur early in this pathogenic process. Because clinical parameters alone have not helped identify which children are at risk for developing the disease and progressing to serious disease,<sup>289</sup> advanced approaches using proteomic and genomic techniques should be considered to compare those who develop NEC with those who do not, as well as those who progress to severe disease with those who have a mild course. Novel treatment strategies such as growth factors should be evaluated. Any trial of treatment should include evaluation of both long- and short-term outcomes. Finally, because no treatment for NEC will be uniformly effective once the disease is established, research efforts should focus on approaches to prevent this disease.

# HIRSCHSPRUNG'S DISEASE

Keith E. Georgeson, MD

**H**arold Hirschsprung, a Danish pediatrician, is credited with the first definitive description of the disease that bears his name.<sup>1</sup> Many earlier scattered reports can be found in the literature that describe children who had symptoms and findings consistent with Hirschsprung's disease (HD), but these descriptions are not definitive enough to be certain of the diagnosis. Some historians give credit to Fredericus Ruysche, a Dutch anatomist, who, in 1691, described a 5-year-old girl with abdominal pain and constipation who eventually died and was noted at autopsy to have megacolon.<sup>2</sup> An understanding of the cause of the constipation and megacolon in HD did not develop until the 1920s when Valla and his associates described the absence of ganglion cells in the myenteric plexus of the distal colon in two brothers with megacolon.<sup>3</sup> Over the next 30 years, poorly understood procedures that were intended to reduce sympathetic hyperactivity of the colon were reported to be, at least temporarily, successful in treating HD. Drs. Swenson, Neuhauser, and Pickett recognized the spastic rectum and distal rectosigmoid colon that defined the site of obstruction in patients with congenital megacolon using fluoroscopy and a barium enema.<sup>4</sup> They established the barium enema as a useful diagnostic tool in HD. Swenson performed a proximal colostomy in six patients with severe constipation and a barium enema demonstrating a classic transition zone. The colostomy was therapeutic in these patients. Later, closure of the colostomy in three of these patients resulted in recurrence of their obstructive symptoms. Based on the findings of the spastic distal colon and the careful clinical observation that the obstructive symptoms recurred with closure of a colostomy proximal to this spastic segment, Swenson conceptualized and performed the first pull-through procedure in a patient with HD.<sup>5</sup> Duhamel, Soave, and others have described operations that differed from Swenson's but clearly integrated concepts that he defined for successful management of HD. Despite the relative success of all of these procedures, the precise etiology and many of the complexities of this disorder remain unknown. Important contributions regarding the etiology, genetics,

pathophysiology, epidemiology, and management of patients with HD have been made in the past 50 years. The diagnosis and treatment of HD are discussed in this chapter. A description is also provided of some aspects of HD that remain poorly understood and are confusing to both researchers and clinicians.

## ETIOLOGY

Cellular and molecular abnormalities in the development of the enteric nervous system, along with incomplete migration of the neural crest cells, are a major part of the cause of HD.<sup>6-8</sup> Neural crest-derived neuroblasts appear in the developing esophagus at about 5 weeks' gestation in the human fetus. These cells then migrate in both a cranial and caudal direction into the rest of the developing gut between 5 and 12 weeks' gestation.<sup>6,9</sup> The Hirschsprung phenotype is variable owing to a wide range of possible abnormalities during the development of the enteric nervous system and the different times at which arrest occurs in the migration of the neural crest-derived cells. The earlier the arrest in neural crest migration, the longer the segment of aganglionosis.<sup>8-10</sup> Many other factors, such as an altered extracellular matrix, abnormalities in neurotrophic factors, and neural cell adhesion molecules have also been suggested as contributing to the development of HD.<sup>9,11</sup>

## GENETIC FACTORS

HD often occurs as an isolated phenotype. However, there are strong associations that support a genetic etiology for the disease. Siblings of children with HD have an increased risk of being born with HD.<sup>12-14</sup> There is an unbalanced gender ratio of approximately 4:1 favoring males over females. HD is also associated with known chromosomal anomalies.<sup>12-16</sup> Genetic studies have documented at least 10 mutations in different genes associated with its development. The more common genetic mutations that have been identified

**Figure 35-1.** A, Classic case of rectosigmoid Hirschsprung's disease in a 2-year-old child. Note the contracted rectum (solid arrow) and the dilated proximal rectum and sigmoid colon. The transition zone is marked with the dotted arrow. B, A very small, contracted right colon, cecum, and terminal ileum (solid arrow) in a neonate with total colon aganglionosis. The normal, dilated ileum is noted proximal to the transition zone (dotted arrow).

include the *RET* gene (7%-35% of sporadic cases), the *EDNRB* gene (7%), and the *END3* gene (<5%). More than 20 mutations have been described in the *RET* proto-oncogene. Some polymorphisms in this gene are associated with particular HD phenotypes. HD has been associated with other genetic abnormalities, such as trisomy 21, cardiac septal defects, congenital central hypoventilation syndrome, multiple endocrine neoplasia type 2, neurofibromatosis, Waardenburg's syndrome, and anorectal malformations. Trisomy 21 is reported in approximately 7% of children with HD. HD has a complex inheritance with penetrance being highly variable. Studies have reported the risk of HD in the siblings of the proband to be 4%.<sup>14,17</sup>

## PATHOPHYSIOLOGY

The primary clinical feature of HD is obstruction caused by a lack of propagation of the peristaltic wave. This lack of propagation is associated with the absence of ganglion cells in the myenteric and submucosal plexus.<sup>18</sup> The cause of the spasm in the aganglionic bowel is unclear. Cholinergic hyperreneration, inadequate distribution of nitric oxide synthetase, and abnormalities of the interstitial cells of Cajal have all been reported to be associated with HD.<sup>19-21</sup> A comprehensive understanding of how these factors work to cause the disease has not been achieved. The majority (75%) of patients with HD have ganglion cells down to the level of the rectosigmoid colon (Fig. 35-1A). Long-segment HD, which describes aganglionosis of the descending colon, splenic flexure, or transverse colon, occurs in approximately 15% of patients.<sup>12,22-24</sup> Also, even longer segment cases have been described, including total colon aganglionosis, which occurs in 5% to 7% of patients (see Fig. 35-1B). A small number of infants with no ganglion cells at all in the entire gastrointestinal tract have been noted.

The incidence of HD is approximately 1 in 5000 live births. Asian children seem to have the highest incidence at almost 3 per 5000 live births. However, HD is seen in almost all racial groups.<sup>25</sup> It is possible that differences in the recognition of HD occur because of differences in diagnostic capabilities and reporting mechanisms. Although the male-to-female ratio of HD is approximately 4:1, it is 2:1 in longer-segment disease.<sup>16</sup> In medically sophisticated cultures, the diagnosis of HD is often made in the first few weeks or months of life. Delayed passage of meconium in the newborn, constipation with intermittent diarrhea, a distended abdomen with bilious vomiting, and feeding intolerance with poor weight gain or even weight loss are frequent clinical signs of HD.

Most neonates pass a meconium stool in the first 48 hours of life.<sup>26</sup> However, the majority of children with HD fail to pass meconium in the first 48 hours of life.<sup>27-29</sup> The onset of explosive, foul-smelling stools associated with fever and abdominal distention heralds the onset of HD enterocolitis.<sup>30-32</sup> If unrecognized, HD-associated enterocolitis is a potentially fatal complication. In patients with a rectosigmoid colon transition zone, prompt saline irrigation of the sigmoid colon along with fluid resuscitation and antibiotic therapy are important measures to decrease the risk of death in these patients. Infants and children with longer segment disease and a more proximal transition zone are not as effectively treated by rectal irrigation. Some of these patients will require immediate exploration with a colostomy proximal to the aganglionic bowel. A delayed diagnosis of HD may lead to an increased risk of serious and occasionally fatal enterocolitis.<sup>27,33</sup>

## DIAGNOSIS

Infants and children who failed to pass meconium in the first 24 to 48 hours of life, who suffer from severe constipation with bouts of intermittent diarrhea, who

**Figure 35-2.** A and B, These two barium enema examinations in different infants demonstrate Hirschsprung's disease. The aganglionic rectum (*arrows*) in both studies is small and contracted. The proximal ganglionic colon is dilated. A transition zone between the aganglionic and ganglionic colon is nicely seen in the both studies.

have abdominal distention, or who present with bilious vomiting are likely candidates for the diagnosis of HD. Diagnostic tests include full-thickness rectal biopsy (gold standard), contrast enema (sensitivity [SN] 65%-80%, specificity [SP] 65%-100%), anorectal manometry (SN 75%-100%, SP 85%-95%) and rectal suction biopsy (SN > 90%, SP > 95%).<sup>34-42</sup> Typically, patients with HD show gaseous distention of the colon and small bowel. In patients with a classic rectosigmoid transition zone, the sigmoid colon is often noted to be redundant and dilated. A contrast enema often shows the presence of a transition zone and irregular colonic contractions in the distal, aganglionic segment (Fig. 35-2). Often, irregular mucosal ulcerations are seen on the contrast enema due to enterocolitis. Some authors have reported an even lower sensitivity for detecting HD with a contrast enema in neonates and believe that a contrast enema in the neonatal period should be cautiously interpreted.<sup>43-45</sup>

Although anorectal manometry is rarely used in neonates to establish the diagnosis,<sup>46,47</sup> it is a useful technique in older children.<sup>48</sup> The classic finding is the absence of the rectoanal inhibitory reflex when the rectum is distended. In normal children, distention of the rectum results in a transient increase in rectal pressure with a reduction in the anal internal sphincter pressure. Children with HD lack this inhibitory reflex and relaxation of the internal sphincter (Fig. 35-3).<sup>48</sup>

The standard diagnostic tool for documenting HD is an open or suction rectal biopsy. Normal colon has demonstrable myenteric and submucosal ganglion cells (Fig. 35-4A). The absence of ganglion cells in both the myenteric and submucosal plexus and the finding of hypertrophic nerve fibers are diagnostic of HD (see Fig. 35-4B). Additionally, the presence of increased acetylcholinesterase staining in the submucosa and mucosa is confirmatory of HD (see Fig. 35-4C). In some pediatric centers, the presence

**Figure 35-3.** A, In the child undergoing anorectal manometry without Hirschsprung's disease, the rectoanal inhibitory reflex is normal. Note the drop in the internal sphincter pressure with rectal distention. B, A child with Hirschsprung's disease is seen to have abnormally increased contraction of the anal canal and no relaxation of the internal sphincter with rectal distention. (The *arrow* points to the initiation of rectal distention in both A and B.)

of increased staining of acetylcholinesterase in the mucosa and submucosa is adequate to confirm the diagnosis in a patient with typical symptoms and a contrast enema that demonstrates a transition zone. A suction rectal biopsy, at least 2 cm or more above the dentate line, is the commonly used method for confirming HD in most centers. The presence of

**Figure 35-4.** **A**, This biopsy specimen of normal ganglionated bowel has been stained with hematoxylin and eosin. A ganglion cell (arrow) is seen in the submucosa. **B**, This rectal biopsy specimen in a neonate with Hirschsprung's disease has been stained with hematoxylin and eosin. Ganglion cells cannot be found in the wall of the rectum. Also, the submucosal nerve trunks (arrow) are noted to be greater than 40  $\mu\text{m}$  in diameter, which strongly correlates with aganglionosis. **C**, This rectal biopsy specimen in a neonate with Hirschsprung's disease has been stained with acetylcholinesterase. The increased staining in the mucosa and submucosa (arrows) is diagnostic of Hirschsprung's disease. (Courtesy of Dr. D. Kelly, Children's Hospital of Alabama, Birmingham, AL.)

ganglion cells within 2 cm of the dentate line is variable. Both the absence of ganglion cells and an increase in acetylcholinesterase staining can be determined on these specimens.<sup>49</sup> However, it is more difficult in older children to acquire adequate material on suction biopsy and these children usually require an open biopsy to obtain adequate tissue for diagnosis. Other enzyme-staining techniques have also been used to diagnose HD, such as lactate dehydrogenase, succinic dehydrogenase, and NADPH-diaphorase enzyme histochemistry.<sup>50</sup>

There also have been reports describing the use of rapid frozen section analysis for determining enzymatic activity of the ganglion cells in the transition zone because anatomically normal-appearing ganglion cells may lack normal enzymatic activity.<sup>42</sup> With this approach, the transition zone is defined as the point where the ganglion cells have normal enzymatic activity. The proximal point of this enzymatically determined transition zone is then used as the neorectum for the coloanal anastomosis. Using the enzymatic activity of the ganglion cells to determine the proximal part of the transition zone has been reported to result in a lower incidence of complications and enterocolitis after pull-through for HD. Nakao and coworkers reported a 91% sensitivity using acetylcholinesterase staining for the diagnosis of HD and a false-negative rate of 8%.<sup>42</sup> Rectal suction biopsy is clearly more sensitive than both anorectal manometry and contrast enema for the diagnosis of HD. However, the biopsy should be deep enough to show the absence of ganglion cells and the presence of hypertrophic nerve fibers. Interestingly, children with total colon HD can have elevated acetylcholinesterase activity in the rectum and left colon but may show near-normal levels of acetylcholinesterase activity proximal to the splenic flexure.

Histologic grading of enterocolitis has been proposed by Teitelbaum and coworkers.<sup>51</sup> However, this grading system has not been widely used. Some authors have suggested that an initial histologic enterocolitis index of grade 2 or greater predicts a higher risk of

subsequent clinical enterocolitis.<sup>52</sup> However, other reports have not confirmed this finding.<sup>53</sup>

## TREATMENT

Surgical approaches to HD should only be considered after the diagnosis has been firmly established by either suction or open rectal biopsy. Historically, a two- or three-stage repair was performed with the first stage consisting of a diverting colostomy usually leveled at the point where the transition zone was identified by seromuscular biopsy. The second stage, performed 3 to 12 months later, consisted of resection of the aganglionic bowel with a coloanal anastomosis. The colostomy was closed either during the pull-through operation or subsequently as a third-stage procedure.

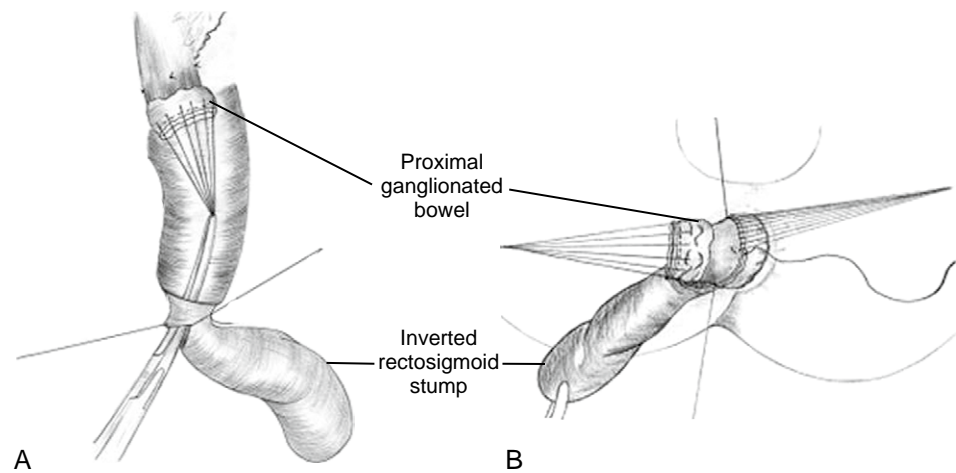

## Surgical Techniques

Multiple operative approaches have been described for managing HD. All these operations conform to the original concepts for correcting HD espoused by Swenson. These principles for effective surgical treatment include resection of the aganglionic portion of bowel and identification of normally ganglionated proximal bowel with a leveled coloanal or enteroanal anastomosis. Additionally, the operation should preserve both fecal and urinary continence and normal sexual function. The most commonly used operations for HD have been developed by Swenson, Duhamel, and Soave.<sup>4,54,55</sup>

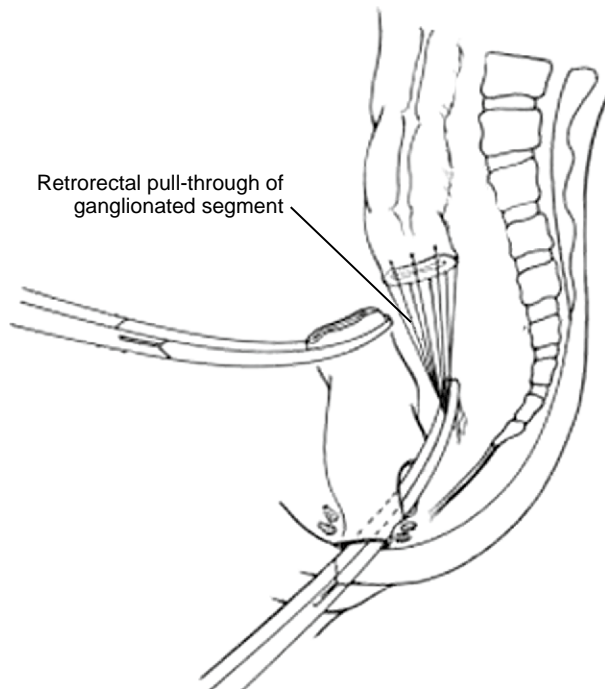

The Swenson technique utilizes a near-total proctectomy with the dissection plane close to the outside of the muscular wall of the rectum (Fig. 35-5). Swenson believed a diagonal resection of the distal rectum resulted in fewer strictures at the anastomotic line.<sup>4</sup>

The Duhamel technique employs dissection behind the rectum and leaves the aganglionic rectum in place. The aganglionic proximal rectum and colon are then resected. The ganglionated bowel is brought down behind the rectum, creating two parallel cylinders

**Figure 35-5.** The principles of the Swenson pull-through procedure are seen in these drawings. **A**, The proximal ganglionated bowel is grasped through an incision in the prolapsed rectosigmoid stump. **B**, The ganglionated bowel is then sewn to the anus.

(Fig. 35-6). The lumen of the neorectum is sutured end to side to the lumen of the native rectum, approximately 2 cm above the dentate line. The septum between the two cylinders of bowel is then ablated. Initially, this ablation was performed using large clamps placed in parallel with the handles of the clamps protruding out of the anus for up to 2 weeks. This technique has been modified several times. Currently, the stapler is used to incise the septum between the neorectum and native rectum. Additionally, the native rectal stump can be cut short, minimizing the redundancy above the common channel to avoid a fecal impaction in the backwater portion of the aganglionic rectum.<sup>54</sup>

**Figure 35-6.** With the Duhamel technique, the ganglionated bowel is delivered through an incision in the posterior aspect of the native aganglionated rectum and sewn to the anus. The septum between the ganglionated pull-through colon and the aganglionated native rectum is then divided using a stapler.

The Soave technique utilizes a mucosectomy of the rectum, leaving a muscular cuff (Fig. 35-7). Soave originally described exteriorizing the neorectum out the anus and leaving it as a protuberant stump. The stump was trimmed 2 to 3 weeks later.<sup>55</sup> Boley described a similar approach with a primary anastomosis.<sup>56</sup> All of these procedures have a laparoscopic or transanal counterpart.

In 1980, So and co-workers introduced the concept of primary pull-through for HD.<sup>57</sup> A single-stage procedure avoids the complications associated with a colostomy and the need for another operation to close the colostomy. A primary single-stage pull-through is appropriate for most infants and children diagnosed with HD.

When indicated, I perform an end colostomy just proximal to the biopsy-documented transition zone. The Brooke technique is utilized to mature the colostomy. The colon should be carefully secured to the inner abdominal wall for a distance of at least 4 cm to avoid prolapse of the colostomy because the proximal colon often shrinks in size after colostomy formation. The distal colon is left as a Hartman pouch unless the transition zone is at or above the splenic flexure.

The single-stage pull-through for HD became more popular with the introduction of the laparoscopic-assisted transanal endorectal pull-through (LATEP).<sup>58</sup> The LATEP allowed the pull-through to be performed without a large abdominal incision. Subsequently, de la Torre described a transanal pull-through (TAP) without abdominal exploration or biopsy.<sup>59</sup> The LATEP and the TAP have become the two most popular methods for primary repair of HD in infants and children. At the Children's Hospital of Alabama, the LATEP is preferred in neonates and children undergoing a primary operation for two reasons. First, laparoscopic biopsies allow confirmation of the extent of the aganglionosis before any division of the colonic mesentery or rectal ablation occurs. This is especially advantageous in the neonate in whom the contrast enema can be somewhat unreliable in predicting the level of the transition zone.<sup>43-45</sup> If a long segment of aganglionosis is identified, delaying the definitive operation until the histopathologic

**Figure 35-7.** **A**, For the Soave operation, there is extramucosal dissection of the rectum after circumferential incision of the rectal mucosa. **B**, The ganglionated colon is pulled through the aganglionic rectal cuff, and a coloanal anastomosis is performed.

results are available from the permanent sections may prevent unnecessary resection of long segments of colon due to errors in frozen section analysis. Second, the use of laparoscopy helps in performing a tension-free coloanal anastomosis by releasing the restraining ligaments to the descending colon and ensuring that there is no twisting of the pull-through colon during the anastomosis. At the Children's Hospital of Alabama, neonates with total colon aganglionosis are managed with an initial leveling small bowel enterostomy, followed 6 to 12 months later by a laparoscopic-assisted Duhamel procedure. The Duhamel technique offers the advantage of creating a larger rectal reservoir in patients with near-total or total colonic HD. Performing an initial ileostomy and delaying the procedure for 6 to 12 months also reduces the incidence of the severe postoperative diaper rash associated with a pull-through of the small intestine in the newborn.

In a neonate, unless contraindications are present, LATEP is performed as soon as the diagnosis is confirmed by suction rectal biopsy.<sup>60</sup> Contraindications to a neonatal primary pull-through include the following:

- Severe enterocolitis
- Massive proximal dilatation
- Inability to determine the transition zone
- Life-threatening comorbidities

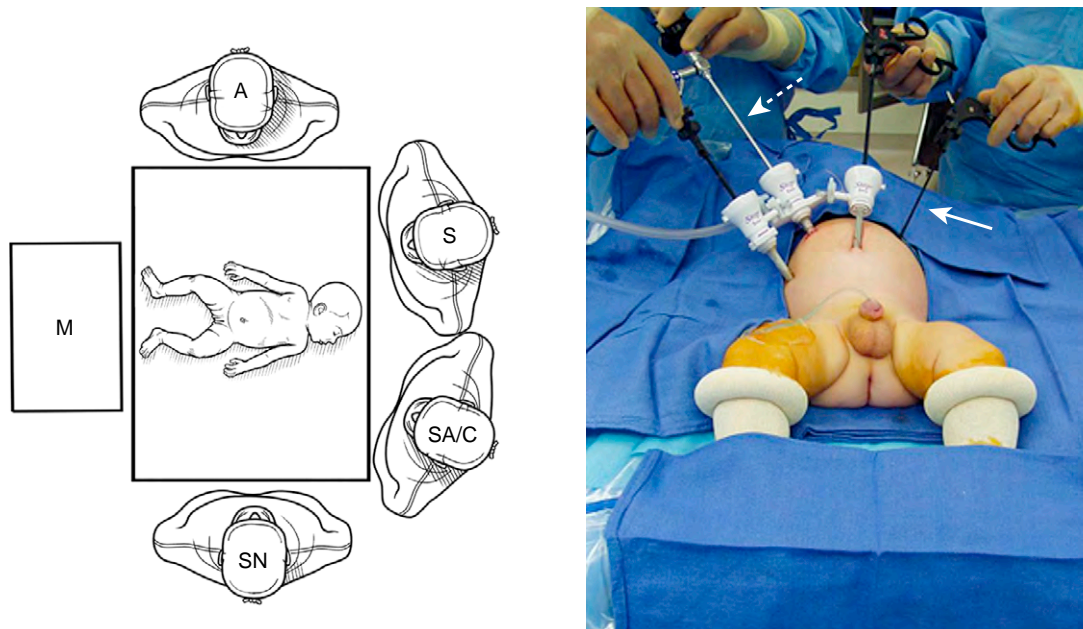

Preoperative decompression of the bowel is performed by a combination of finger dilation of the rectum and irrigation of the colon with saline through a rectal tube with the tip of the tube positioned above the transition zone. The neonates are hydrated intravenously. Two doses of an oral antibiotic regimen consisting of erythromycin and neomycin are given 8 and 4 hours before the scheduled operation. Intravenous administration of a broad-spectrum antibiotic is given immediately before the patient is taken into the operating room.

### Laparoscopic Pull-Through

Infants are positioned transversely near the end of the operating table to allow for access to both the abdomen and the perineum. Positioning works best if the

patient's head is turned to the right side and toward the anesthetist. With this arrangement, the laparoscopic surgeon has better access to the patient's sigmoid and left colon. The laparoscopic portion of the procedure is performed after a thorough body prepping below the nipples. The legs and feet are draped in the operating field after prepping. The pneumoperitoneum is obtained using an open cut-down technique through the umbilicus. Pressures of 10 to 12 mm Hg are well tolerated in all age groups. Modest hyperventilation is useful to prevent hypercarbia in these patients. A 4-mm, 30-degree telescope is used in infants, and a 5-mm, 30-degree scope is helpful in larger patients. Port placement is illustrated in [Figure 35-8](#). As mentioned, the initial cannula (5 mm) is inserted through the umbilicus. A second (4 or 5 mm) cannula is introduced in the right upper abdominal quadrant just below the liver margin. The telescope is then moved to this site. The third port is placed in the right lower abdomen just anterior to the anterior axillary line. The transition zone between ganglionated and aganglionic bowel is identified visually when possible. Seromuscular biopsy specimens for histologic analysis can be obtained using laparoscopic Metzenbaum scissors or by exteriorizing the colon through the umbilicus ([Fig. 35-9](#)). For an intracorporeal biopsy, it is best for the surgeon to use a sharply pointed instrument in the left hand to elevate the seromuscular wall. Broader-tipped instruments can lead to a full-thickness biopsy. Once the biopsy is obtained, it is best to delay further dissection until the transition zone is determined. Visual identification of the transition zone can be inaccurate, especially in infants.

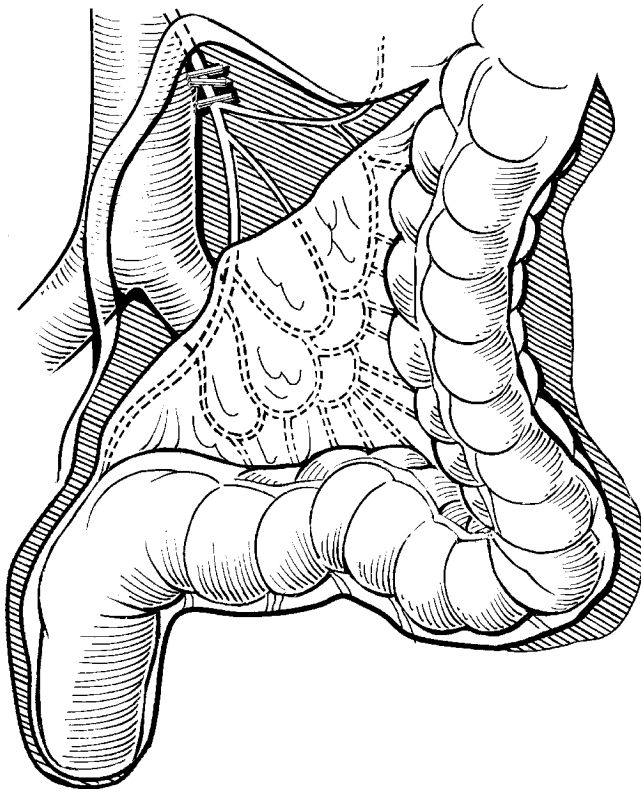

Assuming a rectosigmoid transition zone is found, a window is created through the rectosigmoid mesocolon. This window can be made either with a hook cautery or using an ultrasonic scalpel placed through the 5-mm port in the umbilicus. The mesenteric window should be extended to the peritoneal reflection of the pelvis. In older children, the dissection can be extended below the peritoneal reflection, which makes the transanal dissection easier. However, in infants younger than 1 year of age, the transanal dissection

**Figure 35-8.** The surgeon (S) and surgical assistant/camera holder (SA/C) stand above the patient's head with the monitor (M) positioned beyond the infant's feet. The scrub nurse (SN) can be positioned according to the surgeon's preference, although being positioned at the foot of the operating table appears to be ideal. A, anesthesiologist. The photograph shows port placement for this operation. Usually three or four ports are required. The umbilical port is inserted using an open technique, and the other ports are introduced under direct visualization. The telescope (*dotted arrow*) is placed through the 5-mm port in the right upper abdomen. The surgeon's two primary working ports are the umbilical port for the left hand and the right lower abdominal port for the right hand. A retracting instrument (*solid arrow*) is often helpful and can be inserted through a stab incision in the infant's left upper abdomen. A urinary catheter has been introduced to help decompress the bladder. (From Morowitz MJ, Georgeson KE: Laparoscopic assisted pull-through for Hirschsprung's disease. In Holcomb GW, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy, Philadelphia, Elsevier, 2008, pp 101-108. Reprinted with permission.)

**Figure 35-9.** A, An intracorporeal biopsy is being performed on the sigmoid colon. A fine-tipped grasping forceps has been used to grasp the biopsy site, and Metzenbaum scissors are used to obtain the biopsy specimen. B, This biopsy was performed through the umbilical incision. One port and another instrument have been introduced through the infant's abdominal wall. A site on the colon for the biopsy was visualized and delivered just under the umbilical cannula. The umbilical cannula was removed, and this portion of the colon was grasped and exteriorized. An extracorporeal biopsy was obtained and the biopsy site was closed. This is an alternative means for obtaining the biopsy. (From Morowitz MJ, Georgeson KE: Laparoscopic assisted pull-through for Hirschsprung's disease. In Holcomb GW, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy, Philadelphia, Elsevier, 2008, pp 101-108. Reprinted with permission.)

**Figure 35-10.** When the transition zone is proximal to the mid-sigmoid colon, a pedicled colon flap must be developed for the endorectal pull-through. In this situation, the pull-through colon will derive its vascular supply from the marginal artery. Therefore, to mobilize the descending colon and splenic flexure, it is necessary to ligate and divide either the inferior mesenteric artery just distal to its origin from the aorta (as seen in this drawing) or the left colic artery just after it arises from the inferior mesenteric artery. By ligating these vessels at these sites, the arterial supply through the marginal artery is not compromised. (From Morowitz MJ, Georgeson KE: Laparoscopic assisted pull-through for Hirschsprung's disease. In Holcomb GW, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy, Philadelphia, Elsevier, 2008, pp 101-108. Reprinted with permission.)

is not difficult. The distal branches of the inferior mesenteric artery and vein should be preserved to prevent potential ischemic scarring of the seromuscular cuff after the mucosal sleeve resection.

Infants and children with a longer transition zone (above the proximal sigmoid colon) require pedicle formation for the pull-through of the ganglionated colon. The vascular pedicle is formed by preserving the marginal artery (Fig. 35-10). The lateral fusion fascia and other restraining ligaments should also be divided so that there is no tension on the colon or its vascular pedicle when it is pulled down for the coloanal anastomosis. The appropriate length for the pedicle can be determined by pulling the intended site of anastomosis down into the pelvis and allowing a few extra centimeters for a tension-free coloanal anastomosis.

I usually extend the resection of the aganglionic segment for a distance of 5 to 10 cm proximal to the histologically identified transition zone. This extension allows for removal of dilated, dysfunctional bowel that may be present proximal to the transition zone. If available, rapid frozen evaluation of the enzymatic activity of the ganglion cells is used to accurately level the pull-through colon pedicle. Once the endoscopic dissection has been completed, attention is turned to the transanal dissection. Six to eight perianal retraction sutures are used to evert the anus and expose the rectum (Fig. 35-11A). It is important to avoid overstretching the internal sphincter while placing these sutures. Overstretching of the internal sphincter will lead to long-term fecal soiling and diminish the quality of life for patients with HD. The dissection is always performed outside the anus using downward traction to keep the dissection plane outside the anus. This will avoid the tendency to stretch the internal sphincter by using retractors in the anorectal canal. Moreover, retractors are usually not necessary when the dissection is performed properly. Mucosal traction sutures are usually placed in a vertical orientation before incising the mucosa. These traction sutures should be tied snugly before the transanal dissection to co-apt

**Figure 35-11.** A, The perineal dissection begins with the placement of circumferential 2-0 silk traction sutures from the dentate line to the perineum 2 to 3 cm outward from the anus. B and C, A needle-tipped electrocautery is used to circumferentially incise the rectal mucosa approximately 5 mm proximal to the anal columns. Fine silk traction sutures are then placed in the rectal mucosa to help retract the mucosa during circumferential dissection. (From Morowitz MJ, Georgeson KE: Laparoscopic assisted pull-through for Hirschsprung's disease. In Holcomb GW, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy, Philadelphia, Elsevier, 2008, pp 101-108. Reprinted with permission.)

the anus and prevent soiling during the dissection. Also, this allows more robust traction for defining the submucosal plane. A circular incision is made at the anorectal line near the top of the rectal columns (see Fig. 35-11B, C). This submucosal plane is then developed using both blunt and sharp dissection. Generous use of the electrocautery for hemostasis is helpful. It seems best to dissect the two side planes initially and then to connect them with the anterior and posterior planes. The dissection is continued circumferentially proximally until bleeding ceases because of the previous separation of the mesentery from the colon during the laparoscopic mobilization. Another sign of adequate transanal dissection is the increasing ease of withdrawing the colon out through the anus.

After the colorectum has been exteriorized through the anus, the peritoneal cavity is entered posteriorly. This dissection is continued circumferentially by dividing the seromuscular wall using cautery. The posterior wall of the cuff is split down to the intended point of anastomosis. This division of the cuff allows for the creation of a larger neorectal reservoir. The colon is pulled down to a point where the biopsies have indicated an appropriate transition zone. As previously mentioned, an additional 5- to 10-cm margin of ganglionated bowel is resected when possible. The colon is transected and the coloanal anastomosis is performed (Fig. 35-12). In some cases of longer segment

HD, a mini-reservoir can be developed by using the Heineke-Mikulicz technique (Fig. 35-13). A vertical incision is made in the pull-through colon, beginning 1.5 cm above the point of intended anastomosis and extended 3 cm proximally. The incision is then closed transversely like a Heineke-Mikulicz pyloroplasty. A watertight anastomosis is then performed between the anus and the neorectum at the anorectal line. It is important that the neorectum is relatively lax so that a new anorectal angle forms. If the neorectum is pulled down under tension, the anorectal angle is lost and the patient may have a more difficult time developing continence later in life. This is more problematic with the transanal approach when compared with the laparoscopic assisted technique. Also, this lack of tension at the anastomosis helps to avoid ischemia of the distal colon pedicle and/or retraction of the colon pull-through.

Once the anastomosis is completed, the pneumoperitoneum is re-established and the abdominal cavity is inspected laparoscopically. The rectal cuff should also be inspected to make certain it is straight and not folded down into the anorectal canal. If there is a potential internal hernia space under the pedicle of the neorectum, it should be closed with interrupted sutures. The pedicle should also be observed for twisting. If the pedicle is twisted, the anastomosis should be taken down and performed again. In most instances, an oral diet is started 1 to 2 days after the pull-through.

**Figure 35-12.** A, The muscular cuff of the rectum has been divided and the ganglionic colon has been exteriorized through the anal canal. Note that the anastomosis will be performed proximal to the biopsy site (*arrow*). B, The pull-through colon is being completely transected above the biopsy site and made ready for the coloanal anastomosis. C, The anastomosis is being performed with interrupted 4-0 absorbable sutures. D, The everted stay sutures have been cut, allowing the anastomosis to retract cephalad. (From Morowitz MJ, Georgeson KE: Laparoscopic assisted pull-through for Hirschsprung's disease. In Holcomb GW, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy, Philadelphia, Elsevier, 2008, pp 101-108. Reprinted with permission.)

**Figure 35-13.** **A**, To create the mini-reservoir, a full-thickness linear incision is made through the anterior wall of the ganglionic colon beginning 1.5 cm above the transected bowel and continuing for 3 cm proximally. **B**, The linear incision is then closed transversely in a Heineke-Mikulicz fashion. **C**, The coloanal anastomosis and the reservoir closure are seen. (From Morowitz MJ, Georgeson KE: Laparoscopic assisted pull-through for Hirschsprung's disease. In Holcomb GW, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy, Philadelphia, Elsevier, 2008, pp 101-108. Reprinted with permission.)

The length of postoperative hospitalization is about 4 days unless the patient has other medical problems.<sup>60</sup> A clinic visit is scheduled 2 weeks after the operation. During this visit, an interval history and physical examination, including a digital rectal examination, is performed. Postoperative anorectal dilatations are sometimes needed at home.

TAP (without laparoscopic assist) is almost identical to the previously described transanal dissection of the LATEP. Some pediatric surgeons prefer the prone jack-knife position similar to the position for a posterior sagittal anorectoplasty for the TAP.<sup>61</sup> Other surgeons prefer the supine position and advocate initial leveling biopsies by way of a transumbilical celiotomy.<sup>62</sup> A randomized, long-term study comparing the LATEP and the TAP has not been reported.

## POSTOPERATIVE ISSUES

Complications after pull-through can be classified as either early (weeks to months) or late (months to years). Early postoperative complications include anastomotic leak and cuff abscess, bowel obstruction, perineal excoriation, stoma complications, and wound infection. Late complications include bowel obstruction, constipation, enterocolitis, incontinence, and stricture. There is some overlap between the early and late complications. An anastomotic leak has been reported in 5% to 10% of cases, and a cuff abscess is seen in about 5% of cases. Factors that increase the risk of these complications include tension on the anastomosis or ischemia of the pull-through segment. Anastomotic leaks are usually treated by surgical exploration and diverting colostomy.<sup>63-66</sup>

Bowel obstruction is seen in both the early and late postoperative periods. It occurs in 5% to 10% of children after pull-through.<sup>66,67</sup> It is sometimes responsive to bowel decompression without the necessity of operative release, but may require urgent operative exploration in some circumstances. Factors increasing

the risk of adhesions include prior operations, use of the open pull-through technique, and an anastomotic leak. Some authors have suggested that the laparoscopic or transanal approaches decrease the incidence of adhesive bowel obstruction.<sup>66</sup> I have not yet seen an adhesive obstruction as the cause of a postoperative bowel obstruction after a LATEP for HD.

Perineal excoriation due to an increase in stool frequency is common after the definitive repair of HD. It is frequently seen after a Swenson or Soave pull-through and may be less common after the Duhamel operation. Protective creams and antifungal agents (topical and oral) help to prevent or treat the excoriated skin. Neoanal prolapse, retraction, and peristomal skin breakdown are infrequent postoperative complications. Usually, mild strictures of the anal anastomosis can be easily corrected by daily postoperative dilatation by the parent beginning 3 weeks after the primary pull-through and continuing for 1 to 2 months.

Enterocolitis is a major cause of morbidity after surgery for HD. However, its pathogenesis is not completely understood.<sup>68,69</sup> Obstruction at the level of the anus certainly plays a role, particularly if it causes intestinal stasis and leads to proliferation of luminal pathogens. However, the very high incidence of Hirschsprung enterocolitis cannot be explained by partial obstruction alone. The reported incidence of Hirschsprung enterocolitis varies widely, but seems to be in the 30% to 40% range in carefully conducted studies.<sup>31,68,70</sup> In one recent retrospective study, it was reported that an initial admission for Hirschsprung enterocolitis was unusual beyond 2 years after the pull-through.<sup>53</sup> Risk factors for Hirschsprung enterocolitis are reported to be diagnosis at a young age, anastomotic stricture, and malnutrition.<sup>31,53</sup> Some researchers have suggested that a short rectal muscular cuff may also decrease the incidence of enterocolitis by reducing the obstruction caused by the spastic cuff.<sup>70</sup> It seems that keeping the cuff as short as possible and splitting the remaining cuff posteriorly during the primary pull-through operation may help reduce postoperative enterocolitis.

Yamataka has described resection of the posterior half of the muscle cuff to avoid infolding and stricture of the cuff in an attempt to reduce the secondary constipation and enterocolitis.<sup>71</sup> Intestinal stasis combined with immature mucosal immunity seems to contribute to the development of enterocolitis.<sup>72</sup>

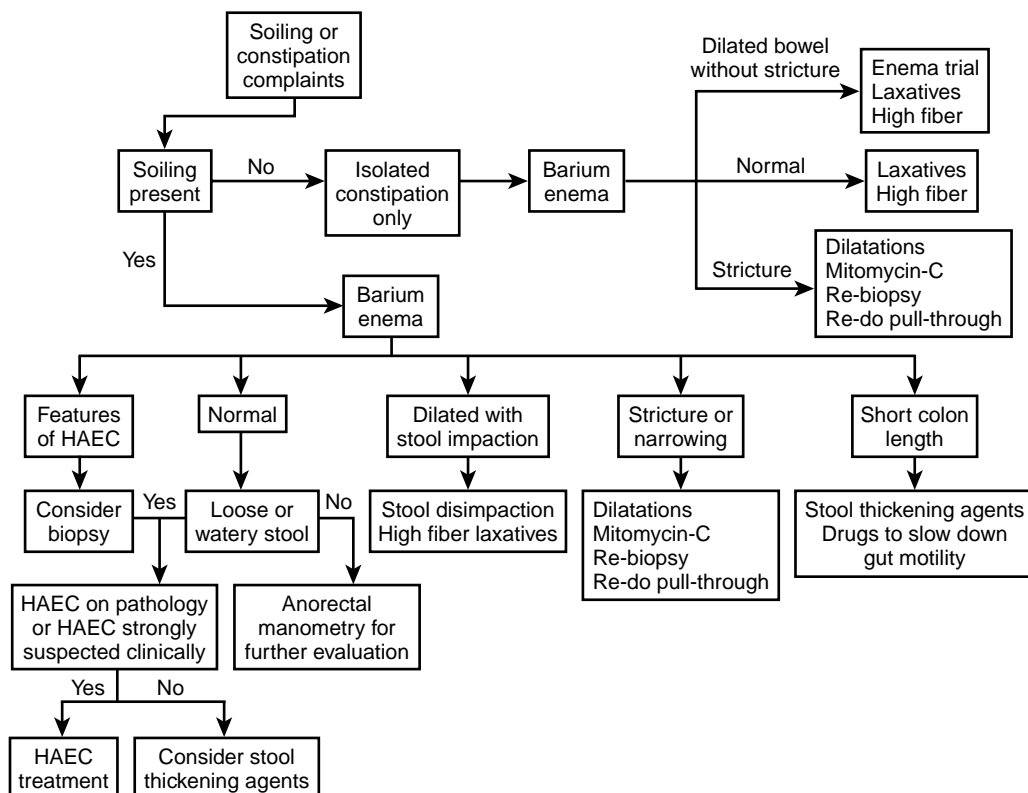

An anastomotic stricture after the definitive pull-through procedure is another important postoperative complication. The incidence of anastomotic stricture varies widely depending on the method of reporting. The risk factors include anastomotic ischemia, cuff ischemia, anastomotic leak, and a small circular anastomosis.<sup>73,74</sup> As previously noted, Swenson believed that performing an oblique coloanal anastomosis may help to prevent stricture formation.<sup>4</sup> Stricture formation has been consistently associated with a higher risk of postoperative enterocolitis.<sup>53</sup> Most strictures can be managed by daily home dilatation. A few strictures require more aggressive measures such as the injection of mitomycin after aggressive dilatation. Occasionally, surgical ablation of the stricture or a re-do pull-through are needed to ameliorate the problem.

Stool frequency is high (10 or more per day) during the immediate postoperative period after pull-through. This frequency generally improves with time. By 6 months to 1 year after surgery, the stool frequency has usually declined to two to four times per day.<sup>74</sup> An algorithm for evaluation of post-pull-through soiling or constipation at my institution is shown in Figure 35-14. Constipation is sometimes seen a few months after pull-through and may depend on the type of operation. A

higher incidence of constipation has been noted after the Duhamel or Rehbein technique.<sup>66,73</sup> Post-pull-through constipation has been reported in as low as 8% to 10% of children, but this incidence is probably underestimated. In one published study, it was reported that 37% of children had difficulty in evacuating stool after an operation for HD.<sup>75</sup> This functional form of constipation may be managed with nonoperative measures such as a high-fiber diet, laxatives, and enemas, but may require more aggressive management such as placement of a cecostomy or sigmoidostomy button, or even a re-do pull-through in the most severe cases.<sup>74,76,77</sup>

Fecal continence is best assessed after 4 years of age. In a series of carefully evaluated patients, the incidence of soiling was much higher than previous reports have indicated.<sup>76</sup> Most surgeons likely underestimate the presence of fecal soiling and incontinence in their patients. Catto-Smith and coworkers assessed continence after operation for HD in a cohort of 84 children with a mean age of 12 years.<sup>75</sup> They noted that fecal urgency was common (58%), and many patients were unable to hold back their stool or discriminate stool consistency (32%). Loose (liquid or pasty) stools were more common in children with long segment disease. Also, nearly 20% of the children were using continence aids or kept extra underwear available beyond the toilet training years.

Specific food intolerance is common after operation, with 44% of children using modified diets to avoid loose stools or constipation.<sup>75,77</sup> Anorectal manometry

**Figure 35-14.** This algorithm is useful for evaluation of post pull-through soiling and constipation. HAEC, Hirschsprung-associated enterocolitis.

results showed higher baseline sphincter pressures and marked blunting of the sensation of rectal distention in children with significant soiling.<sup>73,75</sup> These authors, however, noted that continence and stool consistency improved with age. Enuresis has been reported in 5% to 26% of children and has been attributed to pelvic nerve injuries or neuropathy.<sup>73,75</sup>

Late mortality has been reported to be between 1% and 5% of the children undergoing operation for HD.<sup>63,78</sup> Although the exact cause of death is not consistently reported, a large percentage of the deaths are associated with enterocolitis (Fig. 35-15). With improvement in the recognition and treatment, mortality due to enterocolitis should decrease.

Stooling issues including constipation, incontinence, and enuresis may have the most impact on the postoperative quality of life of the child with HD and their parents. A trend toward improvement in stooling problems as the child gets older has been noted in several studies.<sup>75,78</sup> Improvement in continence as the child ages is probably due to the increased sophistication of the child as he or she grows, and to a better understanding of bowel management by pediatric surgeons and gastroenterologists. The presence of long-segment disease has been associated with a worse quality of life.<sup>75,79</sup> Children seem to cope with their disease in later years by developing stronger psychosocial skills.<sup>80</sup> The goal of the surgeon, however, should be to minimize these problems by providing meticulous operative, postoperative, and

long-term care. HD is a lifelong disorder and should be thoughtfully explained to the family before any surgical procedures. Mechanisms for adequate long-term follow-up care should be in place at the time of postoperative discharge.

**Figure 35-15.** Enterocolitis can be a major cause of morbidity and mortality, both before any operative procedure for Hirschsprung's disease and in the postoperative period. Most of the deaths in the postoperative period are related to enterocolitis. In this autopsy specimen, note the several areas of perforation (*dotted arrow*) along the colon due to significant enterocolitis. Also note that the patient had undergone a diverting colostomy and had a mucous fistula (*solid arrow*).

# IMPERFORATE ANUS AND CLOACAL MALFORMATIONS

Marc A. Levitt, MD • Alberto Peña, MD

“Imperforate anus” has been a well-known condition since antiquity.<sup>1-3</sup> For many centuries, physicians, as well as individuals who practiced medicine, tried to help these children by creating an orifice in the perineum. Many patients survived, most likely because they suffered from a type of defect that is now recognized as “low.” Those with a “high” defect did not survive treatment. In 1835, Amussat was the first to suture the rectal wall to the skin edges, which could be considered the first actual anoplasty.<sup>2</sup> During the first 60 years of the 20th century, most surgeons performed a perineal anoplasty without a colostomy for the so-called low malformations. A colostomy performed during the newborn period was followed by an abdominal perineal pull-through for the treatment of high malformations. The decision to create the colostomy was based mainly on the radiologic information obtained by an invertogram.<sup>4</sup> During the era of the abdominoperineal pull-through operation, the specific recommendation was to pull the bowel as close to the sacrum as possible to avoid trauma to the genitourinary tract. Stephens made a significant contribution by performing the first objective anatomic studies in human specimens. In 1953, he proposed an initial sacral approach followed by an abdominoperineal operation, if necessary.<sup>5</sup> The purpose of the sacral stage of the procedure was to preserve the puborectalis sling, considered a key factor in maintaining fecal incontinence. Since then, different surgical techniques have been proposed.<sup>6-9</sup> Their common denominator is the protection and use of the puborectalis sling.

The posterior sagittal approach for the treatment of imperforate anus was performed first in 1980, and its description was published in 1982.<sup>10,11</sup> This new approach allowed direct exposure of this important anatomic area. Also, the unique opportunity arose to correlate the external appearance of the perineum with the operative findings and, subsequently, with the clinical results. Since its original description, significant innovations in terminology and classification have emerged.

## INCIDENCE, TYPES OF DEFECTS, AND TERMINOLOGY

Anorectal atresia occurs in one of every 4000 to 5000 newborns and is slightly more common in males.<sup>12-14</sup> The estimated risk for a couple having a second child with an anorectal malformation is approximately 1%.<sup>15-18</sup> The most frequent defect in male patients is anorectal atresia with a rectourethral fistula,<sup>19</sup> and is anorectal atresia with a rectovestibular fistula in females.<sup>19</sup> Imperforate anus without a fistula is a rather unusual defect. It occurs in about 5% of the entire group of malformations, and is associated with Down syndrome.<sup>19,20</sup> Historically, persistent cloaca was considered an unusual defect, whereas a high incidence of rectovaginal fistula was reported in the literature.<sup>21</sup> In retrospect, it seems that the presence of a cloaca is a much more common defect in females.<sup>22</sup> A cloaca is the third most common defect in female patients after vestibular and perineal fistulas, whereas a rectovaginal fistula actually is a rare defect, present in fewer than 1% of all cases.<sup>22,23</sup> It is likely that most patients suffering from a persistent cloaca were erroneously thought to have a rectovaginal fistula. Many of these patients underwent surgery with repair of the rectal component but were left with a persistent urogenital sinus.<sup>22,24</sup> Additionally, most rectovestibular fistulas were erroneously called “rectovaginal fistula.”<sup>22</sup> A recto-bladder neck fistula in male patients is the only true supralelevator malformation and occurs in about 10% of male patients.<sup>19</sup> Because it is the only malformation in males in which the rectum is unreachable through a posterior sagittal incision, it requires an abdominal approach (either laparotomy or laparoscopy) in addition to a perineal approach.

Anorectal malformations represent a wide spectrum of defects. The terms “low,” “intermediate,” and “high” are arbitrary and not useful in therapeutic or prognostic terms. Within the group of anorectal malformations traditionally referred to as “high,” there are defects included with different therapeutic and

prognostic implications.<sup>25</sup> For instance, retroprostatic fistula and recto-bladder neck fistula were both considered high, yet the first can be repaired with a posterior sagittal approach alone and the second requires an additional abdominal approach. Furthermore, the prognosis for each type is completely different. Therefore, a more therapeutic and prognostically oriented classification is depicted in Table 36-1.

## MALE ANORECTAL DEFECTS

### Rectoperineal Fistulas

Rectoperineal fistula is what traditionally was known as a “low defect.” The rectum is located within most of the sphincter mechanism. Only the lowest part of the rectum is anteriorly mislocated (Fig. 36-1). Sometimes, the fistula does not open into the perineum but rather follows a subepithelial midline tract, opening somewhere along the midline perineal raphe, scrotum, or even at the base of the penis. This diagnosis is established by perineal inspection. No further investigations are required. Usually, the anal fistula opening is narrow (stenotic). The terms *covered anus*, *anal membrane*, *anteriorly mislocated anus*, and *bucket-handle malformations* all refer to perineal fistulas.

### Rectourethral Fistulas

Imperforate anus with a rectourethral fistula is the most frequent defect in male patients.<sup>19</sup> The fistula may be located at the lower (bulbar) (Fig. 36-2A) or the higher (prostatic) part of the urethra (see Fig. 36-2B).

Immediately above the fistula, the rectum and urethra share a common wall. The lower the fistula, the longer is the common wall. This is an important anatomic fact with significant technical and surgical implications. The rectum is usually distended and surrounded laterally and posteriorly by the levator muscle. Between the rectum and the perineal skin, a

portion of striated voluntary muscle called the muscle complex is present. The contraction of these muscle fibers elevates the skin of the anal dimple. At the level of the skin, a group of voluntary muscle fibers, called parasagittal fibers, are located on both sides of the midline. Lower urethral fistulas are usually associated with good-quality muscles, a well-developed sacrum, a prominent midline groove, and a prominent anal dimple. Higher urethral fistulas are more frequently associated with poor-quality muscles, an abnormally developed sacrum, a flat perineum, a poor midline groove, and a barely visible anal dimple. Of course, exceptions to these rules exist. Occasionally, the infant passes meconium through the urethra, which is an unequivocal sign of a rectourinary fistula.

### Recto-Bladder Neck Fistulas

In this defect, the rectum opens into the bladder neck (Fig. 36-3). The patient usually has a poor prognosis for bowel control because the levator muscles, the striated muscle complex, and the external sphincter frequently are poorly developed. The sacrum is often deformed and short. In fact, the entire pelvis seems to be underdeveloped. The perineum is often flat, which is evidence of poor muscle development. About 10% of males with anorectal atresia fall into this category.<sup>19</sup>

### Imperforate Anus without Fistula

Interestingly, most patients with this unusual defect have a well-developed sacrum and good muscles, and have a good prognosis in terms of bowel function.<sup>19</sup> The rectum usually terminates approximately 2 cm from the perineal skin. Although the rectum and urethra do not communicate, these two structures are separated only by a thin, common wall. About half of

**Figure 36-1.** This drawing shows the course of a perineal fistula in a male. The rectum is located within most of the muscle complex. Only the most distal aspect of the rectum is misplaced.

**Figure 36-2.** These drawings depict anorectal atresia with rectourethral fistulas. **A**, Rectourethrobulbar fistula **B**, Rectourethroprostatic fistula.

the patients with no fistula also have Down syndrome, and more than 90% of patients with Down syndrome and imperforate anus have this specific defect, suggesting a chromosomal link.<sup>18,20</sup> The fact that these patients have Down syndrome does not seem to interfere with their good prognosis for bowel control.<sup>20</sup>

### Rectal Atresia

In this extremely unusual defect in male patients (~1% of the entire group of malformations), the lumen of the rectum is totally (atresia) or partially (stenosis) interrupted.<sup>19</sup> The upper pouch is represented by a dilated rectum, whereas the lower portion is represented by a small anal canal that is in the normal location and is 1 to 2 cm deep (Fig. 36-4). These two

**Figure 36-3.** Schematic representation of a recto-bladder neck fistula. Note that the fistula enters into the bladder neck near the junction between the urethra and the bladder.

structures may be separated by a thin membrane or by dense fibrous tissue. The repair involves a primary anastomosis between the upper pouch and anal canal (see Fig. 36-4B) and is ideally approached posteriorly sagittally. Patients with this defect have all the necessary elements to be continent and have an excellent functional prognosis. Because they have a well-developed anal canal, they have normal sensation in the anorectum and have almost normal voluntary sphincters. Patients with rectal atresia must be screened for a presacral mass.<sup>26</sup>

## FEMALE ANORECTAL DEFECTS

### Rectoperineal Fistulas

From the therapeutic and prognostic viewpoint, this common defect is equivalent to the perineal fistula described in the male patient.<sup>19</sup> The rectum is well positioned within the sphincter mechanism, except for its lower portion, which is anteriorly located. The rectum and vagina are well separated (Fig. 36-5). The key anatomic issues are the anal opening in relation to the sphincter mechanism, and the length of the perineal body.

### Rectovestibular Fistulas

Rectovestibular fistula is the most common defect in girls and has an excellent functional prognosis. The diagnosis is based on clinical examination. A meticulous inspection of the neonatal genitalia allows the clinician to observe a normal urethral meatus and a normal vagina, with a third hole in the vestibule, which is the rectovestibular fistula (Fig. 36-6). About 5% of these patients will have two hemivaginas with a vaginal septum.

A number of pediatric surgeons repair this defect without a protective colostomy. This is a well-recognized trend in the management of anorectal malformations.<sup>27-30</sup> The advantage of this approach is

**Figure 36-4.** This newborn was found to have rectal atresia. **A**, Note the normal anal position and short depth of the anal canal. **B**, Operative repair. A dilator has been inserted into the anus and the anastomosis (arrow) is identified just proximal to the distal anal canal.

that it avoids the potential morbidity of a colostomy and reduces the number of operations to one from as many as three (colostomy, main repair, and colostomy closure). Many patients do very well with a primary neonatal operation without a protective colostomy. However, a perineal infection followed by dehiscence of the anal anastomosis or perineal body, or recurrence of the fistula provokes severe fibrosis that may interfere with the sphincter function. If these complications occur, the patient may have lost the best opportunity for an optimal functional result because secondary operations do not render the same prognosis as a successful primary operation.<sup>31</sup> Thus, a protective colostomy is still the best way to avoid these complications. The decision to perform a colostomy or primary repair in these cases must be made individually by the surgeon, taking into consideration his or her experience and the clinical condition of the patient. At our institution, neonates born with this anomaly, without significant associated defects, undergo operation without a colostomy.

The term *vaginal fistula* is frequently erroneously used in patients who actually have a vestibular fistula or a cloaca. A true vaginal fistula occurs in less than 1% of all cases<sup>22</sup> and is not considered part of the proposed classification.

**Figure 36-5.** Schematic drawing of a perineal fistula in a female. Most of the rectum is in the muscle complex. Only the most distal aspect of the rectum is anteriorly positioned.

## Imperforate Anus without Fistula

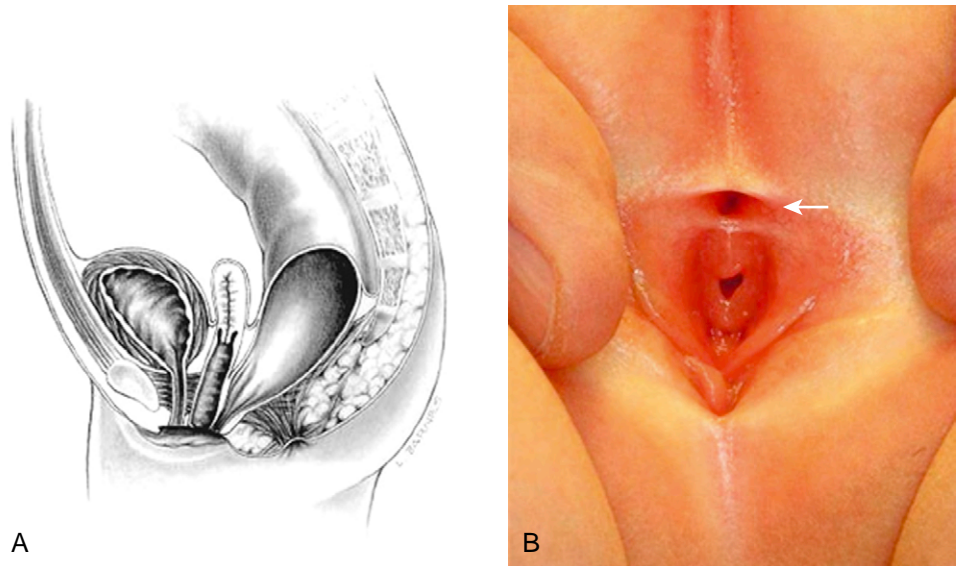

This defect in female patients carries the same therapeutic and prognostic implications as described for male patients.

## Persistent Cloaca

This group of defects represents the extreme in the spectrum of complexity of female malformations. A cloaca is defined as a defect in which the rectum, vagina, and urinary tract meet and fuse, creating a single common channel.

The diagnosis of persistent cloaca is a clinical one. This defect should be suspected in a female born with imperforate anus and small-looking genitalia. Careful separation of the labia discloses a single perineal orifice. The length of the common channel varies from 1 to 7 cm. This distance has technical and prognostic implications. Common channels longer than 3 cm usually are associated with complex defects (Fig. 36-7A). Mobilization of the vagina is difficult in such cases. Therefore, in patients with a long common channel, some form of vaginal replacement is often needed during the definitive repair. A common channel of less than 3 cm usually means that the defect can be repaired with a posterior sagittal operation without opening the abdomen (see Fig. 36-7B). When the rectum opens high into the dome of the vagina (Fig. 36-8), an abdominal approach must be utilized to mobilize the bowel. Frequently, the vagina is abnormally distended and full of secretions (hydrocolpos) (Fig. 36-9A). The distended vagina compresses the trigone and interferes with drainage of the ureters and is frequently associated with megaureters. This condition may be diagnosed prenatally.<sup>32,33</sup> The dilated vagina can also become infected (pyocolpos) and may lead to perforation and peritonitis. However, such a large vagina may represent a technical advantage for the repair, providing more vaginal tissue to facilitate the reconstruction. A frequent finding in cloacal malformations is the presence of different degrees of vaginal and uterine septation or duplication (see Fig. 36-9B). The rectum usually enters between the two hemivaginas. Rarely, patients may have cervical atresia. During puberty, they are unable to drain menstrual blood through the vagina. These patients accumulate menstrual blood in the peritoneal cavity and often require

**Figure 36-6.** A, Schematic drawing of a rectovestibular fistula. B, A female neonate with a rectovestibular fistula. Note the patient is in the prone position and the rectal fistula (arrow) is located in the posterior aspect of the vestibule.

**Figure 36-7.** A, Schematic diagram of a long common channel in a female with a cloacal anomaly. B, The more commonly encountered short common channel cloaca is depicted.

**Figure 36-8.** A schematic diagram of the rectum inserting high into the posterior vagina with a short common urethral and vaginal channel is shown.

emergency operations.<sup>34</sup> An evaluation of a patient's müllerian anatomy, either at the time of the definitive repair or at the colostomy closure, is vital and can prevent future problems. Low cloacal malformations (<3 cm) are usually associated with a well-developed sacrum, a normal-appearing perineum, and adequate muscles and nerves. Therefore, a good functional prognosis should be expected.

### Complex Malformations

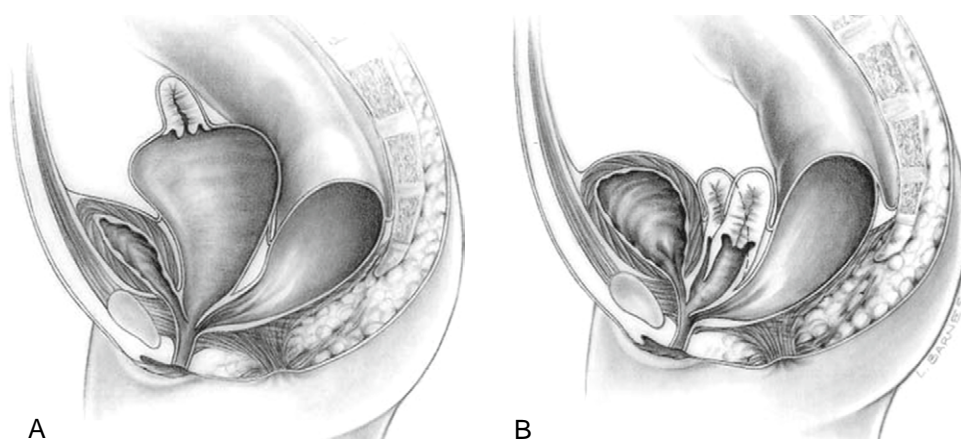

Unusual and bizarre anatomic arrangements can be seen. Each case represents a unique challenge to the surgeon, with different prognoses and therapeutic implications. No general guidelines can be drawn for the management of these patients. Each case must be individualized.

## ASSOCIATED DEFECTS

### Sacrum and Spine

Sacral deformities appear to be the most frequently associated defect.<sup>35</sup> One or several sacral vertebrae may be missing. A single missing vertebrae does not

**Figure 36-9.** **A**, Schematic depiction of a cloacal anomaly with insertion of the rectum into the common channel and subsequent vaginal obstruction with hydrocolpos. **B**, Schematic depiction of a cloacal anomaly and uterine duplication. The rectum is shown entering between the two hemivaginas.

seem to have any important prognostic implications.<sup>19</sup> However, more than two absent sacral vertebrae represent a poor prognostic sign in terms of bowel continence and, sometimes, urinary control. A hemisacrum is usually associated with a presacral mass and poor bowel control.<sup>26</sup> Other sacral abnormalities, such as spinal hemivertebra, have a negative implication for a patient's bowel control.

A sacral ratio allows for a more objective evaluation of the sacrum (Fig. 36-10). The normal sacral ratio in children is 0.77. Children with anorectal malformations suffer from different degrees of sacral hypodevelopment, and the sacral ratio can vary from 0.0 to 1.0. We have never seen a patient develop good bowel control with a sacral ratio of less than 0.3.

Emphasis has been placed on the diagnosis and treatment of a tethered cord, which is a defect frequently associated with anorectal malformations.<sup>36-44</sup> It has been assumed that the presence of a tethered cord is associated with poor functional prognosis in these children. A review of our own series showed that

25% of patients with an anorectal malformation suffer from tethered cord.<sup>45</sup> Although it is true that most of these children have a poor prognosis, the presence of a tethered cord by itself coincides with a very high defect, very abnormal sacrum, or spina bifida. Therefore, it is difficult to know whether the tethered cord itself is responsible for the poor prognosis. Also, we have not found evidence that the operation to release the tethered cord changes the functional bowel prognosis of the patient.<sup>42-45</sup>

### Genitourinary Defects

The frequency of associated genitourinary defects varies from 20% to 54%.<sup>46-58</sup> The accuracy and thoroughness of the urologic evaluation may account for the reported variation.

In our experience, 48% of patients (55% girls and 44% boys) had associated genitourinary anomalies.<sup>52</sup> These figures may not reflect the real incidence of genitourinary defects because our hospital is a referral

**Figure 36-10.** Drawings with landmarks necessary for the calculation of the sacral ratio. **A**, Lateral view. **B**, Anteroposterior view. The normal ratio is 0.77.

center where we see a high proportion of complex malformations that are not necessarily representative of the entire spectrum of defects.

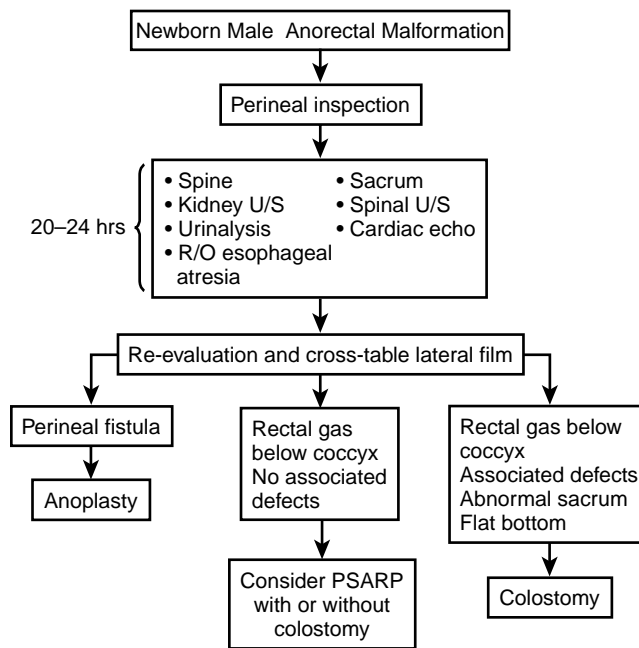

The higher the malformation, the more frequent are the associated urologic abnormalities. Patients with persistent cloacas or recto-bladder neck fistulas have a 90% chance of having an associated genitourinary abnormality.<sup>52</sup> Conversely, children with low defects (perineal fistulas) have less than a 10% chance of having an associated urologic defect. Hydronephrosis, urosepsis, and metabolic acidosis from poor renal function represent the main sources of morbidity in infants with anorectal malformations. Thus, a thorough urologic investigation is mandatory in cases of high defects, but is not as urgent in cases of rectovestibular and rectourethral fistulas. The evaluation in every child with imperforate anus must include an ultrasonographic study of the kidneys and abdomen to evaluate for the presence of hydronephrosis or any other urologic obstructive process. In patients with a cloaca, this study is especially important to exclude the presence of hydrocolpos. If this study is abnormal, further urologic evaluation is necessary.

## NEWBORN MANAGEMENT

A decision-making algorithm for the initial management in male patients is seen in Figure 36-11. During the past few years, the tendency by the pediatric surgical community has been to operate on patients with anorectal malformations primarily without a protective colostomy.<sup>27-30,59,60</sup> We promote this trend, but also alert all surgeons to the potential negative consequences of performing these operations without the necessary preoperative evaluation and experience.

When asked to evaluate a male newborn with an anorectal malformation, a thorough perineal inspection must be performed. This usually gives the key clues to the type of malformation. It is important not to make a decision about a colostomy or a primary operation before 24 hours of life. The reason is that significant intraluminal pressure is required for the meconium to be forced through a fistulous orifice. Passage of meconium through a fistula will be the most valuable sign for the location of that fistula. If meconium is seen on the perineum, a perineal fistula is present. If there is meconium in the urine, a rectourinary fistula exists. Radiologic evaluations may not show the correct anatomy before 24 hours because the rectum is collapsed. It takes a significant amount of intraluminal pressure to overcome the muscle tone of the sphincters that surround the lower part of the rectum. Therefore, radiologic evaluations done too early (before 24 hours) most likely will show a "very high rectum" and may lead to an incorrect diagnosis.

During the first 24 hours, the neonate should receive intravenous fluids and antibiotics and be evaluated for associated defects that may represent a threat to life. These include cardiac malformations, esophageal atresia, and urinary defects.<sup>35,61</sup> A radiograph of

**Figure 36-11.** Algorithm for the management of male newborns with anorectal malformations based on the physical examination and radiographs. PSARP, posterior sagittal anorectoplasty; U/S, ultrasonography; R/O, rule out.

the lumbar spine and the sacrum should be obtained as well as a spinal ultrasonogram to evaluate for a tethered cord. Ultrasonography of the abdomen will evaluate for hydronephrosis.

If the neonate has signs of a perineal fistula, we recommend that an anoplasty, without a protective colostomy, be performed during the first 48 hours of life. After 24 hours, if there is no meconium on the perineum, we recommend obtaining a cross-table lateral radiograph with the patient in the prone position. If air in the rectum is located below the coccyx, (Fig. 36-12) and the patient is in good condition with no significant associated defects, one may consider performing a posterior sagittal operation without a protective colostomy. A more conservative alternative would be to perform the posterior sagittal repair and a protective colostomy at the same stage.

Conversely, if the rectal gas does not extend beyond the coccyx, or the patient has meconium in the urine, an abnormal sacrum, or a flat bottom, we strongly recommend a colostomy. This allows for a future distal colostogram, which will precisely delineate the anatomy. We would then perform a posterior sagittal anorectoplasty 1 to 2 months later, provided the neonate is gaining weight appropriately.

Performing the definitive repair at age 1 to 3 months has important advantages, including less time with an abdominal stoma, less size discrepancy between the proximal and distal bowel at the time of colostomy closure, and easier anal dilation (because the infant is smaller). In addition, at least theoretically, placing the rectum in the right location early in life may represent an advantage in terms of the potential for acquired local sensation.<sup>62</sup>

**Figure 36-12.** Technique for a cross-table lateral radiograph. **A**, A roll has been placed beneath the hips of the infant to elevate the buttocks and allow air to migrate superiorly to the end of the rectum. **B**, Actual cross-table lateral radiograph. Air is visualized distal to the coccyx (arrow).

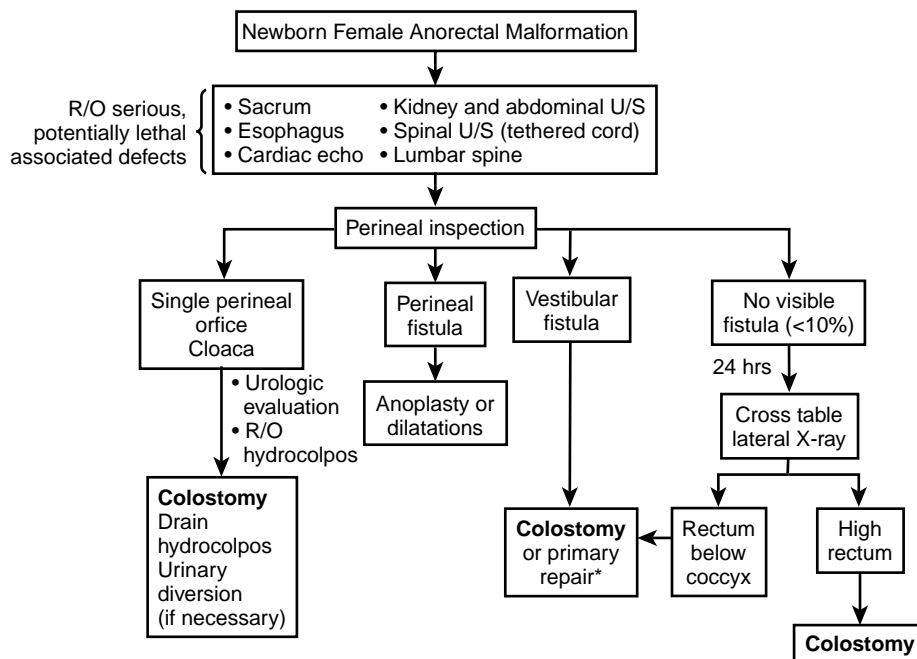

All of these potential advantages of an early operation must be weighed against the possible disadvantages of an inexperienced surgeon who is not familiar with the minute anatomic structures of an infant's pelvis.

A temptation to repair these defects without a protective colostomy always exists.<sup>27,28,59,60</sup> Repair without a colostomy limits the anatomic information (provided by a distal colostogram) that may be very helpful to the surgeon. The worst complications involve patients operated on without a colostomy or a properly performed distal colostogram.<sup>63</sup> Proceeding with the posterior sagittal approach looking blindly for the rectum has resulted in a spectrum of serious complications, including damage to the urethra, complete division of the urethra, pull-through of the urethra, pull-through of the bladder neck, injury to the ureters, and division of the vas deferens or seminal vesicles.<sup>63</sup>

A decision-making algorithm for the initial management of newborn females is seen in Figure 36-13.

Again, the perineal inspection is the most important step to guide diagnosis and decision making. The first 24 hours should also be used to evaluate for serious associated defects, as previously described. The perineal inspection may disclose the presence of a single perineal orifice. This single finding establishes the diagnosis of a cloaca, which carries a high risk of an associated urologic defect. The patient needs a complete urologic evaluation, including abdominal and pelvic ultrasonography, to look for hydronephrosis and hydrocolpos.

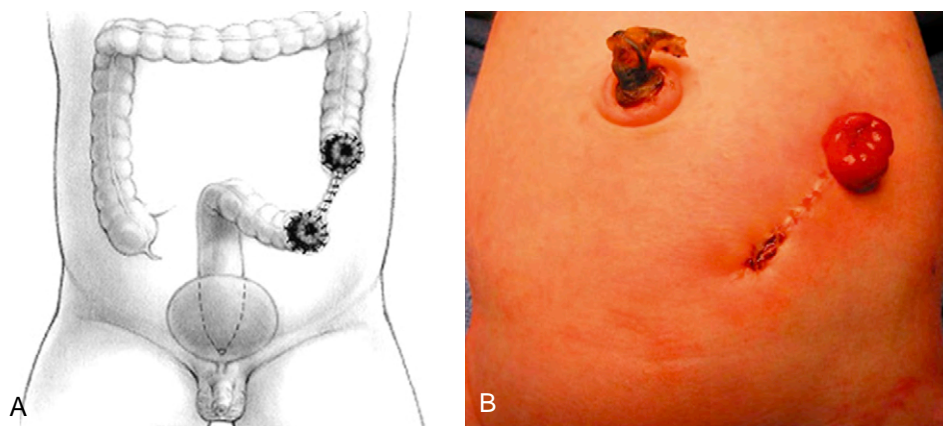

Patients with a cloaca require a colostomy. It is important to perform the divided sigmoid colostomy in such a manner as to leave enough redundant, distal rectosigmoid colon to allow for the subsequent pull-through (Fig. 36-14). When performing the colostomy, it is mandatory to drain the hydrocolpos when present. This can be achieved with a red rubber catheter. Because a significant number of these patients have two hemivaginas, the surgeon must be certain that both

\* Depending on the experience of the surgeon and general condition of the patient

**Figure 36-13.** Decision-making algorithm for female newborns with anorectal malformations. U/S, ultrasonography; R/O, rule out.

**Figure 36-14.** An ideal colostomy for infants with high anorectal malformations is seen in the drawing (A) and infant (B). Note the colostomy and mucous fistula are separated and that adequate distal colonic length remains for the subsequent rectal pull-through.

hemivaginas are drained. Occasionally, a vaginovaginoscopy in the vaginal septum will have to be created to drain both hemivaginas with one catheter. At times, the hydrocolpos is so large that it may produce respiratory distress. It is the hydrocolpos that compresses the trigone and causes bilateral hydronephrosis, and drainage of the hydrocolpos allows for decompression of the urologic system. Rarely, if the common channel is very narrow and does not allow the bladder to drain, the neonate may require a vesicostomy or suprapubic cystostomy to decompress the bladder. However, in the vast majority of cases, drainage of the hydrocolpos is all that is required. Endoscopic examination of the cloaca is recommended to delineate the anatomy. This is best done later (in several months) during a separate anesthetic because the neonatal perineum is swollen and endoscopy is difficult.

The presence of a vestibular fistula represents the most common finding in female patients (see Fig. 36-6). When newborns with a vestibular fistula undergo primary repair at our institution, we keep the patient 5 to 7 days, do not allow any oral intake, and use parenteral nutrition. Conversely, when the patient undergoes a primary repair of a vestibular fistula or perineal fistula without colostomy later in life, we are very strict about preoperative bowel irrigation 24 hours preoperatively to ensure that the intestine is completely clean. We then keep the patient on parenteral nutrition 7 to 10 days with nothing by mouth, all in an attempt to avoid a perineal infection.

The perineal inspection may show the presence of a perineal fistula. When present, we recommend performing a primary anoplasty without a colostomy. In fewer than 5% of girls, there is no visible fistula and there is no evidence of meconium after 24 hours of observation. This small group of patients requires a cross-table lateral prone radiograph (see Fig. 36-12). If the radiograph shows gas in the rectum very close to the skin, it means that the patient very likely has a very narrow perineal fistula. Conversely, if the distal extent of the rectal gas is located 1 to 2 cm above the skin, the patient most likely has an imperforate anus with no fistula. If the patient is in stable condition, one can perform a primary operation without a colostomy, depending on the surgeon's experience. Most of these

patients with no fistula also have Down syndrome.<sup>20</sup> In the event that associated conditions make the rectal repair unfeasible in the newborn period, a colostomy should be performed, with definitive repair later.

Occasionally, if the infant with a rectoperineal or rectovestibular fistula has severe associated defects or is ill, the surgeon may elect to dilate the fistula to facilitate emptying of the colon while these other issues are addressed. Definitive repair can be performed in a few months.

A divided descending colostomy is ideal for the management of anorectal malformations (see Fig. 36-14). The completely diverting colostomy provides bowel decompression as well as protection for the final reconstruction of the malformation. In addition, the colostomy is used for the distal colostogram, which is the most accurate diagnostic study to determine the detailed anatomy of these defects.<sup>64</sup>

The descending or upper sigmoid colostomy has definitive advantages over a right or transverse colostomy.<sup>65</sup> It is important to have a relatively short segment of defunctionalized distal colon, but not too short as to interfere with the subsequent pull-through. The ideal location is just at the point where the proximal sigmoid comes off the left retroperitoneum. In some patients, atrophy of the bowel can occur distal to a more proximal colostomy. Mechanical cleansing of the distal colon at the time of colostomy creation is much less difficult when the colostomy is located in the descending portion of the colon. In the case of a large rectourethral fistula, the patient frequently passes urine into the colon. A more distal colostomy allows urine to escape through the distal stoma without significant absorption. With a more proximal colostomy, the urine remains in the colon and is absorbed, leading to metabolic acidosis. A loop colostomy permits the passage of stool from the proximal stoma into the distal bowel. This can lead to urinary tract infections, distal rectal pouch dilation, and fecal impaction (Fig. 36-15). Prolonged distention of the rectal pouch may produce an irreversible hypomotility disorder, leading to severe constipation later in life. Also, the problem of colostomy prolapse is more frequent in loop colostomies.<sup>66</sup> The most common error we have seen is a colostomy established in the lower rectosigmoid that

**Figure 36-15.** A markedly dilated distal rectal pouch secondary to fecal impaction.

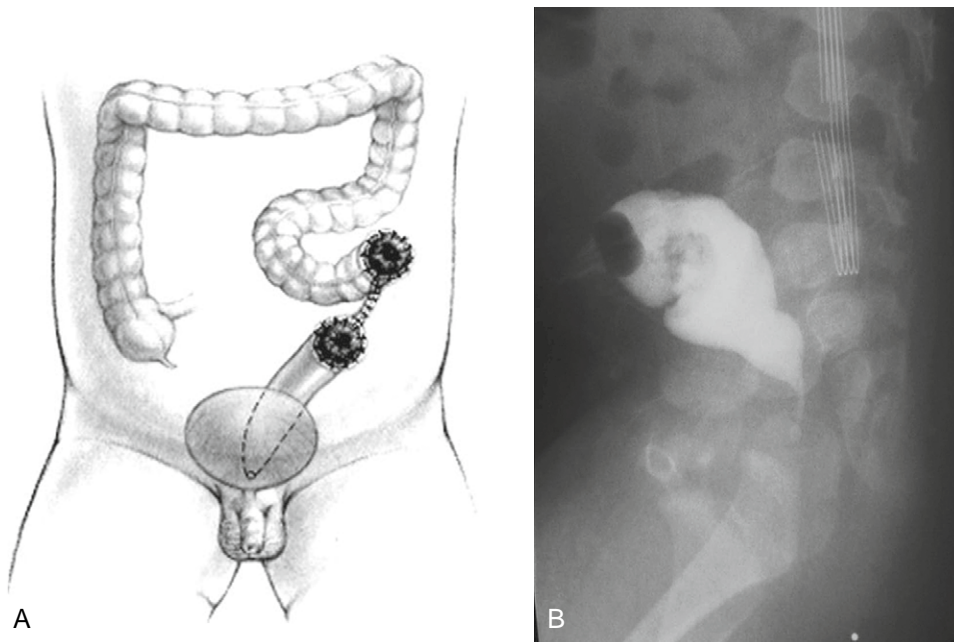

interferes with the mobilization of the rectum during the pull-through (Fig. 36-16).

Historically, there have been many surgical techniques to repair anorectal malformations. These include endorectal dissection,<sup>6,8,9</sup> anterior perineal approaches,<sup>67</sup> and many different types of anoplasties.<sup>68</sup> Most pediatric surgeons now use the posterior sagittal approach with or without laparotomy or laparoscopy to repair these malformations. The debate recently has been centered more on the possibility of performing these operations primarily without a

colostomy, or for which cases a laparoscopic approach is best suited.

The patient is placed in the prone position with the pelvis elevated. An electrical stimulator is used to elicit muscle contraction during the operation. The demonstrated contraction serves as a guide to keep the incision in the midline, leaving an equal amount of muscle on both sides. The length of the incision varies with the type of defect and can be extended to achieve the necessary exposure needed to have a satisfactory repair. Thus, a perineal fistula requires a minimal posterior sagittal incision (2 cm), whereas higher defects may require a full posterior sagittal incision that runs from the lower portion of the sacrum toward the base of the scrotum in the male or to the single perineal orifice in females with a cloaca. The incision includes the skin and subcutaneous tissue and splits the parasagittal fibers, muscle complex, and levator muscles in the midline. In simple defects (perineal and vestibular), the incision divides only the parasagittal fibers and the muscle complex in the midline. It is not usually necessary to open the levator muscle. Once the sphincter mechanism has been divided, the next most important step of the operation is the separation of the rectum from the urogenital structures, which represents the most delicate part of the procedure. Any kind of blind maneuver at this point in the operation exposes the patient to the possibility of serious injury.<sup>63</sup>

About 90% of defects in boys can be repaired via a posterior sagittal approach without opening the abdomen and without laparoscopy. Each case has individual anatomic variants that mandate technical modifications. An example is the size discrepancy frequently seen between an ectatic rectum and the space available for the pull-through. If the discrepancy is significant, the surgeon must tailor the rectum to fit. As repairs are being performed earlier in life and patients undergo

**Figure 36-16.** A, It is important not to create the colostomy too distal because there will not be sufficient rectal length to allow for pull-through. B, This problem is seen on the lateral view of the barium enema, where there is insufficient distal rectal length for the pull-through. This is because of an inappropriately placed colostomy and mucous fistula.

adequate colostomies, rectal dilatation is less commonly seen. Therefore, tapering is less frequently required.

If a colostomy has been done, the posterior sagittal approach should never be attempted without a technically adequate high-pressure distal colostogram to determine the exact position of the rectum and the fistula.<sup>64</sup> Attempting the repair without this important information significantly increases the potential damage to the seminal vesicles, prostate, urethra, and bladder innervation.<sup>63</sup>

## REPAIR OF SPECIFIC DEFECTS IN MALE INFANTS

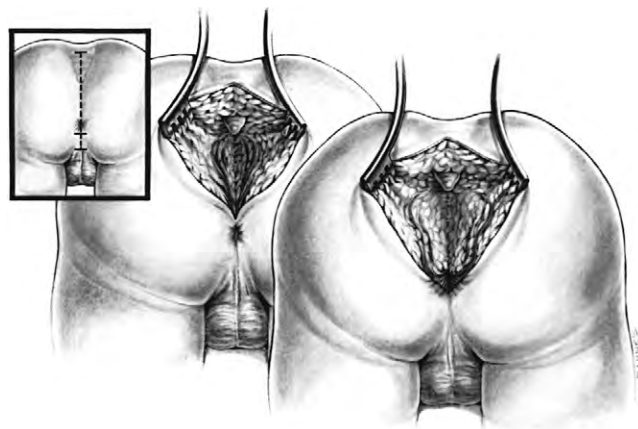

### Perineal Fistula

The operation in these infants is performed in the prone position with the pelvis elevated. Multiple 6-0 silk stitches are placed in the fistula orifice. An incision is created dividing the sphincter mechanism located just posterior to the fistula. The incision usually measures about 2 cm in length. The sphincter is divided, and the posterior rectal wall is identified by its characteristic whitish appearance. This plane is easy to find. Dissection of the rectum continues laterally following this specific plane. The last part of the dissection consists of separating the anterior rectal wall from its intimate relation to the urethra. The most common and serious complication in these relatively simple operations involves injury to the urethra.<sup>63</sup> The patient must have a urinary catheter inserted preoperatively. The best way to avoid urethral injury is to continuously be aware of the fact that the common wall has no plane of dissection and that the surgeon must create two walls out of one.

### Rectourethral Fistulas

A urinary catheter is inserted. In about 20% of cases, this catheter goes into the rectum rather than into the bladder. Under these circumstances, the surgeon may attempt the bladder catheterization again using a Coudé catheter or catheter guide, or can relocate the catheter into the bladder under direct visualization during the operation.

The incision is performed as previously described (Fig. 36-17). The parasagittal fibers, muscle complex, and levator muscle fibers are completely divided in the midline. Sometimes, the coccyx can be split in the midline with cautery, particularly in those cases of a rectoprostatic fistula when the surgeon requires more exposure in the upper part of the incision. The higher the malformation, the deeper the levator muscle. When the entire sphincter mechanism has been divided, the surgeon should identify the rectum. It is at this point in the operation that the importance of a good high-pressure distal colostogram cannot be overstated. If the radiologic image showed the presence of a bulbourethral fistula (Fig. 36-18), the rectum is going to be found just below the levators, with little risk of inadvertent injury to the urinary tract. In this

**Figure 36-17.** This drawing shows a posterior sagittal incision in a male patient with a rectourethral fistula. Separation of the parasagittal fibers and exposure of the muscle complex are shown.

situation, the rectum actually bulges through the incision when the sphincter mechanism is divided (Fig. 36-19). Mobilization of the rectum is rather minimal because only a short gap exists between the rectum and perineum.

Conversely, if the preoperative distal colostogram shows a rectoprostatic fistula, the surgeon must be particularly careful because the rectum joins the urinary tract much higher (Fig. 36-20). The initial search for the rectum lower than the coccyx risks injury to the bulbar urethra. If the colostogram shows a recto-bladder neck fistula, the posterior sagittal approach is not appropriate as a means of identifying the distal bowel.

**Figure 36-18.** A lateral view of a high pressure, distal colostogram shows a rectobulbar urethral fistula (arrow). The bladder (asterisk) also filled during the study.

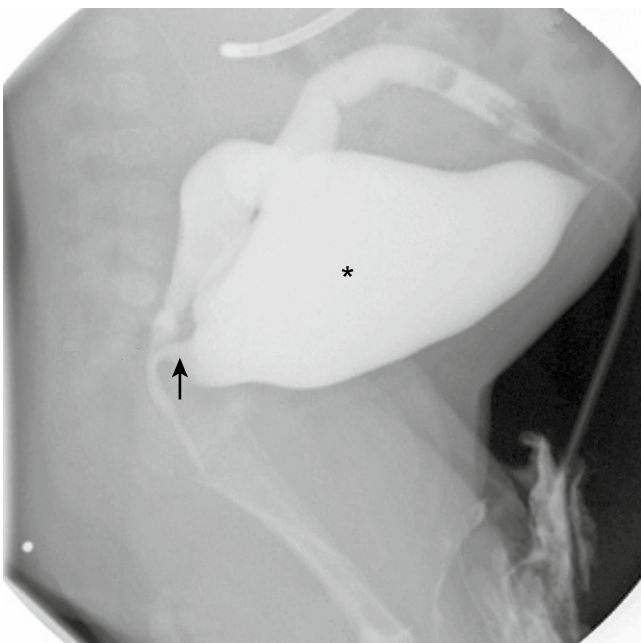

**Figure 36-19.** Schematic drawing of the posterior sagittal approach. The muscle complex and the levator muscles have been divided, and the rectum is visualized below the levator muscle complex.

The rectum must be identified and separated from the urinary bladder through an abdominal approach.

In all cases in which the rectal fistula is at the bulbar level or higher, silk traction sutures are placed in the posterior rectal wall on both sides and the rectum is opened in the midline. The incision is extended distally, exactly in the midline, down to the fistula. Additional silk traction sutures are situated around the edges of the opened posterior rectal wall. When the fistula opening is visualized, silk sutures are placed around the orifice of the fistula as well.

The anterior rectal wall above the fistula is part of a common wall, with no natural plane of separation

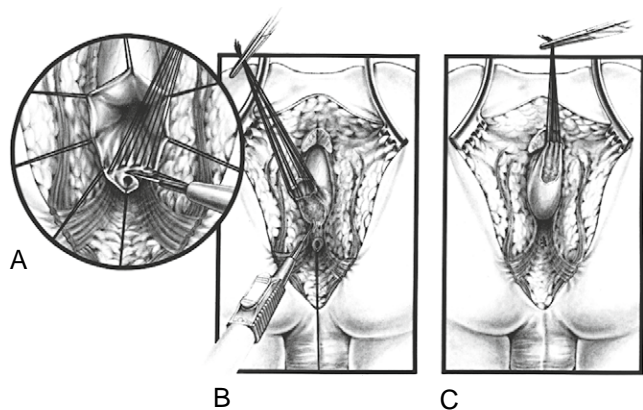

**Figure 36-20.** This distal colostogram shows the rectum entering the prostatic urethra (rectoprosthetic urethral fistula) (arrow). Note filling of the bladder (asterisk) as well.

between the urinary tract and the rectum. The plane of separation must be created in the common wall. For this, multiple 6-0 silk traction stitches are placed in the rectal mucosa immediately above the fistula orifice. The rectal mucosa is then separated from the urethra for 5 to 10 mm above the fistula (Fig. 36-21). This is a submucosal dissection. It is this dissection that is the source of the most serious complications during this repair. We recommend creating a lateral plane of dissection on either side of the rectum to help delineate the rectal wall from the urethra and prostate. The rectum is covered by a thin fascia that contains fat, vessels, and nerves that must be preserved on the back side of the bladder. This tissue should be completely stripped from the rectum to be sure that one is working as close as possible to the rectal wall. This is the only way to prevent denervation of the bladder or injury to the vas deferens. Once the rectum is fully separated from the deep structures of the urinary tract, a circumferential perirectal dissection is performed to gain enough rectal length to reach the perineum.

In cases of a rectoprosthetic fistula, the perirectal dissection is considerably more difficult. During this dissection, uniform traction is applied on the multiple silk traction sutures that were originally placed on the rectal edges and also on the mucosa above the fistula. Uniform traction shows the rectal wall and allows identification of fibrous bands and vessels that hold the rectum in the pelvis. These bands must be carefully separated from the rectal wall using cautery because they contain vessels that tend to retract into the pelvis once divided. The rectum should be dissected as close as possible to the rectal wall without injuring the rectal wall itself. Perhaps in these cases, a surgeon with advanced laparoscopic skills would feel more comfortable with this dissection performed laparoscopically.<sup>60,69-71</sup>

At the completion of the dissection in prostatic fistula cases, many of the extrinsic vessels that supply the rectum have been sacrificed. The rectum should be viable, however, provided the intramural blood supply was preserved by not injuring the rectal wall. One might think that this denervation would provoke a motility disorder, leading to severe constipation, but this has not been our experience. Patients with lower defects (who undergo less dissection) are bothered by more severe postoperative constipation than are patients with higher defects.<sup>19</sup> We do not have an explanation for this, unless there is an inherent motility disorder that is more prevalent in lower defects.

The circumferential dissection of the rectum must continue until the surgeon feels that enough length has been gained to allow for a rectoperineal anastomosis without tension. At this point, the size of the rectum can be evaluated and compared with the available space. If necessary, the rectum can be tapered, removing part of the posterior wall. In such cases, the rectal wall is reconstructed with two layers of interrupted long-lasting absorbable stitches. The anterior rectal wall is frequently thinned to some degree as a consequence of the mucosal separation between the rectum and urethra. To reinforce this wall, both smooth muscle layers

**Figure 36-21.** A schematic representation of the separation of the rectal fistula from the urethra is shown. **A**, Separation of the rectum from the urethra using silk traction stitches in the rectum. **B**, Proximal dissection of the rectum from the urethra. **C**, Depiction of the rectum completely separated from the underlying urethra.

can be approximated with interrupted 5-0 long-lasting absorbable stitches. The urethral fistula is closed with the same suture material. The rectal tapering should never be performed anteriorly because this would leave a rectal suture line adjacent to the urethral fistula repair and may lead to a recurrent fistula.

The limits of the sphincter mechanism are electrically determined and marked with temporary silk stitches at the skin level. Sometimes, in patients with a good sphincter mechanism, these limits are easily visible, even without electrical stimulation. The limits of the sphincter are represented by the crossing of the muscle complex with the parasagittal fibers. These are the voluntary muscles that run from the levator all the way down to the skin parallel with the direction of the rectum. This muscle structure crosses the parasagittal fibers that run perpendicular and lateral to the muscle complex and parallel to the posterior sagittal incision. The perineal body is reconstructed, bringing together the anterior limits of the sphincter previously marked with the temporary silk stitches. The rectum must then be placed in front of the levator and within the limits of the muscle complex (Fig. 36-22). Long-lasting 5-0 absorbable stitches are placed on the posterior edge of the levator muscle.

The posterior limit of the muscle complex must also be reapproximated behind the rectum. These stitches should incorporate part of the rectal wall to anchor it to avoid rectal prolapse (see Fig 36-22B).<sup>72</sup> An anoplasty is performed with 16 interrupted long-lasting absorbable stitches. The ischioanal fossa and the subcutaneous tissue are reapproximated, and the wound is closed with subcuticular 5-0 absorbable monofilament suture material (Fig. 36-23).

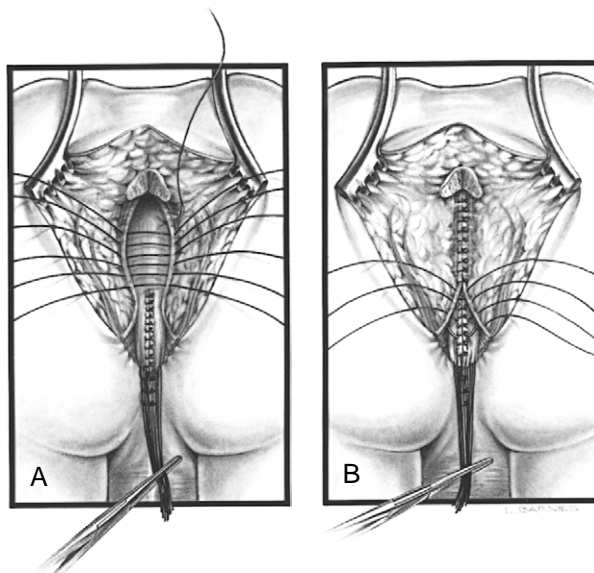

All these patients have a urinary catheter inserted before the beginning of the operation that remains in place for 7 to 10 days. The patient receives broad-spectrum antibiotics for 24 hours. These patients can be fed after recovery from anesthesia because they have a diverting colostomy.

## Recto-Bladder Neck Fistulas

In these patients, the rectum connects to the bladder neck approximately 2 cm below the peritoneal reflection. A very important anatomic feature that must be remembered is that the higher the malformation, the shorter the common wall between the rectum and the urinary tract. This means that in these cases the rectum joins with the urinary tract at nearly a right angle, with little common wall. Thus, separation of the rectum from the bladder is much easier. The laparoscopic approach provides an excellent view of the peritoneal reflection, the ureters, and the vas deferens, which must be kept under direct vision to prevent injury to them.

For this repair, a total body preparation is performed. The entire lower part of the patient's body is included in the sterile field, and the operation is begun laparoscopically.

We recommend dividing the peritoneum around the distal rectum to create a plane of dissection to be followed distally. The dissection should stay right on the rectal wall. The rectum rapidly narrows as it reaches its communication with the bladder neck, at which point it is divided and the bladder side of the fistula is sutured or ligated with an endoloop. The vessels that supply the distal rectum are divided with electrocautery or between ligatures until there is enough length to pull the rectum comfortably down to the perineum. These vessels should be divided close to the rectal wall, preserving the inferior mesenteric artery trunk because the arcade may have been disrupted by the initial colostomy. This dissection preserves perfusion to the rectum because the rectum has an excellent intramural blood supply. In these cases, the distal rectum can be very ectatic and may require tapering. If the colostomy was created too distal in the sigmoid, it

**Figure 36-22.** Position of the rectum after separation from the urethra is shown. **A**, Technique of passing the rectum in front of the levator muscle complex. **B**, Technique of anchoring the rectal wall to the levator complex to avoid rectal prolapse.

**Figure 36-23.** A, Technique of anoplasty. Four quadrant stay sutures are placed followed by three sutures between each quadrant. B, Subcuticular skin closure.

may interfere with this mobilization. Once the rectum is mobile, a cannula with blunt trocar or mosquito clamp is passed through the perineum, just anterior to the coccyx. Great care must be taken to avoid passing the cannula and trocar too anteriorly because injury to the bladder neck or ectopic ureters could occur. The distal rectum is grasped and pulled through to be situated in the center of the sphincter mechanism. Often, in these patients, the center of the sphincter is quite anterior, near the base of the scrotum. Traction on the rectum from below can help demonstrate further lines of tension that must be divided to allow the rectum to reach the perineum. We prefer a small posterior sagittal incision so that the posterior edges of the muscle complex can be visualized and tacked to the posterior rectal wall.<sup>72</sup>

### Imperforate Anus without Fistula

In these cases, the blind end of the rectum is usually located at the level of the bulbar urethra and easily reachable from the posterior sagittal approach. The rectum must be carefully separated from the urethra because both structures have a common wall, even though no fistula is present. The rest of the repair is performed as described for the rectourethral fistula defect.

### Rectal Atresia and Stenosis

The approach to these malformations is also posterior sagittal. The upper rectal pouch is opened as is the small distal anal canal. An end-to-end anastomosis is performed under direct visualization (see Fig. 36-4), followed by a meticulous reconstruction of the

sphincter mechanism posterior to the rectum. If a presacral mass is identified, it is removed with presacral dissection at the time of this operation.

## REPAIR OF SPECIFIC DEFECTS IN FEMALE INFANTS

### Rectoperineal Fistulas

This defect is repaired in the same way as described for male patients. The rectum is not usually attached to the vagina. Therefore, the chance of a vaginal injury is low.

### Vestibular Fistulas

The complexity of this defect is frequently underestimated. Multiple 5-0 silk stitches are placed at the mucocutaneous junction of the fistula. The incision is shorter than the one used to repair the male rectourethral fistula. The incision continues down to and around the fistula into the vestibule. Once the entire sphincter mechanism is divided, the surgeon identifies the posterior rectal wall by its characteristic whitish appearance. The fascia that surrounds the rectum must be removed to be sure that the dissection is as close as possible to the rectal wall. The dissection is aided by working along each side of the rectum, as well as from below, while applying tension on multiple silk traction sutures. A long common wall exists between the vagina and the rectum, and two walls must be created out of one by using a meticulous, delicate technique. The dissection continues cephalad until the rectal and vaginal walls are fully separated and an areolar plane

**Figure 36-24.** In this operative photograph of a female patient undergoing repair of a rectovestibular fistula, note the complete separation of the rectum (arrow) from the anteriorly positioned vagina (asterisk). A catheter has been inserted into the vagina.

between the two is encountered (Fig. 36-24). If the rectum and the vagina are not completely separated, a tense anal anastomosis predisposes the patient to dehiscence, retraction, and stricture.<sup>31</sup>

Once the dissection is complete, the perineal body is repaired (Fig. 36-25A). The anterior edge of the muscle complex is reapproximated as previously described. The sutures include the posterior edge of the muscle complex and the posterior rectal wall to avoid rectal prolapse.<sup>72</sup> The anoplasty is performed as previously described (see Fig. 36-25B,C).

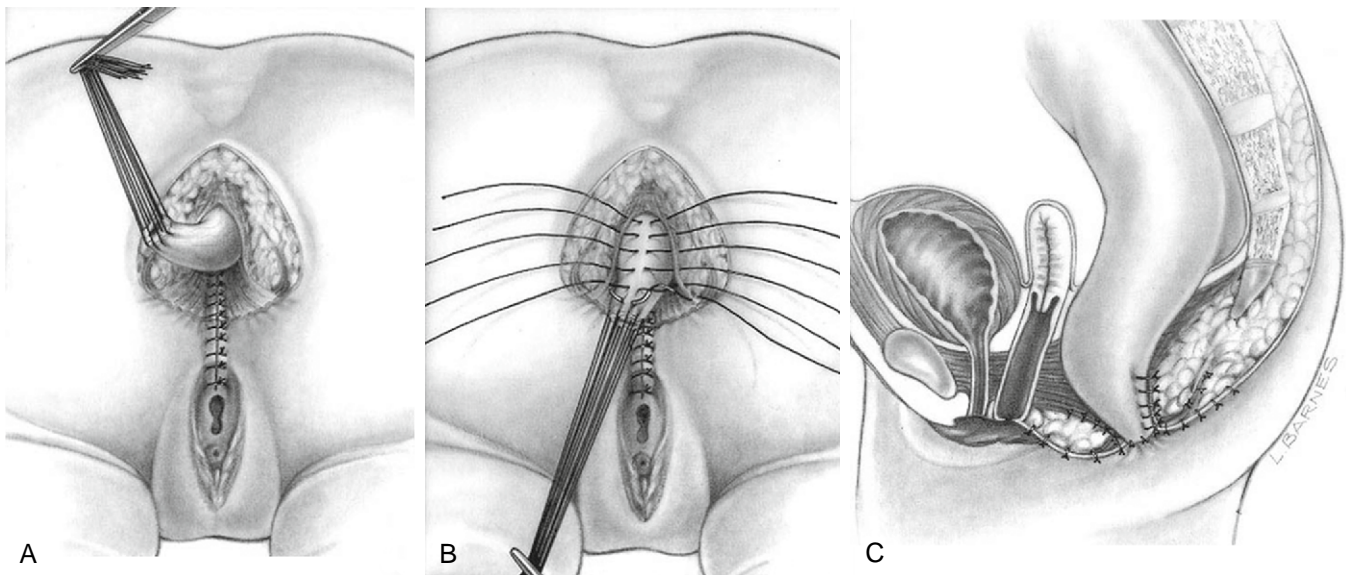

### Cloaca Repair

Before undertaking repair of a cloaca, the surgeon should perform an endoscopic study, with the specific purpose of determining the length of the common

channel. A review of over 400 patients identified two well-characterized groups of patients with cloaca.<sup>73</sup> These two groups have different technical challenges and must be recognized preoperatively. The first is represented by patients who are born with a common channel shorter than 3 cm. Fortunately, these patients comprise the majority and they can usually undergo repair with a posterior sagittal approach alone, avoiding a laparotomy. The operation to repair this particular variant is reproducible and can be accomplished by most general pediatric surgeons. The second group is represented by patients with a long common channel (>3 cm). These patients usually need a laparotomy for correction. In this group of patients, intraoperative decision-making requires a large experience and special training in urology. Therefore, referral to a specialized center is in the best interest of the patient.

### Cloacas with a Common Channel Shorter Than 3 cm

The incision extends from the middle portion of the sacrum down to the single perineal orifice (Fig. 36-26A). The sphincter mechanism is divided in the midline. The first structure that the surgeon finds after division of the sphincter mechanism is the rectum (see Fig. 36-26B). However, because of the complexity of these malformations, bizarre anatomic arrangements of the rectum and vagina are sometimes encountered. The rectum is opened in the midline (see Fig. 36-26C), and silk sutures are placed along the edges of the posterior rectal wall. The incision is extended distally through the posterior wall of the common channel. Placing a mosquito clamp into the single perineal orifice facilitates this midline split. The entire common channel is exposed, which allows for measurement and confirmation of its length under direct vision. The separation of the rectum from the vagina, which share

**Figure 36-25.** Schematic drawings of the final stages of the repair of a rectovestibular fistula in a female. **A**, Reconstruction of the perineal body. **B**, Positioning the rectum in front of the levator muscle complex. **C**, Sagittal view of the completed operation.

**Figure 36-26.** Drawings of the initial steps of the posterior sagittal approach for cloacal repair. **A**, The incision extends from the sacral prominence to the common orifice. **B**, The exposure of the rectum and common channel above the levator complex. **C**, The technique of opening the rectum and placement of traction sutures in the rectal opening.

a common wall (Fig. 36-27), is performed as described for the repair of a rectovestibular fistula.

Once the rectum has been completely separated from the vagina, the total urogenital mobilization begins.<sup>74</sup> Before developing this approach, we tried to separate the vagina from the urinary tract, which was technically challenging and had significant morbidity, with most concern being for a urethrovaginal fistula. The total urogenital mobilization consists of bringing both vagina and urethra to the perineum as a single unit.

**Figure 36-27.** A schematic representation of total urogenital mobilization with separation of the rectum from the vagina. (From Peña A: Total urogenital mobilization: An easier way to repair cloacas. *J Pediatr Surg* 32:263-268, 1997.)

After the rectum has been dissected away from the urogenital complex, multiple silk traction sutures are placed at the edge of the vagina and the common channel in order to apply uniform traction on the urogenital sinus as it is mobilized. Another series of fine traction sutures is placed transversely approximately 5 mm proximal to the clitoris (Fig. 36-28). The urogenital sinus is transected between the last row of silk stitches and the clitoris. The anterior aspect is dissected full thickness from the pubic symphysis, taking advantage of the fact that a natural plane exists between it and the pubis. This dissection is usually easy and relatively bloodless. At the upper edge of the pubis, there are fibrous, avascular suspensory ligaments that give support to the vagina and bladder. While applying traction to the multiple urogenital sinus sutures, the suspensory ligaments are divided, providing 2 to 3 cm of additional mobilization. Lateral and posterior dissection of the urogenital sinus will provide an additional 0.5 to 1.0 cm in length, allowing for complete urogenital mobilization (Fig. 36-29). Both the urethral meatus and the vaginal introitus can then be anastomosed to the perineum in the appropriate positions. Approximately 60% of all cloacas can be satisfactorily repaired with this technique. This technique has the additional advantage of preserving an excellent blood supply to both the urethra and vagina while placing the urethral opening and the smooth-walled urethra in a visible location to facilitate intermittent catheterization when necessary (Fig. 36-30). What used to be the common channel is divided in the midline, creating two lateral flaps that are sutured to the skin, creating the new labia. The vaginal edges are mobilized to reach the skin to create a surprisingly natural-looking introitus. The limits of the rectal sphincter are electrically determined, and the perineal body is reconstructed, bringing together the anterior limits of the sphincter. The rectum is placed within the margins of the sphincter (Fig. 36-31). Because they have a colostomy, these neonates can eat the same day, and their pain is usually easily controlled. They are discharged 48 hours after surgery with their urinary catheter in place.

### *Cloacas with a Common Channel Longer than 3 cm*

When endoscopy shows that the patient has a long common channel, the surgeon must be prepared to face a significant technical challenge. In the presence of a long common channel, the patient should be prepped so that the entire lower body is accessible because it is likely that the patient will require a laparotomy after initial exploration by the posterior sagittal approach. As before, the rectum is separated from the vagina and urethra and the length of the common channel of the urogenital sinus is determined.

A midline laparotomy is recommended. The bladder is opened in the midline, and feeding tubes are placed into the ureters to protect them. The ureters run through the common wall between the vagina and bladder, and the stents allow for their identification

**Figure 36-28.** Total urogenital mobilization. The patient is in the prone position. Silk sutures have been placed around the vagina (top) and transversely across the dissection plane near the clitoris (bottom). A catheter has been inserted in the urethra.

**Figure 36-29.** In this female infant with a cloaca who is in the prone position, the urogenital sinus has been fully mobilized and freed from all of its lateral, anterior, and posterior attachments. The catheter is in the urethra.

**Figure 36-30.** A nearly completed cloacal repair. The urethral meatus (with catheter) and vaginal introitus have been anastomosed to the perineum in their appropriate positions. The patient is in the prone position.

during the difficult dissection of vaginas from the bladder neck.

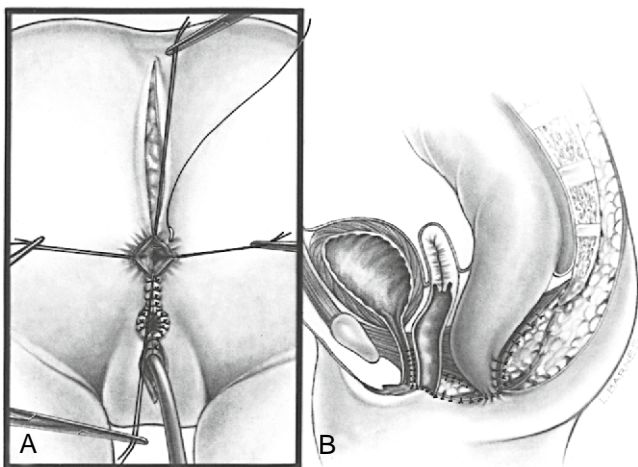

We also confirm the patency of the müllerian structures by injecting saline through a 3-Fr feeding tube through the fimbriae of the fallopian tubes. If one of the tubes is not patent, we recommend excising it, along with its hemiuterus if the system is bifid. The ovary and its blood supply are preserved.<sup>34</sup>

When both müllerian structures are atretic, we recommend leaving both in place and informing the

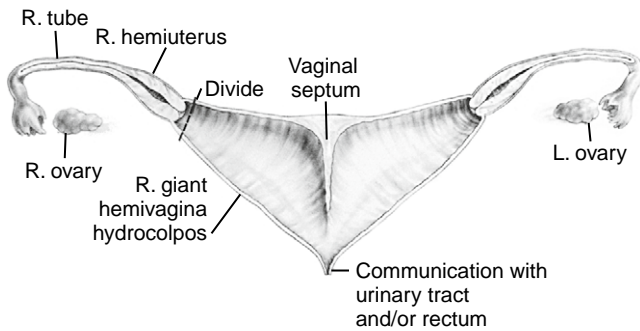

parents. Once the patient develops breast buds, menstruation usually occurs 1 to 2 years thereafter and ultrasonography is used to follow the size of these structures. At that point, laparoscopic inspection or intervention for nondraining structures may be reasonable.

With the abdomen open, surgical decisions must be based on the anatomic findings. In the presence of a single vagina of normal size, the surgeon must separate the vagina from the urinary tract, being sure to preserve its blood supply that comes from the uterine vessels. It is brought to the perineum, and the introitus is constructed. When the vagina is found to be too short, the patient requires some form of vaginal replacement that can be performed using the rectum, colon, or small bowel.

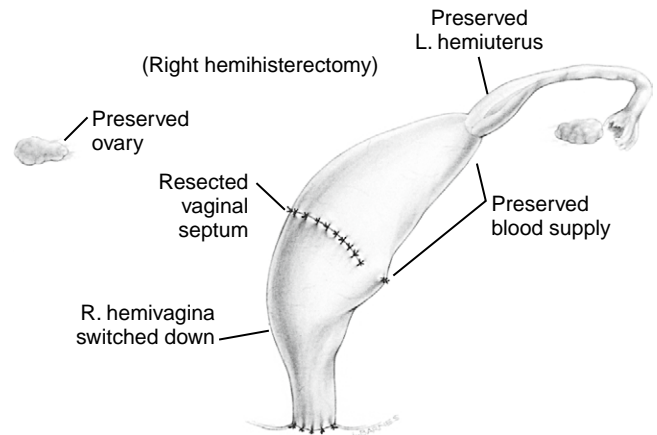

The presence of a common channel longer than 5 cm means that total urogenital mobilization from below will not be enough to repair this malformation. In this scenario, it is advisable to leave the common channel intact for use as the urethra, which will eventually be used for intermittent catheterization. The two small hemivaginas are separated from the urinary tract, and the posterior wall of the previous common channel is closed with interrupted absorbable sutures. This is a very delicate, meticulous, and tedious maneuver. With this dissection, one can gain separation of the vagina from the urinary tract for approximately 2 cm. In other cases, when the vaginas are larger, the entire urogenital mobilization can be delivered into the abdomen. If further dissection does not allow it to reach, then the vaginas can be separated from the urinary tract and the urethra can be tubularized.

**Figure 36-31.** Drawings showing the final stages of cloacal repair. **A**, The repaired urethra and vagina and the anoplasty are being completed. **B**, Sagittal depiction of the finished cloacal repair. (From Peña A: Atlas of Surgical Management of Anorectal Malformations. New York, Springer-Verlag, 1990, p 69.)

**Figure 36-32.** Diagram shows the constellation of persistent cloaca with hydrocolpos in the presence of hemivaginas and hemiuterus. Bilateral hydrocolpos is present with a very high vagina. This circumstance is the ideal anatomy for a subsequent repair via a vaginal switch maneuver. (From Kiely EM, Peña A: Anorectal malformations. In O'Neil JA, Rowe MI, Grosfeld JL, et al [eds]: *Pediatric Surgery*. St. Louis, Mosby-Year Book, 1998, p 1442.)

**Figure 36-33.** Technique of vaginal reconstruction using a vaginal switch maneuver. (From Kiely EM, Peña A: Anorectal malformations. In O'Neil JA, Rowe MI, Grosfeld JL, et al [eds]: *Pediatric Surgery*. St. Louis, Mosby-Year Book, 1998, p 1442.)

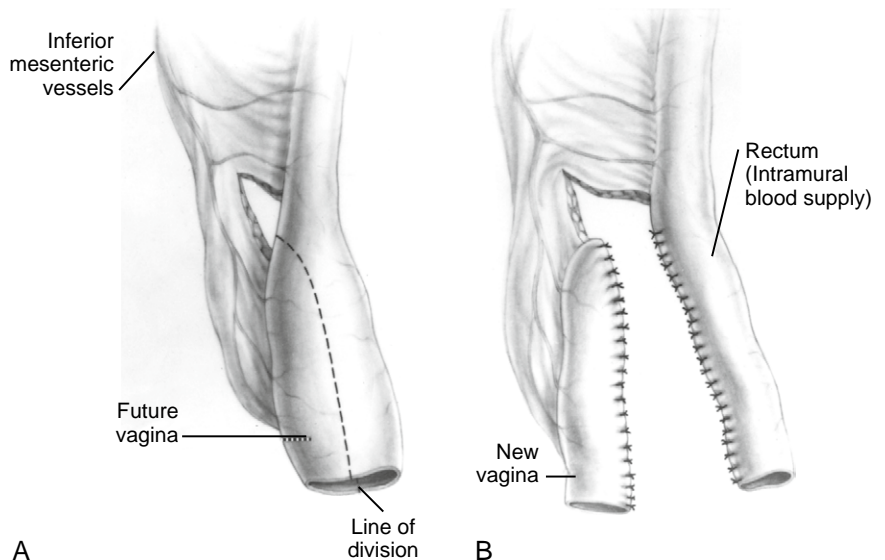

## Vaginal Switch Maneuver

There is a specific group of patients who are born with hydrocolpos and two hemivaginas. The hemivaginas are very large, and the two hemiuteri are separated. The distance between one hemiuterus and the other is longer than the vertical length of both the hemivaginas. In these cases, it is ideal to perform a maneuver called a "vaginal switch" (Figs. 36-32 and 36-33). To perform the "vaginal switch," one of the uteri and its fallopian tube are resected (see Fig. 36-32), preserving the ovary and its blood supply. The blood supply of the ipsilateral hemivagina must be sacrificed, but collateral vessels from the opposite vagina should support both. The vaginal septum is resected, creating a single long vagina. The cut end of the ipsilateral vagina is turned down to the perineum (see Fig. 36-33). This is an excellent technique for constructing a viable and functional vagina.

## Vaginal Augmentation and/or Replacement

A short vagina can be augmented or a totally absent vagina constructed from a bowel segment. The intestinal choices are rectum, colon, or small bowel.

1. *Vaginal reconstruction with rectum.* The vagina can be constructed with the rectum when the patient has a megarectum that can be divided longitudinally, preserving the mesenteric blood supply (Fig. 36-34). Occasionally, when there is adequate length, the rectum can be divided transversely, maintaining vascular pedicles for both rectum and vagina. The blood supply of the rectum will be provided transmurally from branches of the inferior mesenteric vessels.
2. *Vaginal replacement with colon.* The colon is an ideal substitute for the vagina. When available,

**Figure 36-34.** The technique of vaginal replacement using the rectum is depicted. The presence of a megarectum is necessary for successful vaginal reconstruction. **A**, The portion of the existing rectum that will become the vagina. **B**, Division of the rectum and creation of the vagina and remaining rectum.

**Figure 36-35.** Schematic representation of a vaginal replacement using sigmoid colon.

the sigmoid colon is preferable. At times, the location of the colostomy interferes with this type of reconstruction. The most mobile portion of the colon usually has a long mesentery. When the patient has internal genitalia or a little cuff of vagina or cervix, the upper part of the bowel used for replacement must be sutured to the vaginal cuff. When the patient has no vagina and no uterus, the neovagina is closed at its upper end and is used only for sexual purposes (Fig. 36-35).

3. *Vaginal reconstruction with small bowel.* If a colon segment is not available, the most mobile portion of the small bowel is utilized for vaginal reconstruction. Generally, the ileum located approximately 15 cm proximal to the ileocecal

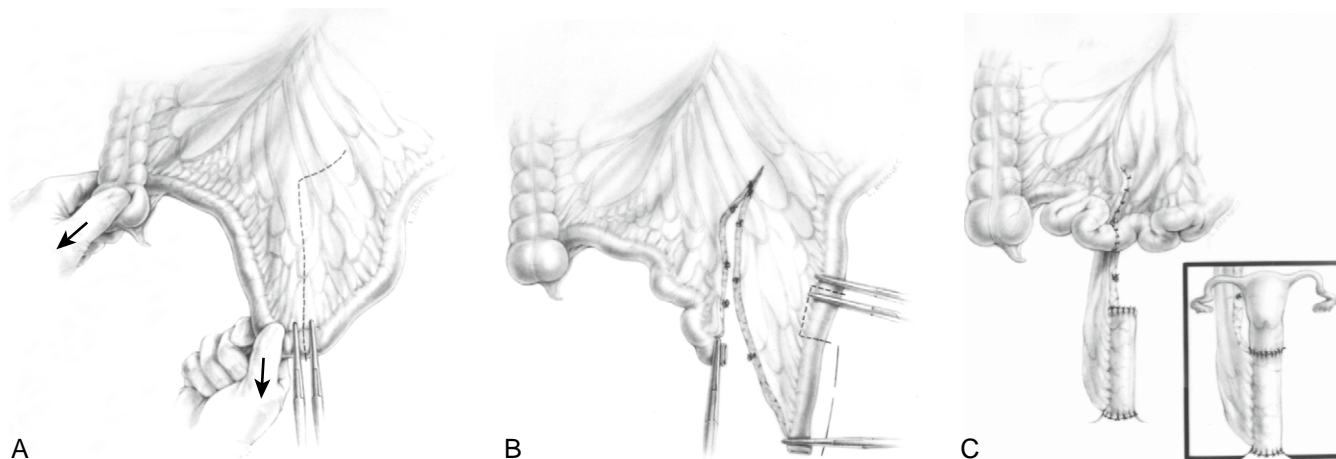

valve (Fig. 36-36A) is isolated and pulled down, preserving its blood supply (see Fig. 36-36B, C).

We do not use skin flaps or vaginal flaps for vaginal replacement because we have found that these other maneuvers give better results.

The most difficult type of cloacal malformation is one in which two little hemivaginas are attached to the bladder neck or even to the trigone of the bladder. In these cases, the rectum also opens in the trigone (Fig. 36-37). Separation of these structures is performed in the abdomen, and the patient is frequently left with a nonfunctional bladder neck. The surgical decision now lies between an attempt to reconstruct the bladder neck or to close it permanently. In the first situation, most of the patients will need intermittent catheterization to empty the bladder. If permanent closure of the bladder neck is elected, a vesicostomy is created, delaying a continent diversion until the patient is 3 to 4 years old. With this type of malformation, vaginal replacement should be performed using one of the substitutes described previously.

## POSTOPERATIVE MANAGEMENT AND COLOSTOMY CLOSURE

Postoperatively, the patients generally have a smooth course. Pain is rarely a complaint except for those who have undergone a laparotomy. After cloaca repair, the urinary catheter remains for 2 to 3 weeks until the perineum is no longer swollen, and the patient can be recatheterized, if necessary. In very complex malformations, as with a bladder neck reconstruction, we prefer to leave a suprapubic tube. In patients in whom the bladder neck was closed, we establish a vesicostomy. Male patients with repaired rectourethral fistulas should have urinary catheter drainage for 7 days. If the catheter becomes dislodged, the patients often can void without difficulty and do not require replacement of the catheter.

**Figure 36-36.** Technique of vaginal replacement using small bowel. **A**, A segment of small bowel is chosen that has adequate mesenteric length for transposition to the pelvis. **B**, The mesentery has been divided, the segment of small bowel chosen for vaginal reconstruction is identified, and the blood supply is evaluated to ensure adequate perfusion. **C**, The completed anastomosis.

**Figure 36-37.** This diagram shows the association between a cloaca with an extremely long channel with hemivaginas and the rectum entering the bladder neck (Drawing by George Rodriguez).

Intravenous antibiotics are administered for 48 hours and antibiotic ointment is applied to the perineal suture line for 7 days. Most patients are discharged 2 days after posterior sagittal repair and 3 to 4 days after a laparotomy.

Anal dilatations are started 2 weeks after the repair with a dilator that fits gently into the anus. Dilation is performed twice daily by the parents, and the size of the dilator is increased weekly until the rectum reaches the desired size, which depends on the patient's age (Table 36-2). Once this desired size is reached, the colostomy can be closed. The frequency of dilatation can be reduced once there is no resistance using the final dilator size. After that, the parents follow a tapering dilatation schedule that is once a day for 1 month, every third day for 1 month, twice a week for 1 month, once a week for 1 month, and once a month for 3 months.

Anal strictures occur in cases in which the blood supply of the distal rectum is insufficient, or when the anoplasty is performed under tension.<sup>31</sup>

At the time of colostomy closure in patients who have undergone cloacal repair, we perform an endoscopy to evaluate the repair. After the colostomy is closed, the patient may have multiple bowel movements and may develop perineal excoriation. A constipating diet may be helpful in the treatment of this problem. After several weeks, the number of bowel movements decreases and most patients will develop constipation. After 1 to 3 months, the patient develops a more regular bowel movement pattern. A good prognosis can usually be predicted in a patient who

has one to three bowel movements per day, remains clean between bowel movements, and shows evidence of feeling or pushing during bowel movements. This type of patient can be toilet-trained. A patient with multiple bowel movements or one who passes stool constantly without showing any signs of sensation or pushing usually has a poor functional prognosis.

In our series, about 20% of the patients with a cloacal malformation and a common channel shorter than 3 cm require intermittent catheterization to empty their bladder. Patients with common channels longer than 3 cm require intermittent catheterization 70% to 80% of the time. Therefore, we leave the urinary catheter until the perineal incisions are healed sufficiently to allow catheterization. Once we are able to see the urethral orifice, we remove the urinary catheter and observe the patient to see if she is capable of spontaneous bladder emptying. A kidney and bladder ultrasonogram can assess this emptying and should be done 2 to 3 weeks after the catheter is removed. If she cannot pass urine, or does not empty her bladder well, we teach the parents how to perform intermittent catheterization. In cases of very long common channels, we prefer to utilize a suprapubic tube. One month after surgery, we perform a suprapubic cystogram and begin clamping the tube. We measure the residual urine, which is an indicator of bladder function. The suprapubic tube remains until we have evidence of good bladder function or the parents learn to catheterize the bladder when needed.

Most patients with persistent cloaca have a flaccid, smooth, large bladder that does not empty completely.<sup>77</sup> Fortunately, most patients with cloacas have a competent bladder neck. The combination of a competent bladder neck with a flaccid bladder makes these patients ideal candidates for intermittent catheterization, which keeps them completely dry. Two exceptions to this rule exist. One is represented by patients who have a very long common channel, with the hemivaginas attached to the bladder neck, leading to a bladder neck that is damaged during the reconstruction. The second group is represented by a small number of patients who are born with separated pubic bones, a condition that can be described as a "covered exstrophy."<sup>78,79</sup> These patients have congenital absence of the bladder neck and will eventually require a continent urinary diversion.

## FUNCTIONAL DISORDERS AFTER REPAIR OF ANORECTAL MALFORMATIONS

Most patients who undergo repair of an anorectal malformation suffer from some degree of a functional defecating disorder.<sup>75,76</sup>

Fecal continence depends on three main factors:

1. *Voluntary muscle structures.* These structures are represented by the levator muscle, the striated muscle complex, and the external sphincter. Normally, they are used only for brief periods when the rectal fecal mass, pushed by the involuntary peristaltic contraction of the rectosigmoid,

**Table 36-2** Size of Dilator According to Age

Age	Hegar Dilator (No.)
1-4 mo	12
4-12 mo	13
8-12 mo	14
1-3 yr	15
3-12 yr	16
>12 yr	17

reaches the anorectal area. This contraction occurs only in the minutes prior to defecation. The voluntary muscle structures that close around the anus are used only occasionally during the rest of the day and night. Patients with anorectal malformations have abnormal voluntary striated muscles with different degrees of underdevelopment. Voluntary muscles can be used only when the patient feels that it is necessary to use them. For that sensation, the patient needs information that can only be derived from an intact sensory mechanism, a mechanism that many patients with anorectal malformations lack.

2. *Sensation.* Exquisite sensation in normal individuals resides in the anal canal. Except for patients with rectal atresia, most patients with anorectal malformations are born without an anal canal. Therefore, sensation does not exist or is rudimentary. Distention of the rectum, however, can be felt in many of these patients, provided the rectum has been located accurately within the muscle structures. This sensation (proprioception) seems to be a consequence of stretching of the voluntary muscle. The most important clinical implication of this is that liquid stool or soft fecal material may not be felt by the patient with anorectal malformations as the rectum is not distended. Thus, to achieve some degree of sensation and bowel control, the patient must be able to (or helped to) form solid stool.
3. *Bowel motility.* Perhaps the most important factor in fecal continence is bowel motility. However, the impact of motility has been largely underestimated. In a normal individual, the rectosigmoid remains quiet for variable periods of time (one to several days), depending on an individual's defecation habits. During that time, anorectal sensation and voluntary muscle structures are almost unnecessary because the stool remains in the rectosigmoid if it is solid.

The patient normally feels the rectosigmoid's peristaltic contraction. Voluntarily, the normal individual can relax the striated muscles, which allows the rectal contents to migrate down into the highly sensitive area of the anal canal. There, accurate information is provided concerning the consistency and quality of the stool. The voluntary muscles are used to push the rectal contents back up into the rectosigmoid and hold them if desired, until the appropriate time for evacuation. At the time of defecation, the voluntary muscle structures relax, allowing the fecal mass to pass into and through the anorectum.

The main factor that initiates emptying of the rectosigmoid is a massive involuntary peristaltic contraction that is helped sometimes by a Valsalva maneuver. Most patients with an anorectal malformation have a disturbance of this sophisticated bowel motility mechanism. Patients who have undergone a posterior sagittal anorectoplasty or any other type of sacroperineal approach, in which the most distal part of the bowel was preserved, often show evidence of an over-efficient bowel reservoir (megarectum) (Fig. 36-38).

**Figure 36-38.** A barium enema is shown in a patient with a megarectum. Note the markedly dilated rectum in relation to the more proximal normal-sized colon.

The main clinical manifestation of this is constipation, which seems to be more severe in patients with lower defects. Females with a vestibular fistula, in particular, are more prone to this problem. A loop colostomy can cause this problem by allowing for a fecal impaction in the blind rectal pouch. The enormously dilated rectosigmoid has normal ganglion cells, but behaves like it has a myopathic type of hypomotility disorder. The overflow fecal incontinence based on rectosigmoid constipation in patients with potential for bowel control can be managed with the appropriate dose of laxatives. Those with a poor sacrum, poor muscles, and thus with no potential for bowel control are treated with a daily enema.

Those patients treated with techniques in which the most distal part of the bowel was resected (endorectal dissection)<sup>6,9</sup> behave clinically as individuals without a rectal reservoir (Fig. 36-39). This is a situation equivalent to a perineal colostomy. Depending on the amount of colon resected, the patient may have loose stools. In these cases, medical management consisting of a daily enema and a constipating diet, with medications to slow down the colonic motility, is indicated.

## EVALUATION OF RESULTS

Each defect described in this chapter has a different prognosis. The patients with lower defects usually have excellent results, except when technical errors

**Figure 36-39.** This barium enema was performed in a patient who has had the rectosigmoid colon resected. Note the straight position of the colon to the anus with no evidence of a rectal reservoir.

have been made, or if they have associated sacral or spinal problems.

Tables 36-3 and 36-4 shows the results obtained in our series. The patients with a sacral ratio of less than 0.3 and flat perineums have fecal incontinence regardless of the type of malformation or quality of the repair.

Because persistent cloacas represent another spectrum of defects, they must be subclassified on the basis of potential for bowel and urinary control. The length

Table 36-4	Urinary Incontinence	
	No. Patients	%
Rectal atresia or stenosis	0/8	0
Perineal fistula	0/38	0
Bulbourethral fistula	2/85	2.4
Imperforate anus without fistula	1/37	2.7

Cloaca: short common channel	5/18	27.8
Vaginal fistula	1/5	20
Cloaca: long common channel	37/48	77.1

of the common channel seems to be the most important prognostic factor.

## Complications

There are several complications related to operative intervention and repairs of anorectal malformations in general. Wound infection in the immediate postoperative period can occur and, fortunately, usually affects only the skin and subcutaneous tissue. All heal secondarily without functional sequelae. Anal strictures may be the consequence of failure to follow the protocol of dilatations. When trying to prevent discomfort for the patient, some surgeons dilate the anus once a week, frequently under anesthesia. This protocol can eventually create a severe, intractable fibrous stricture. Strictures can also occur with devascularization of the rectum during the rectal mobilization.<sup>31</sup> Constipation is the most common functional disorder observed in patients who undergo a posterior sagittal anorectoplasty (see Table 36-3). Patients with the best prognosis have the highest incidence of constipation. Patients who underwent tapering do not have more constipation than those without a tapering procedure. Patients with a very poor prognosis, such as with bladder neck fistula, have a low incidence of constipation

Table 36-3	Global Functional Results

Bladder neck fistula	8/29	28	39/43	90.7	1/8	12.5	7/45	15.6

and a high rate of incontinence. Colostomies that do not allow cleaning and irrigation of the distal colon can lead to megarectum. Patients require proactive aggressive treatment of constipation after colostomy closure to avoid significant problems. Rectal prolapse occurs on occasion and is more prevalent in higher malformations with poor sphincters and is impacted by postoperative constipation.<sup>72</sup> Finally, transient femoral nerve palsy can occur as a consequence of excessive pressure on the groin during the operation. This problem can be avoided by adequate cushioning.

Specific to cloacal repairs, urethrovaginal fistulas had been the most common and feared complication prior to the introduction of the total urogenital mobilization technique.<sup>74</sup> In cases in which vaginal mobilization and separation from the neourethra result in opposing suture lines, 90-degree rotation of the vagina can decrease the incidence of a postoperative fistula.

Fibrosis of the vagina can develop secondary to an excessive dissection during the mobilization of a high vagina.

Regarding male patients, a review of over 500 patients showed significant urologic injuries.<sup>63</sup> Failure to obtain a good distal colostogram to delineate the anatomy precisely was the most important reason for these complications. Neurogenic bladder in male patients, as a result of the anorectal malformation or the repair itself, must be extremely unusual because it only happens in patients with a very abnormal sacrum (see [Table 36-4](#)).<sup>77</sup> In the presence of a relatively normal sacrum, it may reflect a poor surgical technique with denervation of the bladder and bladder neck during the repair.<sup>63</sup>

Finally, fecal incontinence is a very common sequelae of any anorectal malformation repair and is discussed in Chapter 37.

# FECAL INCONTINENCE AND CONSTIPATION

Marc A. Levitt, MD • Alberto Peña, MD

Fecal incontinence represents a devastating problem for all who suffer from it. It often prevents a person from becoming socially accepted, which, in turn, provokes serious psychological sequelae. It is a problem that impacts more children than previously thought, affecting those born with anorectal malformations and Hirschsprung's disease as well as children with spinal cord problems or spinal injuries.

True fecal incontinence must be distinguished from overflow pseudoincontinence. Pediatric patients with true fecal incontinence include some surgical patients with anorectal malformations, those with Hirschsprung's disease, and those with spinal problems, either congenital or acquired. In patients with pseudoincontinence, who have the potential for bowel control but who soil, most often their problem results from severe constipation (encopresis) and sometimes from hypermotility.

Most patients who undergo an anorectal malformation repair suffer from some degree of a functional defecation disorder, and all suffer from an abnormality in their fecal continence mechanism. Approximately 25% of patients are deficient enough in these mechanisms that they are fecally incontinent and cannot have a voluntary bowel movement. The others are capable of having voluntary bowel movements but may require treatment of an underlying dysmotility disorder, which most often manifests as constipation.<sup>1</sup> A small, yet significant, number of patients with Hirschsprung's disease (<5%) suffer from fecal incontinence possibly because of a lost anal canal or damaged sphincters that occurred during surgical repair.<sup>2</sup> Patients with spinal problems or injuries can lack the capacity for voluntary bowel movements or may have this ability to varying degrees.

Patients with true fecal incontinence require an artificial way to be kept clean and in normal underwear. This regimen is termed *bowel management* and involves a daily enema. Patients with pseudoincontinence require proper medical treatment of either constipation or loose stools. This involves getting the stool to the right consistency so that they can have a bowel movement that they voluntarily control.

Understanding this major differentiation is the key to deciding the correct management.

## MECHANISM OF CONTINENCE

Fecal continence depends on three factors: voluntary sphincter muscles, anal canal sensation, and colonic motility.<sup>1</sup>

### Voluntary Muscle Structures

In the normal patient, the voluntary muscle structures are represented by the levators, the muscle complex, and the parasagittal fibers. Normally, they are used only for brief periods of time when the rectal fecal mass, pushed by the involuntary peristaltic contraction of the rectosigmoid colon, followed by relaxation, reaches the anorectal area. This voluntary contraction occurs only at the time of defecation. These muscles are used only occasionally during the rest of the day and night.

Patients with anorectal malformations have abnormal voluntary striated muscles with different degrees of hypodevelopment. Patients with Hirschsprung's disease may have suffered damage to this sphincter mechanism, and patients with spinal problems may have deficient innervation of these muscles.

### Anal Canal Sensation

Voluntary muscles are used only when the patient has the sensation that it is necessary to use them. To appreciate that sensation, the patient needs information that can only be derived from an intact anal sensory mechanism.

Exquisite sensation in normal individuals resides in the anal canal. Except for patients with rectal atresia, most patients with anorectal malformations are born without an anal canal. Therefore, sensation does not exist or is rudimentary. Patients with spinal problems may lack this anal canal sensation as well. Patients with Hirschsprung's disease are born with a normal anal canal, but this can be injured if not meticulously

**Figure 37-1.** Loss of the anal canal (with no visible dentate line) is seen after a Soave pull-through operation. In this patient, the anal dissection was begun too distally.

preserved at the time of their colonic pull-through procedure (Fig. 37-1). Patients with perineal trauma may have an injured or destroyed anal canal.

It seems that patients can perceive distention of the rectum, if the rectum has been properly located within the muscle structures. This surgical point is quite important for patients undergoing pull-through procedures for imperforate anus. This sensation seems to be a consequence of stretching of these voluntary muscles (proprioception). The most important clinical implication is that patients might not feel liquid stool or soft fecal material because such stool consistency does not distend the rectum. Thus, to achieve some degree of sensation and bowel control, the patient must have the capacity to form solid stool. This point is quite relevant in children with ulcerative colitis who have undergone an ileoanal pull-through procedure. They may suffer from varying degrees of incontinence due to the incapacity to form solid stool. Their normal sphincter muscles and anal canal allow them to overcome this problem. Also, some need the help of medications that bulk up the stool.

## Bowel Motility

Perhaps the most important factor in fecal continence is bowel motility. However, the impact of motility has been largely underestimated. In a normal individual, the rectosigmoid remains quiet for variable periods of time (1 to several days), depending on specific defecation habits. During that time, sensation and voluntary muscle structures are almost not necessary because the stool, if it is solid, remains inside the colon. The patient feels the peristaltic contraction of the rectosigmoid that occurs before defecation. Voluntarily, the normal individual can relax the striated rectal muscles, which allows the rectal contents to migrate down into the highly sensitive area of the anal canal. There, the anal canal provides accurate information concerning stool consistency. The voluntary muscles are used to push the rectal contents back up into the rectosigmoid

and to hold them until the appropriate time for evacuation. At the time of defecation, the voluntary muscle structures relax.

The main impetus for rectosigmoid emptying is a massive involuntary peristaltic contraction sometimes helped by a Valsalva maneuver. Most patients with an anorectal malformation suffer from a disturbance of this sophisticated bowel motility mechanism. Patients who have undergone a posterior sagittal anorectoplasty (or any other type of sacroperineal approach in which the most distal part of the bowel was preserved) can show evidence of an overefficient bowel reservoir (megarectum) (Fig. 37-2). The main clinical manifestation of a megarectum is constipation, which seems to be more severe in patients with lower defects.<sup>3</sup> Constipation that is not aggressively treated, combined with an ectatic distended colon, eventually leads to severe constipation. A vicious cycle ensues, with worsening constipation leading to more rectosigmoid dilation, leading to more severe constipation. The enormously dilated rectosigmoid, which has normal ganglion cells, behaves like a myopathic type of hypomotile colon.<sup>1</sup>

Patients with an anorectal malformation, treated with techniques in which the most distal part of the bowel was resected (Fig. 37-3), behave clinically as individuals without a rectal reservoir. This is a situation equivalent to a perineal colostomy. Depending on the amount of colon removed, the patient may have loose stools. In these cases, medical management consisting of enemas, a constipating diet, and medications to slow down the colonic motility is indicated.

**Figure 37-2.** This contrast enema shows a megarectosigmoid colon. (From Peña A, Levitt M: Colonic inertia disorders in pediatrics. *Curr Prob Surg* 39:681, 2002).

Patients with Hirschsprung's disease undergo operative resection of the distal aganglionic colon and rectum. However, their normal anal canal and sphincter mechanism allows the vast majority of them to be continent despite the lack of a rectal reservoir. Some patients with Hirschsprung's disease have bowel hypermotility

and need medications to slow the colon. Amazingly, some patients with an injured anal canal and sphincters (perineal trauma) can be continent if their motility is normal, because the regular contraction of the rectosigmoid can translate into a successful voluntary bowel movement.

**Figure 37-3.** This contrast enema was performed in a patient who had resection of the rectosigmoid colon. Often these patients act like they do not have a rectal reservoir. (From Levitt MA, Peña A: Treatment of chronic constipation and resection of the inert rectosigmoid. In: *Anorectal Malformations in Children*. Heidelberg, Springer, 2006, p 417).

## TRUE FECAL INCONTINENCE

For patients with true fecal incontinence, the ideal approach is a bowel management program consisting of teaching the patient and the parents how to clean the colon once daily with an enema so as to stay completely clean for 24 hours until the next cleanout. This is achieved by keeping the colon quiet between enemas. These patients cannot have voluntary bowel movements and require an artificial mechanism (a daily enema) to empty their colon. The program, although simplistic, is ideally implemented by trial and error over a period of 1 week. The patient is seen each day and an abdominal radiograph is taken so that they can be monitored for the amount and location of any stool left in the colon. The presence or absence of stool in the underwear is also noted. The decision as to whether the type and/or quality of the enemas should be modified, as well as changes in their diet and/or medication, can thus be made daily (Fig. 37-4).<sup>4</sup>

### Which Pediatric Patients Have True Fecal Incontinence?

In children with anorectal malformations, 75% who have undergone a correct and successful operation have voluntary bowel movements after the age of 3 years.<sup>3</sup> About half of these patients occasionally soil their underwear. These episodes of soiling are usually related to constipation. When the constipation is treated properly, the soiling frequently disappears.

**Figure 37-4.** A to C, This series of abdominal radiographs was obtained during inpatient bowel management showing progression toward a completely clean colon with daily adjustment of the enema. After 5 days, a post-contrast abdominal film (C) shows minimal evidence of retained fecal material.

**Table 37-1** Prognostic Signs in Patients with Anorectal Malformations

Good Prognosis Signs	Poor Prognosis Signs
Good bowel movement patterns: 1-2 bowel movements per day—no soiling in between	Constant soiling and passing of stool
Evidence of sensation with passing stool (pushing, making faces)	No sensation (no pushing)
Urinary control	Urinary incontinence, dribbling of urine

Thus, approximately 40% overall have voluntary bowel movements and no soiling. In other words, they behave like normal children. Children with good bowel control still may suffer from temporary episodes of fecal incontinence, especially when they experience diarrhea.

Some 25% of all patients with anorectal malformations suffer from true fecal incontinence, and are the patients who need bowel management to be kept clean. As noted, certain patients with Hirschsprung's disease and those with spinal problems can suffer from true fecal incontinence as well. For these patients, similar principles of bowel management learned from treatment of patients with anorectal malformations can be applied.<sup>4</sup>

For children with anorectal malformations, the surgeon should be able to predict in advance which patients may have a good functional prognosis and which children may have poor prognosis. Table 37-1 shows the most common indicators of good and poor prognosis. After primary repair and colostomy closure, it is possible to establish the functional prognosis (Table 37-2). Parents should be given the information regarding their child's realistic chances for bowel control to avoid needless frustration at the age of toilet training. To avoid creating false expectations for the parents, it is imperative to establish the functional prognosis for each child as early as possible, which is sometimes possible even in the newborn period.

**Table 37-2** Predictors of Prognosis in Patients with Anorectal Malformations

Good Prognostic Signs	Poor Prognostic Signs
Normal sacrum	Abnormal sacrum
Prominent midline groove (good muscles)	Flat perineum (poor muscles)
Some types of anorectal malformations:	Some types of anorectal malformations:
Rectal atresia	Rectal/bladder neck fistula
Vestibular fistula	Cloacas with a common channel > 3 cm
Imperforate anus without a fistula	Complex malformations
Cloacas with a common channel < 3 cm	
Less complex malformations: perineal fistula	

Once the diagnosis of the specific anorectal defect is established, the functional prognosis can be predicted. If the child's defect is associated with a good prognosis (e.g., a vestibular fistula, perineal fistula, rectal atresia, rectourethral bulbar fistula, or imperforate anus with no fistula), one should expect that the child will have voluntary bowel movements by the age of 3 years (provided the sacrum and spine are normal). These children will need careful supervision to avoid fecal impaction, constipation, and soiling.

If the child's defect is associated with a poor prognosis (e.g., a very high cloaca with a common channel longer than 3 cm, a recto-bladder neck fistula, or a very hypodeveloped sacrum), the parents must understand that their child will most likely need a bowel management program to remain clean. This should be implemented when the child is 3 to 4 years of age and before starting school. Children with rectoprostatic fistulas have an almost 50-50 chance of having voluntary bowel movements or of being incontinent. In these children, an attempt should be made to achieve toilet training by the age of 3 years. If this proves to be unsuccessful, bowel management should be implemented. Each summer, after school is finished, further attempts can be made to assess the child's ability to toilet train.

In patients who have undergone repair of imperforate anus and who have fecal incontinence, a reoperation to relocate a misplaced rectum with the hope of obtaining good bowel control should be considered if the child was born with a good sacrum, a good sphincter mechanism, and a malformation with good functional prognosis. A repeat posterior sagittal anorectoplasty can be performed and the rectum relocated within the limits of the sphincter mechanism. Approximately 50% of the children who undergo reoperation under these very specific circumstances have a significant improvement in bowel control.<sup>5</sup>

Patients with true fecal incontinence and a tendency toward constipation cannot be treated with laxatives but instead need bowel management for fecal incontinence. In fact, laxatives in such patients make their soiling worse. This population usually consists of those patients born with a bad prognosis type of defect and with associated defects of the sacrum, a poor muscle complex, or an abnormal spine.

Children operated on for imperforate anus who suffer from true fecal incontinence can be divided into two well-defined groups that require individualized treatment plans. The first and larger group is those with fecal incontinence and a tendency toward constipation. The second group is fecally incontinent with a tendency toward loose stools. Patients with fecal incontinence after operations for Hirschsprung's disease and those with spinal disorders usually fall into the first group and have a tendency toward constipation. A small group of Hirschsprung's patients fall into the hypermotile group. These patients have multiple daily stools and a nondilated colon seen on a contrast enema.

Table 37-3 Food Products and Stool Consistency	
Foods that produce loose stools	Foods that promote constipation
Milk or milk products	Apple sauce
Fats	Apple without skin
Fried foods	Rice
Fruits	White bread
Vegetables	Bagels
Spices	Soft drinks
Fruit juices	Banana
French fries	Pasta
Chocolate	Pretzels
	Tea
	Potato
	Jelly (not jam)
	Boiled, broiled, baked meat, chicken or fish

### Children with True Fecal Incontinence and Constipation (Colonic Hypomotility)

In these children, the motility of the colon is slow. The basis of the bowel management program in these patients is to clean the child's colon once a day with an enema. No special diet or medications are necessary. The fact that they suffer from constipation (hypomotility) is helpful, because it helps them to remain clean between enemas. The real challenge is to find the appropriate enema capable of evacuating the colon completely. Definitive evidence that the colon is empty after an enema requires a plain abdominal radiograph (see Fig. 37-4). Soiling episodes or "accidents" occur when there is incomplete cleaning of the bowel with feces that progressively accumulates.

### Children with True Fecal Incontinence and Loose Stools (Colonic Hypermotility)

The great majority of children with anorectal malformations who suffer from this problem were repaired before the introduction of the posterior sagittal technique. The older procedures frequently included a rectosigmoid resection.<sup>6,7</sup> Therefore, this group of children has an overactive colon because they lack a rectal reservoir (see Fig. 37-3). Rapid transit of stool results in frequent episodes of diarrhea. This means that even when an enema cleans their colon rather easily, stool keeps passing fairly quickly from the cecum to the descending colon and into the anus. For treatments, a constipating diet and/or medications to slow down the colon are necessary. Also, eliminating foods that further loosen bowel movements will help the colon slow down (Table 37-3). A small subset of patients with Hirschsprung's disease behaves like they have hypermotility and can be managed similarly.

The keys to success of the bowel management program are dedication and sensitivity from the medical team. The basis of the program is to clean the colon and

keep it quiet, thus keeping the patient clean for the 24 hours after the enema. This program is an ongoing process that is responsive to the individual patient and differs for each child. It is usually successful within a week, during which time the family, patient, physician, and nurse undergo a process of trial and error, tailoring the regimen to the specific patient. More than 95% of the children who follow this program are artificially clean and dry for the whole day and can have a completely normal life.<sup>4</sup>

One should embrace the philosophy that it is unacceptable to send a child with fecal incontinence to school in diapers when his or her classmates are already toilet trained. Proper treatment to prevent this is perhaps more important than any surgical procedure.

### BOWEL MANAGEMENT: KEY STEPS

The first step is to perform a contrast enema with hydrosoluble material. The study should never be done with barium. It is very important to obtain a postevacuation film. This contrast study shows the type of colon that is present: dilated-constipated (see Fig. 37-2) or nondilated-tendency toward loose stool (Figs. 37-3 and 37-5). The enema volume and type can be estimated from this study.

The bowel management program is then implemented according to the patient's type of colon, and

Figure 37-5. This contrast study shows a nondilated colon.

the results are evaluated daily. Changes in the volume and content of the enema are made until the colon is successfully cleaned. For this, an abdominal radiograph that is obtained every day is invaluable in determining whether the colon is empty (see Fig. 37-4).

There are different types of solutions to use for enemas: some are ready made and can be bought in a drugstore. Some can be prepared at home based on water and salt (0.9% saline can be made by adding 1.5 teaspoons of salt to 960 mL of water). The use of phosphate enemas is most convenient because they are available in prepared containers. However, saline enemas are often just as effective, and some families find them easier and less expensive. Occasionally, children will complain of cramping with the phosphate enema but often have no complaints with saline enemas. Children should never receive more than one phosphate enema a day because of the risk of phosphate intoxication. Others with impaired renal function should avoid them entirely. The saline enema can be mixed with glycerin and/or soap to make it more effective.

The daily enema should result in a bowel movement within 30 to 45 minutes, followed by a period of 24 hours of complete cleanliness. If a single enema is not sufficient to clean the colon (as demonstrated by a radiograph) or if the child keeps soiling, then the child requires more aggressive treatment. Administering the enema with a balloon catheter helps prevent enema leakage (Fig. 37-6). The "right" enema is the one that can empty the child's colon and allow him or her to stay clean for the following 24 hours. This can be achieved only by trial and error and learning from previous attempts.

Children with loose stools have an overactive colon. Most of the time they do not have a rectal reservoir. This means that even when an enema cleans their colon rather easily, new stool passes quickly from the cecum to the descending colon and the anus. To prevent this, a constipating diet, bulking agents (e.g., pectin), and/or medications (e.g., loperamide) to slow down the colon are used. Eliminating foods that loosen bowel movements will help the colon to move more slowly (see Table 37-3).

Parents should be provided with a list of constipating foods to utilize and a list of laxative foods to avoid. The constipating diet is rigid: banana, apple, baked bread, white pasta with no sauce, boiled meat, and so on. Fried foods and dairy products must be avoided (see Table 37-3). Most parents learn which meals provoke loose stools and which constipate their child. To determine the right combination, treatment is initiated with enemas, a very strict diet, loperamide, and pectin. Most children respond to this aggressive management within 1 to 2 weeks. The child should remain on a strict diet until clean for 24 hours for 2 to 3 days in a row. They can then choose one new food every 2 to 3 days and the effect of this new food on the child's colonic activity is observed. If the child soils after eating a newly introduced food, that food must be eliminated from the diet. Over several months,

the most liberal diet possible should be sought. If the child remains clean with a liberal diet, the dose of the medication can gradually be reduced to the lowest effective dose to keep the child clean for 24 hours.

In children in whom a successful bowel management program has been implemented, the parents frequently ask if this program will be needed for life. The answer is "yes" for those patients born with no potential for bowel control. However, because there is a spectrum of defects, there are patients with some degree of bowel control. These patients are subjected to the bowel management program to avoid embarrassing accidents of uncontrolled bowel movements. As time goes by, the child becomes more cooperative and more interested in his or her problem. It is conceivable that later in life, a child may be able to stop using enemas and remain clean by following a specific regimen of a disciplined diet with regular meals (three meals per day and no snacks) to provoke bowel movements at a predictable time. Every summer, children with some potential for bowel control can try to find out how well they can control their bowel movements without the help of enemas. This is attempted during vacations to avoid accidents at school or during a time that they can stay home and try some of the toilet training strategies.

For patients with a colostomy and no potential for bowel control, a key question is whether to perform a pull-through operation or leave the permanent

**Figure 37-6.** Note that inflation of the balloon on the catheter helps prevent enema leakage in this retrograde contrast study.

**Figure 37-7.** Some patients have the capacity to have good bowel control with a daily enema administered through their colostomy.

stoma. We believe that if the patient has the capacity to form solid stool, a pull-through procedure can be performed and a daily enema given thereafter helps to keep them clean. For these patients, we believe that successful bowel management provides a better

quality of life compared with a permanent stoma. Thus, for this group of patients, bowel management is initiated with a daily enema via the stoma (Fig. 37-7). If the stoma remains quiet for 24 hours between enemas, then that stoma could be pulled through and a daily enema using the Malone technique utilized (Fig. 37-8).<sup>8</sup>

Most preschool- and school-age children enjoy a good quality of life while undergoing the bowel management program. However, when they reach puberty, many express dissatisfaction. They believe that their parents are intruding on their privacy by giving them enemas. It is feasible, but rather difficult, for them to administer the enema themselves. For this specific group of children, a continent appendicostomy or Malone procedure has been developed (see Fig. 37-8).<sup>8</sup> Using the appendix, a valve mechanism is created and connected to the umbilicus. The appendicostomy can be catheterized to administer the enema fluid but will avoid leakage of stool through it. If the child has had the appendix removed, it is possible to create a new one from a colonic flap (a continent neo-appendicostomy).

The Malone procedure is just another way to administer an enema. Therefore, before performing it, the child has to be perfectly clean with a bowel management regimen.

## PSEUDOINCONTINENCE

Pseudoincontinence occurs when a patient behaves like he or she is fecally incontinent but really has severe constipation and overflow soiling. Once the disimpaction is treated and the patient receives enough laxatives to avoid constipation, he or she starts having voluntary bowel movements.

**Figure 37-8.** Some patients are able to have bowel continence with a daily prograde enema administered through an appendicostomy. (From Levitt MA, Soffer SZ, Peña A: Continent appendicostomy in the bowel management of fecal incontinent children. *J Pediatr Surg* 32:1631, 1997.)

The colon absorbs water from the stool and serves a reservoir function. These processes depend on colonic motility, which is an area of physiology that is not well understood and for which treatments of problems are limited. In normal individuals, the rectosigmoid stores the stool. Every 24 to 48 hours, it develops active peristaltic waves, indicating that it is time to empty. A normal individual feels this sensation and decides when to relax the voluntary sphincter mechanism.

If a child is fecally continent, then management involves treatment of constipation, using laxatives, which helps to provoke peristalsis and to overcome the dysmotility. Patients who have undergone successful surgery for Hirschsprung's disease or for anorectal malformations (good prognosis type) with a normal spine should be fecally continent.

Constipation in children with anorectal malformations is extremely common, particularly in the more benign types.<sup>3,9</sup> It is also common in patients after successful surgery for Hirschsprung's disease and occurs in a large group of patients considered to have idiopathic constipation.<sup>1</sup> When left untreated, constipation can be extremely incapacitating. Although diet impacts colonic motility, its therapeutic value is negligible in the most serious forms of constipation. While it is true that many patients with severe constipation suffer from psychological disorders, a psychological origin for the constipation cannot explain the severe forms, because it is not easy to voluntarily retain stool when an autonomous rectosigmoid undergoes peristalsis. Passage of large, hard pieces of stool may provoke pain and make the patient behave like a stool retainer. This may complicate the problem of constipation, but it is not the original cause.

Constipation is a self-perpetuating disease. A patient who suffers from a certain degree of constipation and is not treated adequately will only partially empty the colon, leaving larger and larger amounts of stool inside the rectosigmoid. This results in greater degrees of distal colonic enlargement. It is clear that dilation of a hollow viscus produces poor peristalsis. This explains why constipation leads to fecal retention, leading to megacolon, which exacerbates the constipation. In addition, the passage of large, hard pieces of stool may produce anal fissures, leading to painful stooling and a reluctance by the patient to have bowel movements.

The clinician must decide which type of patient is being treated. Patients with anorectal malformations and Hirschsprung's disease with good prognosis for bowel control are those more likely to have constipation. In these patients, an aggressive, proactive treatment of their constipation is the best approach. Additionally, the child must be deemed capable of being fecally continent and having the capacity for voluntary bowel movements before initiating treatment for constipation because laxatives will make an incontinent constipated child worse.

When children with anorectal malformations and Hirschsprung's disease are managed early with aggressive treatment of constipation, children with good prognosis should toilet train without difficulty. When constipation is not managed properly, they

behave much like children with idiopathic constipation and may have overflow pseudoincontinence. Because of a hypomotility disorder that interferes with complete emptying of the rectosigmoid, most of these patients suffer from different degrees of dilation of the rectum and sigmoid, a condition known as megarectosigmoid (see Fig. 37-2).<sup>1</sup> These can be children who were born with a good prognosis type of anorectal defect and who underwent a technically correct operation, but did not receive appropriate treatment for constipation. Subsequently they developed fecal impaction and overflow pseudoincontinence. These may also be children with severe idiopathic constipation who have a very dilated rectosigmoid.

First, the impaction needs to be removed with enemas and colonic irrigations to clean the megarectosigmoid. Subsequently, once the colon is clean, the constipation is treated with the administration of large doses of laxatives. The dosage of the laxative is increased daily until the right amount of laxative is reached to completely empty the colon every day.

If medical treatment proves to be extremely difficult because the child has a severe megasigmoid and requires an enormous amount of laxatives to empty, the surgeon can offer a segmental resection of the colon. After the resection, the amount of laxatives required to treat these children can be significantly reduced or even eliminated. Before performing this operation, it is mandatory to confirm that the child is definitely suffering from overflow pseudoincontinence rather than true fecal incontinence with constipation. Failure to make this distinction may lead to an operation in which a fecally incontinent constipated child is changed to one with a tendency to have loose stool, which will make the patient's condition much more difficult to manage.

The dysmotility of the colon in patients with Hirschsprung's disease, even after successful surgery to remove the aganglionic bowel, is not understood. These patients can also benefit from proactive medical treatment of their constipation. The clinician must understand that the dysmotility observed is essentially incurable. It is, however, manageable, but requires careful follow-up for life. Treatments cannot be given on a temporary basis. If they are tapered or interrupted, the constipation will recur.

Some clinicians treat these patients with colostomies or colonic washouts via a catheterized stoma or button device, and monitor the improvement of colonic dilatation with contrast studies.<sup>10</sup> Once the distal colon regains a normal caliber, the physician assumes that the patient is cured and discontinues the washouts or closes the colostomy. Unfortunately, these patients' symptoms quickly recur. Washouts are often ineffective in such patients because they simply retain the fluid. We believe that washouts are really only for patients with true fecal incontinence who are incapable of having voluntary bowel movements and thus require a daily irrigation to empty their colon. On the other hand, the patient with pseudoincontinence is capable of emptying the colon with the help of adequate doses of laxatives and thus does not need washouts.

Determining which patient the clinician is managing can be a challenge. If the patient is incontinent, washouts with a bowel management regimen are appropriate. If the patient is continent, then aggressive management of the constipation after ensuring disimpaction is the treatment choice.

Fecal impaction is a stressful event resulting from retained stool for several days or weeks, crampy abdominal pain, and sometimes tenesmus. When laxatives are prescribed to such a patient, the result is exacerbation of the crampy abdominal pain and sometimes vomiting. This is a consequence of increased colonic peristalsis (produced by the laxative) acting against a fecally impacted colon. Therefore, disimpaction, proven by radiograph, must precede initiation of laxative therapy.

Soiling of underwear is an ominous sign of severe constipation. A patient who is old enough to have bowel control, but soils the underwear day and night and does not have spontaneous bowel movements, may have overflow pseudoincontinence. These patients behave similarly to fecally incontinent individuals. When the constipation is treated adequately, the great majority of these pseudoincontinent children regain bowel control. Of course, this clinical presentation may also occur in a patient with true fecal incontinence. When uncertain, the clinician can start the 3- to 4-year-old who is having trouble with toilet training on a daily enema. Once clean with this regimen, and if the child has the potential for bowel control, then an attempt at a laxative program can be tried.

A contrast enema with hydrosoluble material (never barium) is an extremely valuable study. In the constipated patient, it usually shows a megarectosigmoid with dilation of the colon all the way down to the level of the levator mechanism (see Fig. 37-2). There is usually a dramatic size discrepancy between a normal transverse and descending colon and the dilated megarectosigmoid. The size of the colon guides the dosing of the laxatives. It seems that the more localized the dilatation of the rectosigmoid, the better the results of a colonic resection in reducing or eliminating the laxative requirement.

Rectal and colonic manometry is sometimes used in the evaluation of these patients. Manometry is performed by placing balloons at different levels in the colon and recording the waves of contraction or the electrical activity.<sup>11,12</sup> Scintigraphy, a nuclear medicine study, is also being used to assess colonic motility.<sup>13</sup> These are sophisticated studies that do not yet help guide therapeutic decisions. The key information the surgeon needs to know is if and where a colonic resection would prove beneficial to the patient who requires enormous doses of laxative to empty the bowel.

Histologic studies of the colon in these patients mainly show hypertrophic smooth muscle in the area of the dilated colon and normal ganglion cells. In the near future, it is hoped more sophisticated histopathologic research will enhance our knowledge about colonic dysmotility.

## TREATMENT

Patients with anorectal malformations, severe constipation, and the potential for bowel control, as well as those with severe idiopathic constipation in whom dietary measures or gentle laxatives do not work, require a more aggressive regimen. Drugs that are designed to increase the colon's motility (containing senna) are best when compared with medications that are only stool softeners. Softening of the stool without improving the colonic motility will likely make the patient worse. With soft stool they no longer have control, whereas they do reasonably well with solid stool that allows them to feel rectal distention. This is a common misconception. Often the switch from stool softener to laxative makes an enormous difference.

In many cases, the laxative regimen we employ uses the same medications that have been tried previously but were unsuccessful. This is because the protocol is different in that the laxatives are only started with a radiographically clean colon and the dosage is adapted to the patient's response. The response is monitored daily with an abdominal radiograph with the laxative dose adjusted, if necessary. Almost always, the patient previously had received a lower dose than what was really needed.

## Disimpaction

The disimpaction process is a vital and often neglected step. This includes the administration of enemas three times a day until the patient is disimpacted, which is confirmed radiologically. The contrast enema using water-soluble material not only shows the anatomy, but also is a helpful tool for cleaning the colon. If the patient remains impacted after 3 days, then he or she is given a balanced electrolyte solution via nasogastric tube in the hospital and the enema regimen is continued. If this is unsuccessful, a manual disimpaction under anesthesia may be necessary. It is important to remember not to prescribe laxatives to a patient who is fecally impacted. To do so may provoke vomiting and crampy abdominal pain. In addition, the patient will become reluctant to take laxatives because of the fear of these symptoms.

## Determining the Laxative Requirement

Once the patient has been disimpacted, an arbitrary amount of laxative, usually a senna derivative, is started. The initial amount is based on the information that the parents give about the previous response to laxatives and the subjective evaluation of the megasigmoid on the contrast enema. An empirical dose is given, and the patient is observed for the next 24 hours. If the patient does not have a bowel movement in the 24 hours after giving the laxative, it means the laxative dose was not strong enough and must be increased. An enema is also required to remove the stool produced during the previous 24 hours. Stool

**Figure 37-9.** A and B, These drawings show resection of a dilated sigmoid colon, which can be very effective in select patients with an anorectal malformation and severe constipation.

in these extremely constipated patients should never remain in the rectosigmoid for more than 24 hours.

The routine of increasing the amount of laxatives and giving an enema, if needed, is continued every night until the child has a voluntary bowel movement and empties the colon completely. Ideally, this routine is checked with a daily radiograph. Each day that the patient has a bowel movement (which is usually with diarrhea), a radiograph should confirm that the bowel movement was effective, meaning that the patient completely emptied the rectosigmoid. If the patient passed stool but did not empty completely, the dose of laxative should be increased. If the patient passed stool and successfully emptied the colon, then that laxative dose should be continued on a daily basis. If the patient passed multiple stools and the abdominal film is clear, then the laxative dose can be reduced slightly.

It is important to remember that this condition covers a wide spectrum and patients may have laxative requirements much larger than the manufacturer's recommendation. Occasionally, in the process of increasing the amount of laxatives, patients throw up or feel nauseated and cramping with the medication before reaching any positive effect. In these patients, a different medication can be tried. Some patients vomit all kinds of laxatives and are unable to reach the amount of laxative that produces a bowel movement that empties the colon. Such a patient is considered to have an intractable condition and is a candidate for surgical intervention. Usually, however, the dosage that the patient needs to empty the colon completely (as demonstrated radiologically) can be achieved. At that dose, the patient should stop soiling because he or she is successfully emptying the colon each day. Because the colon is empty, the patient remains clean until the next voluntary bowel movement.

At this point, the patient and the parents have the opportunity to evaluate the quality of life that they have with this kind of treatment, understanding that this treatment will most likely be lifelong. For many of these patients, a sigmoid or rectosigmoid resection can provide symptomatic improvement leading to significant reduction or complete elimination of laxatives.

### Rectosigmoid Resection

For the past 15 years, we have been performing a sigmoid resection for the treatment of select patients with severe constipation and voluntary bowel movements.<sup>14</sup> The megarectosigmoid is resected and the descending colon is anastomosed to the rectum (Fig. 37-9). In a recent review of our patients with anorectal malformations, 315 who suffered from severe constipation were fecally continent but required significant laxative doses to empty the colon.<sup>15</sup> Of these, 53 underwent a sigmoid resection with preservation of the rectum. Of those undergoing sigmoid resection, 10% of patients no longer required laxatives, had daily bowel movements, and did not soil. Thirty percent of patients decreased their laxative requirement by 80% and the remaining 60% of patients decreased their laxative requirement by 40%. These patients must be followed closely because the condition is not cured by the operation. The remaining rectum is most likely abnormal. Without careful observation and treatment of constipation, the colon can re-dilate.

In patients with anorectal malformations, keeping the rectum intact is vital because they need it for continence. It is their reservoir in which they feel the distention of the stool. In contrast, patients with idiopathic constipation who have not undergone any rectal surgery and have a normal anal canal and sphincters, the rectum and sigmoid can be resected with preservation of fecal continence. The resection of the

**Figure 37-10.** In patients with idiopathic constipation who have not undergone previous operations and have a normal anal canal and sphincter, an extensive resection of the rectosigmoid colon can be performed transanally.

rectosigmoid down to the pectinate line can be done in a similar manner used for patients with Hirschsprung's disease, with anastomosis of the nondilated colon (that is assumed to have normal motility) to the rectum above the pectinate line (Fig. 37-10). An extensive rectosigmoid resection can be done completely transanally.<sup>16</sup> We have performed this operation in 25 patients and have seen dramatic improvement in their ability to empty their colon.

The most dilated part of the colon is resected because it seems to be the most seriously affected and the nondilated part of the colon is assumed to have a more normal motility. Unfortunately, we lack a more scientific way to assess the dysmotile anatomy. Perhaps emerging colonic motility studies will help with surgical planning. It seems that the patients who improve the most are those who have a more localized form of megarectosigmoid. Patients with more generalized dilation of the colon do not respond as well and may require a more extensive resection.

# ACQUIRED ANORECTAL DISORDERS

Casey M. Calkins, MD • Keith T. Oldham, MD

## PERIANAL AND PERIRECTAL ABSCESS

Perianal or perirectal abscesses are often encountered during infancy. The majority of patients in a pediatric surgical practice are seen prior to 12 months of age. The abscess typically presents as a fluctuant, tender mass in the perianal region (Fig. 38-1). Patients are usually otherwise well. A history of stool abnormalities is typically not elicited, either before development of the abscess or during its maturation. Perianal abscesses are much more common in male infants and are infrequent in toddlers and older children.<sup>1</sup> Crohn's disease, immunodeficiency, glucose intolerance, and perianal trauma can be causative stimuli. It is unusual to find complex ischiorectal abscesses in children unless associated with chronic inflammatory bowel diseases. During infancy, abnormal crypt architecture may predispose the patient to the development of an infection within the crypts of Morgagni.<sup>1</sup> However, some have disputed the role of abnormal crypt architecture in the development of perianal abscess and subsequent fistula-in-ano.<sup>2</sup>

Sitz baths (or their equivalent for the infant) are prescribed if the abscess does not appear to be fluctuant and in need of immediate drainage. Approximately one third of abscesses thus treated resolve without recurrence.<sup>3</sup> Approximately two thirds require incision and drainage. This continues to be the mainstay of surgical therapy, albeit recent reports have surfaced that describe favorable outcomes for patients treated with needle aspiration and oral antibiotic therapy.<sup>4</sup> Although surgical drainage can be accomplished in the infant without anesthesia or with a topical anesthetic ointment, we prefer a brief anesthetic to allow for adequate drainage and optimal patient comfort. Considerable debate exists with regard to making an effort to delineate a fistula at the time of abscess drainage.<sup>5,6</sup> We prefer simple abscess drainage as the initial step in an infant with a perianal abscess. A small wick of gauze is typically left within the cavity. Removal of the packing along with sitz baths is undertaken on the first postoperative day.

## FISTULA-IN-ANO

As many as 40% to 50% of perianal abscesses progress to a fistula-in-ano.<sup>7</sup> Fistula-in-ano also appears predominantly in male infants.<sup>8</sup> The child is usually seen after two or more flareups of a perianal abscess that either continues to drain or forms a small pustule that ruptures, only to form again (Fig. 38-2).<sup>9</sup> The fistula is commonly located lateral to the anus rather than in the midline. Occasionally, two fistulas may occur simultaneously in one child. In a few patients, fistulas have occurred in a serial fashion. An intriguing theory has been suggested that fistula-in-ano results from infection in abnormally deep crypts that are under the influence of androgens.<sup>1</sup> The fact that fistula-in-ano almost never follows a perianal abscess in female children lends credence to this theory.<sup>10</sup>

The preferred surgical procedure for fistula-in-ano is fistulotomy. With the patient under general anesthesia, the anus is gently serially dilated with Hegar dilators and a small nasal speculum suffices as an anoscope. A fine malleable probe is inserted through the fistula and gently advanced until it is visualized to exit the base of the involved crypt (Fig. 38-3A), remembering that the tract is direct and does not follow Goodsall's rule for fistulas seen in adult patients. An incision is made along the probe and is deepened through the superficial portion of the external sphincter (see Fig. 38-3B). The base of the exposed fistula is denuded of granulation tissue with a curet. The wound is left open, which provides some distress on the part of the parents but little discomfort on the part of the child (see Fig. 38-3C). Although suture closure has been reported to result in satisfactory healing without infection, we prefer to leave the tract open.<sup>1</sup> We instruct the parents to provide a sitz bath after each bowel movement, at least twice daily, and to separate the skin edges of the fistulotomy site during bathing to promote healing by secondary intention. We reserve cryptectomy and tract excision for patients with recurrence, which is rare after an adequate fistulotomy.

**Figure 38-1.** Perianal abscesses are often seen in male infants. The abscess typically presents as a fluctuant, tender mass in the perianal region. Incision and drainage is the initial management of these abscesses.

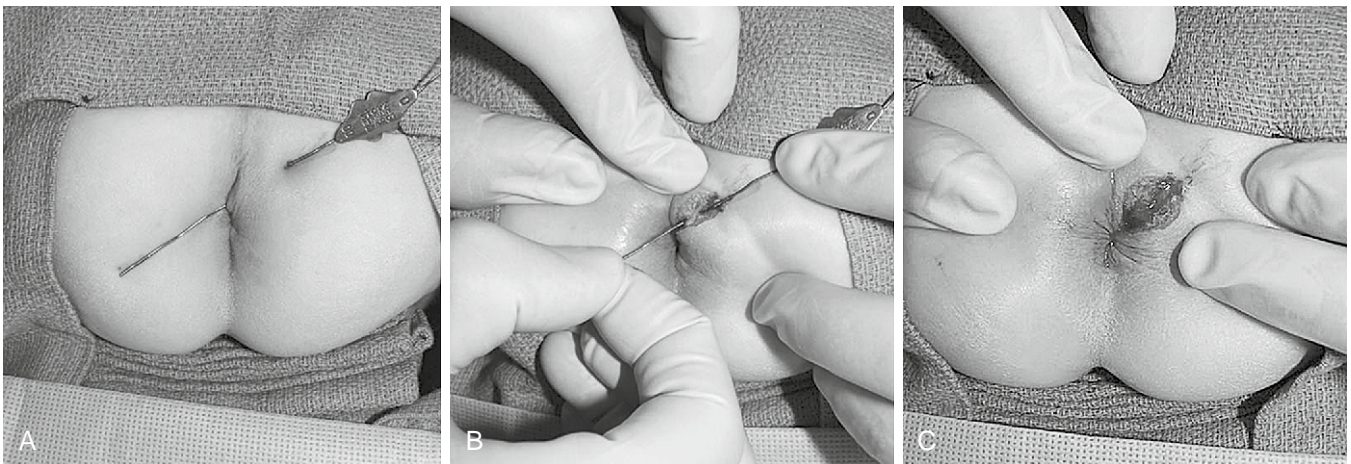

**Figure 38-2.** As many as one half of the perianal abscesses progress to a fistula-in-ano. In this photograph, the fistula is seen at 1 o'clock when the infant is in the lithotomy position.

## ANAL FISSURE

An anal fissure commonly develops in a toddler whose diet changes from liquid to solid and whose stool consistency changes from soft to firm. A period of constipation often precedes a hard, bulky stool that results in a posterior midline tear in the anoderm below the mucocutaneous junction. The discomfort in having a bowel movement associated with the fissure often leads to further constipation, which, in turn, aggravates the fissure with each stool and prevents healing. Anal fissure in the pediatric population is typically seen in the toddler who is capable of repressing the urge to defecate because of this anticipated pain. The diagnosis is made through the history of blood streaking on the stool, the child's crying during bowel movements, and the recognition of a split in the anoderm. Operative interventions such as lateral internal sphincterotomy<sup>11</sup> or fissurectomy<sup>12</sup> are rarely necessary. We prefer to manage these patients with sitz baths and an osmotic stool softener such as polyethylene glycol, although any form of stool softener is sufficient. Sitz baths promote good anal hygiene and relax the anal sphincter. Although 0.2% nitroglycerin ointment has become a popular treatment for anal fissure in adults, its use in children is still limited, although some studies have shown promising efficacy.<sup>13-15</sup> Nevertheless, we believe its use should be entertained for the older child without evidence of inflammatory bowel disease. The same is true for chemical sphincterotomy by botulinum toxin, which has gained popularity in adults. However, it has not been demonstrated to be superior to topical nitroglycerin and has not been well studied in children.<sup>14</sup>

An anal fissure in an older child or a teenager is often associated with chronic inflammatory bowel disease, usually Crohn's.<sup>16</sup> Demonstration of an anal fissure often precedes the diagnosis of Crohn's disease. Medical treatment of Crohn's disease typically results

**Figure 38-3.** A, At the time of operation, a small, fine, malleable probe is inserted through the fistula and can usually be gently advanced until it is visualized to exit the base of the involved crypt. B, An incision is then made along the probe and is deepened through the superficial portion of the external sphincter. C, After complete unroofing of the tract, the incision is usually left open, which may provide some distress on the part of the parents but usually does not cause much discomfort for the child.

in healing of the fissure.<sup>17,18</sup> Also, topical application of tacrolimus ointment is a promising new therapy.<sup>19</sup> Internal sphincterotomy appears to be a relatively safe undertaking in this patient population when local measures and immunomodulator therapy fail.<sup>16,20</sup>

## ANAL SKIN TAGS AND HEMORRHOIDS

A perianal skin tag is rarely an indication of other disease, although it may result from a healed fissure. Although it is generally of no consequence, when large enough it can be bothersome and can affect adequate perianal hygiene. In these cases, local excision is reasonable.

Hemorrhoids are uncommon in the pediatric population, and rarely is surgical therapy a necessary aspect of treatment. External hemorrhoids are located in the distal one third of the anal canal and covered by anoderm. Symptoms from external hemorrhoids are generally due to thrombosis, and examination reveals a tender, bluish mass at the mucocutaneous junction (Fig. 38-4). Treatment consists of incision of the hemorrhoid and extrusion of the clot with subsequent sitz baths, dietary modification (fiber supplementation), and stool softeners. Internal hemorrhoids are extremely rare in children unless associated with portal hypertension. The treatment of bleeding from internal hemorrhoids due to portal hypertension should be aimed at decreasing portal pressure, either pharmacologically or surgically. In patients without portal

**Figure 38-4.** This adolescent presented with pain secondary to thrombosis of an external hemorrhoid (arrow). The hemorrhoid was incised and the clot extruded.

hypertension, initial treatment of internal hemorrhoids should be focused on conservative measures such as provision of stool bulking agents and topical treatment (sitz baths and topical pharmaceutical preparations). Rubber band ligation or operative hemorrhoidectomy is performed when conservative measures fail.

## RECTAL PROLAPSE

Rectal prolapse is a relatively common problem in young children and causes great distress to the child and the parents. Prolapse can range from an intermittent mucosal prolapse that occurs during defecation and reduces spontaneously to full-thickness prolapse of the rectum, which requires manual reduction. Worse is if the prolapse cannot be reduced, which may result in vascular compromise. Rectal prolapse in children is likely precipitated by weakness of the pelvic supporting musculature (levator mechanism) and loosely attached rectal submucosa to the underlying muscularis. The latter may improve with time (especially in cases where the weakness is due to malnutrition or dehydration),<sup>21</sup> whereas a weak and dilated pelvic floor may not. Straining during stooling and long periods of sitting on the toilet, because of protracted diarrhea or constipation (which may occur in cystic fibrosis), allows stretching of the pelvic diaphragm and other less well-defined suspensory structures of the rectum, resulting in prolapse.<sup>22</sup> Up to 20% of cases of rectal prolapse initially seen between 6 months and 3 years of age will later be diagnosed with cystic fibrosis.<sup>23</sup> A chloride sweat test should be undertaken to substantiate the diagnosis when there is no apparent underlying cause.<sup>24</sup>

The diagnosis is usually made by the parent, who notices a rosette of mucosa when the child complains of discomfort at the anus while defecating. Bleeding is occasionally noted as the primary symptom. Rarely is rectal prolapse in children the source of significant disability. The prolapse either reduces spontaneously as the child gets off the toilet or the parent pushes it back in. Many 3-year-old children very quickly learn to reduce their own prolapse. It generally does not recur until the next stool. It is uncommon for the child to be able to produce the prolapse in the examining room. Occasionally, the prolapse can be demonstrated during a brief session on the commode. The typical prolapse is a rosette of mucosa, sometimes slightly longer posteriorly than anteriorly (Fig. 38-5). One should be able to slip a finger alongside the prolapse and feel the sulcus 1 to 2 cm up inside the anus. Sometimes what appears to be rectal prolapse is an intussusception of the sigmoid colon.<sup>25</sup> In these cases, an intact rectal suspension system exists but a dilated levator mechanism produced by straining at stool, coupled with a redundant sigmoid colon, allows for its intussusception. A deeper sulcus suggests sigmoid intussusception rather than rectal prolapse. It is often difficult to differentiate the two clinically, even in the face of rectal examination at the time of prolapse or radiologic defecography and/or barium enema obtained to clarify the situation.

**Figure 38-5.** Rectal prolapse occurring in a child who had severe burns on his legs. Despite its being reduced repeatedly for several weeks, this prolapse continued to occur several times daily and required surgical correction.

The pelvic diaphragm is a muscular structure. If the prolapse is prevented from recurring, the muscle fibers shorten and the situation may be self-limiting. However, if the child continues straining during stooling once the pelvic diaphragm and rectal sphincters have been stretched, there is little chance that the prolapse will correct itself.

The nonoperative treatment of rectal prolapse consists of attempts to alter the disorder that led to the prolapse. A change in defecation habits and provision of stool softeners that eliminates the persistent urge to defecate may allow the pelvic musculature to resume its normal tone. One of the early reports advised against allowing the child to use the commode until the problem was resolved, suggesting that the child defecate in a squatting position on a newspaper.<sup>26</sup> We advocate that patients with rectal prolapse be restricted from spending prolonged periods of time on the commode. In addition, a child-specific commode or a step stool in front of an adult commode will assist the child in toilet training and may eliminate straining-like behaviors. In patients who are identified with cystic fibrosis, enzymatic supplementation and addressing malnutrition may be all that is required to eliminate episodes of prolapse.<sup>27</sup>

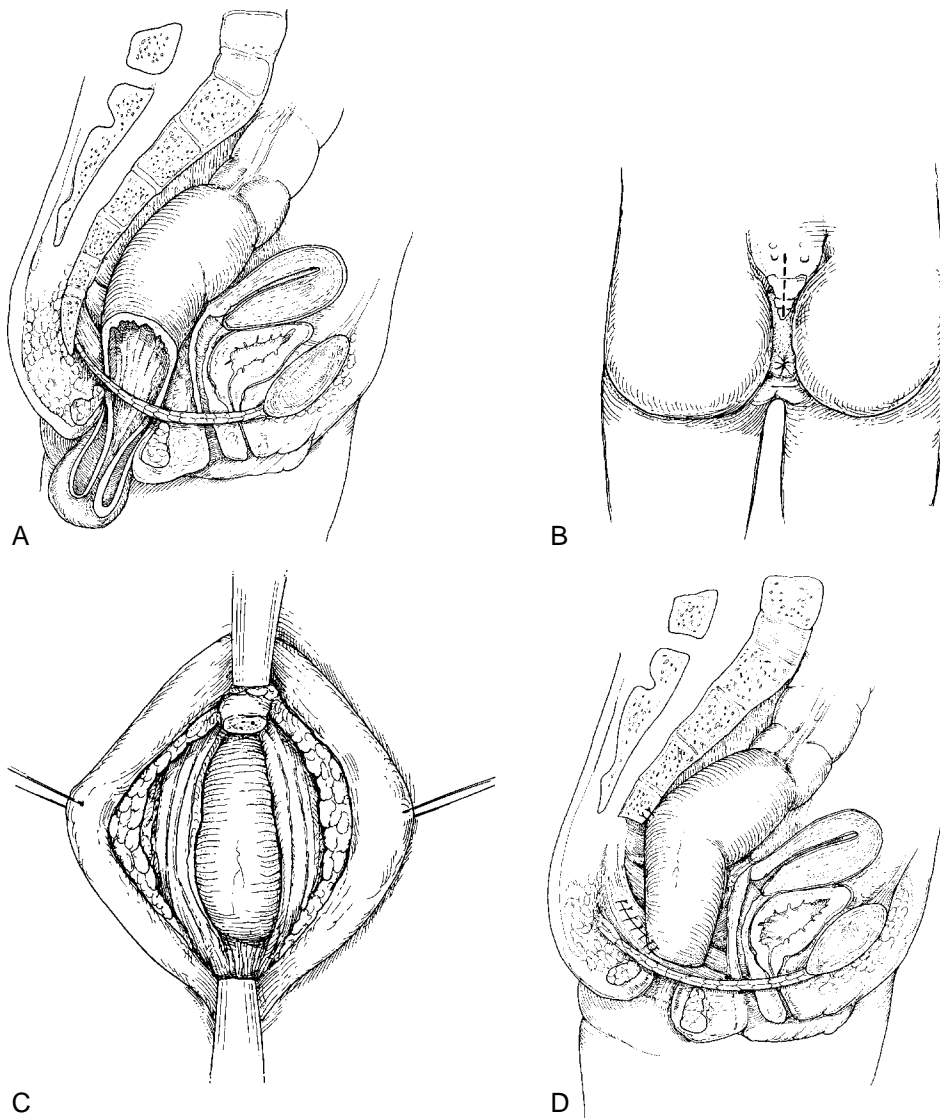

Surgical therapy has taken a number of forms. Perianal cerclage tightens the anal outlet and prevents prolapse from recurring while the musculature of the pelvic floor re-establishes its normal anatomic relationship.<sup>24</sup> The fact that the cerclage procedure is commonly used bespeaks its effectiveness, although one must be cautious to avoid placing the cerclage too tightly to avoid erosion of the anus. This is typically avoided by tying the cerclage over an appropriately

sized Hegar dilator.<sup>28</sup> Sclerotherapy with any number of compounds (30% saline, Deflux, 25% glucose, 5% sodium morrhuate) injected into the retrorectal space produces an inflammatory response and scar that theoretically prevents the rectum from sliding downward. Whatever the injection material, it sometimes must be repeated.<sup>29-33</sup> We have found sclerotherapy to be especially effective in children with mucosal prolapse when combined with stool softeners and behavior modification. An open sclerosing procedure, in which the retrorectal space is developed and packed with gauze, is not performed routinely today.<sup>34,35</sup> It was performed through an incision posterior to the anus but anterior to the coccyx. The gauze packing is removed gradually over a 10-day period. The packing produces enough inflammatory response that the rectum remains suspended.

Various methods of cauterization therapy have been tried for rectal prolapse.<sup>22,36,37</sup> Endorectal cauterization or mucosal stripping as an alternative to suspension and plication procedures may be effective by allowing restoration of the suspensory apparatus. However, there is little evidence that rectal prolapse is due to mucosal overabundance, and we do not recommend this approach as a primary form of surgical therapy.

In patients with full-thickness prolapse, or for those who have failed other surgical forms of therapy, operative fixation techniques are generally needed. Transanal suture fixation of the rectum (initially described in 1909) has recently been used in a group of children with good success.<sup>38,39</sup> Its benefit probably derives from prevention of recurrent prolapse, while inflammation produced by the mattress suture, which extends from the rectal lumen to the skin, produces adhesions. An extensive plication or reefing of the posterior rectal wall via a coccygectomy incision has recently been reported to have good results, but the morbid potential for fistula formation makes this a technique that we do not routinely employ.<sup>40</sup> Laparoscopic rectopexy is an alternative to standard open rectopexy and is performed with two operating ports and a port for laparoscopic visualization.<sup>41,42</sup> The rectum is mobilized and sutured to the periosteum of the sacral promontory in multiple locations with nonabsorbable suture. The operation has been successfully completed in children as young as 10 months of age, and early results are encouraging.

Open posterior rectopexy has been advocated as the primary therapeutic modality for rectal prolapse not responsive to more conservative measures.<sup>43</sup> Through a natal cleft incision, the coccyx is removed, the muscular hiatus is narrowed, and the rectum is suspended from the cut edge of the sacrum so that it cannot slide downward (Fig. 38-6). This maneuver immediately re-establishes the levator ani suspensory mechanism and narrows the anorectal hiatus, which is the ultimate therapeutic intention of all the methods of treatment. Ashcraft and colleagues reported this technique in 46 patients over a 17-year period.<sup>44</sup> Of these patients, 42 had satisfactory resolution of their rectal prolapse. The operation can be performed satisfactorily as an outpatient procedure. Modification

**Figure 38-6.** A, A cut-away sagittal view illustrates the failure of the rectal suspensory mechanism to hold the rectum within the pelvis. B, The posterior sagittal incision is depicted. C, The coccyx has been removed and the posterior rectal wall exposed. D, The pelvic diaphragm is closed posterior to the reduced rectum. The rectum is sutured laterally to the pelvic diaphragm. The rectum is further suspended from the cut edge of the sacrum. (A and D redrawn from Ashcraft KW, Amoury RA, Holder TM: Levator repair and posterior suspension for rectal prolapse. *J Pediatr Surg* 12:241-245, 1977; B and C from Ashcraft KW: *Atlas of Pediatric Surgery*. Philadelphia, WB Saunders, 1994, p 217.)

of this approach by tapering a redundant and patulous rectum has considerable merit when the size of the rectum limits the ability to adequately narrow the anorectal hiatus.<sup>45</sup>

## RECTAL TRAUMA

Rectal trauma in pediatric patients generally occurs by one of two mechanisms. The first is by way of penetrating trauma after an accidental impalement injury or, occasionally, a gunshot (Fig. 38-7). The second, and more common, occurs as the result of sexual abuse. Digital or penile penetration of the anorectum or other instrumentation may cause bleeding or bruising. The most common clinical presentation is that of a chronic stellate laceration of the anus with edema (Fig. 38-8).

Perianal condylomata are a common sequelae in cases of sexual abuse. Careful questioning may reveal that a male member of the immediate family has penile condylomata. However, as many as 25% of males who

carry human papillomavirus in the urethra have no external evidence of the virus.<sup>46</sup>

The patient with an accidental injury to the anus usually is seen immediately after the incident occurs. An accurate and consistent history of the mechanism of injury is critical. Sexual abuse is suspected when an inconsistent history of the mechanism of injury is elucidated. As with other forms of sexual abuse involving genital penetration in female patients or manipulation in male patients, difficulty is often encountered in obtaining an adequate history from the victim owing to fear, threats of retaliation, or guilt. Unexplained injuries to the rectum must be considered a manifestation of sexual abuse until proven otherwise and must be investigated through the appropriate social service authorities.<sup>47-49</sup>

The child who has an acute traumatic rectal injury is often difficult to examine adequately, owing to the associated discomfort. Penetration of a foreign object by impalement typically requires rectal examination and sigmoidoscopy under general anesthesia. A retrograde urethrogram and/or voiding cystourethrography

**Figure 38-7.** This teenager sustained a gunshot wound to the buttocks with a suspected injury to the rectum. He underwent sigmoidoscopy followed by a diverting colostomy. Several days postoperatively, this contrast study was performed and revealed extravasation (*arrow*) from the rectal injury.

should be obtained when there is suspicion of urethral and/or bladder injury. Although a child who is sexually abused and who has either condylomata or lacerations of a more chronic nature can be examined while awake, we prefer to examine the child using general anesthesia to make a complete assessment of the nature and extent of the injury and to proceed with surgical treatment, when necessary. Photographs are taken to document the extent of the findings for medicolegal purposes.

Treatment of penetrating rectal injuries often requires a diverting colostomy.<sup>50</sup> However, primary repair without fecal diversion can be performed safely in select cases.<sup>51,52</sup> When in doubt, one should always divert the fecal stream to avoid the consequences of perineal sepsis after repair of an anorectal injury. In general, isolated intraperitoneal rectal injuries can be treated with primary repair. Injuries

**Figure 38-8.** This male child was the victim of chronic sexual abuse and shows the typical stellate lacerations of the anal mucosa and skin.

to the proximal two thirds and accessible distal one third of the extraperitoneal rectum can be managed with repair and selective fecal diversion. Inaccessible or severe distal extraperitoneal rectal injuries should be treated by fecal diversion and presacral drainage.<sup>53</sup> Accessible injuries of the distal rectum and anal canal can be repaired with the intent of reapproximating the underlying sphincter muscle mechanism and the overlying mucosa. When the injury is full thickness in nature, fecal diversion should be undertaken. When fecal diversion is necessary, closure of the colostomy is performed once satisfactory healing is demonstrated.

Treatment of sexual abuse lesions involves interruption of the abuse pattern, which may require removal of the child from the home environment. Immediate consultation with child protective services or the local equivalent is mandatory. In the sexual abuse victim who is found to have an acute laceration extending up the rectal wall, it is rarely necessary to perform a diverting colostomy, because these lacerations are not usually full thickness. However, patients with a full-thickness injury should be managed by repair and diverting colostomy. When present, treatment of condylomata depends on the extent of disease. Although small lesions may be responsive to repeated applications of topical agents such as podophyllin or imiquimod, more extensive lesions require surgical removal. Intralesional interferon may be a useful adjunct to surgical methods to decrease recurrence.<sup>54</sup>

# INTUSSUSCEPTION

Romeo C. Ignacio, Jr., MD • Mary E. Fallat, MD

**I**ntussusception is one of the most frequent causes of bowel obstruction in infants and toddlers. Nevertheless, an individual pediatrician may encounter this condition only rarely. It was first described in 1674 by Paul Barbette of Amsterdam and was defined by Treves in 1899 as the prolapse of one part of the intestine into the lumen of the immediately adjoining part.<sup>1</sup> John Hutchinson reported the first successful operation for intussusception in 1873.<sup>2</sup> In 1876, Harold Hirschsprung described hydrostatic reduction, which led to a 23% reduction in mortality.<sup>3</sup> Ravitch popularized the use of contrast enema reduction for intussusception, which gradually became the accepted initial treatment for pediatric intussusception in stable patients.<sup>4</sup>

## PATHOPHYSIOLOGY

Intussusception is the acquired invagination of one portion of the intestine into the adjacent bowel. It is described by the proximal, inner segment of intestine (intussusceptum) first and the outer distal, receiving portion of intestine (intussusciptiens) last. Eighty to 95 percent of pediatric intussusceptions are ileocolic. The ileoileal, cecocolic, colocolic, and jejunojejunal varieties occur with increasing rarity.<sup>5</sup> Occasionally, an intussusception may have an identifiable lesion that serves as a lead point, drawing the intussusceptum into the distal bowel by peristaltic activity. As the mesentery of the proximal bowel is drawn into the distal bowel, it is compressed, resulting in venous obstruction and edema of the bowel wall. If reduction of the intussusception does not occur, arterial insufficiency will ultimately lead to ischemia and bowel wall necrosis. Although spontaneous reduction undoubtedly occurs, the natural history of an intussusception is to progress to a fatal outcome as a result of sepsis unless the condition is recognized and treated appropriately. For many reasons, the morbidity and mortality rates have decreased dramatically at children's hospitals in North America since the mid 1940s.<sup>6</sup>

## Idiopathic (or Primary) Intussusception

The vast majority of cases of intussusception do not have a pathologic lead point and are classified as primary or idiopathic intussusceptions. In idiopathic intussusception, the lead point is generally attributed to hypertrophied Peyer's patches within the ileal wall.<sup>5</sup> Intussusception occurs frequently in the wake of an upper respiratory tract infection or an episode of gastroenteritis, providing an etiology for the enlargement of the lymphoid tissue. Adenoviruses, and to a much lesser extent rotaviruses, have been implicated in up to 50% of cases.<sup>7,8</sup> Most cases of primary intussusception occur in children between the ages of 6 to 36 months of age when there is a high susceptibility to these viruses. Other contributing evidence that viruses might play a role in idiopathic intussusception includes the rise in cases during seasonal respiratory viral illnesses and the documented increase in the incidence of intussusception associated with previous rotaviral immunization.<sup>9</sup> The most recent immunization, Rotashield, has not been associated with a similar increase in intussusception.<sup>10-12</sup>

## Secondary Intussusception

An intussusception may have an identifiable lesion that serves as a lead point, drawing the proximal bowel into the distal bowel by peristaltic activity. These anatomic lead points tend to increase in proportion to age, especially after 2 years of age.<sup>5,13,14</sup> The incidence of a definite anatomic lead point ranges from 1.5% to 12%.<sup>6,12,13</sup> The most common pathologic lead point is a Meckel's diverticulum followed by polyps and duplications (see Fig. 41-6). Other benign lead points are the appendix, hamangiomas, carcinoid tumors, foreign bodies, ectopic pancreas or gastric mucosa, hamartomas from Peutz-Jeghers syndrome (Fig. 39-1), and lipomas. Malignant causes, which are very rare, include lymphomas, lymphosarcomas, small bowel tumors, and melanomas.<sup>15</sup> The occurrence of malignant lesions increases with age. Small bowel

**Figure 39-1.** A, Operative view of the outside of the jejunum shows a palpable mass as the lead point of a reduced intussusception. B, A hamartomatous polyp is characteristic of Peutz-Jeghers syndrome. C, Mucocutaneous macular lesions are seen in this patient with Peutz-Jeghers syndrome. Note extension of the pigmentation beyond the vermillion border.

intussusceptions related to gastrojejunostomy tubes also have been described.<sup>16</sup>

Various systemic diseases, such as Henoch-Schönlein purpura and cystic fibrosis, may also be complicated by intussusception. The majority of abdominal complaints in Henoch-Schönlein purpura are due to vasculitis in the gastrointestinal tract. However, submucosal hemorrhages within the bowel wall can function as lead points in Henoch-Schönlein purpura and cause similar abdominal complaints. Patients with cystic fibrosis are prone to intussusception due to the inspissated secretions and thick fecal matter in the intestinal lumen. This thick, tenacious stool acts as a lead point to produce repeated intussusceptions, more typically seen in children aged 9 to 12 years.<sup>5</sup> Other rare diseases associated with intussusception are celiac disease and *Clostridium difficile* colitis.<sup>17</sup>

## INCIDENCE

Idiopathic intussusception can occur at any age. However, the greatest incidence occurs in infants between ages 5 and 10 months.<sup>18</sup> The incidence of intussusception is highest in the first and second years of life and is uncommon below 3 months of age and after 3 years of life. The condition has been described in premature infants and has been postulated as the cause of small bowel atresia in some cases.<sup>19</sup> Most patients are well-nourished, healthy infants. Approximately two thirds are male.<sup>5</sup>

## CLINICAL PRESENTATION

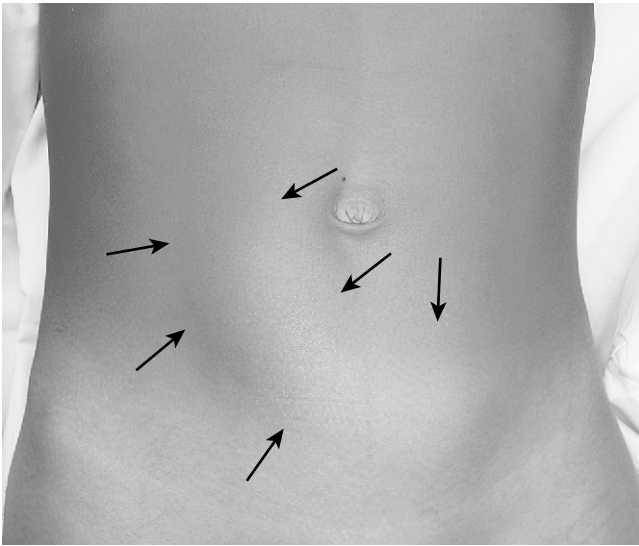

The classic presentation of intussusception is a young child with intermittent, crampy abdominal pain associated with “currant jelly” stools and a palpable mass on physical examination, although this triad is seen in less than a fourth of children.<sup>20</sup> The abdominal pain is sudden in onset in a child who was previously comfortable. The child may stiffen and pull the legs up to the abdomen. Hyperextension, writhing, and breath holding may be followed by vomiting. The attack often ceases as suddenly as it started. Between

attacks, the child may appear comfortable or may fall asleep. After some time, the child becomes lethargic between episodes of pain. The symptoms are associated with anorexia and dehydration. Small or normal bowel movements may result initially from the straining as the colon evacuates distal to the obstruction. As the obstruction worsens, the child will have bilious emesis and worsening abdominal distention. Later in the course, the stools may be tinged with blood. The progression of bowel ischemia, sloughing of mucosa, and compression of the mucous glands within the intussusceptum leads to the evacuation of dark, red mucoid clots or “currant jelly” stools. The latter is often a late sign. A diagnostic pitfall is to wait for this sign to occur.

## PHYSICAL EXAMINATION

The child’s vital signs are usually normal early in the course of the disease. During painless intervals, the child might look comfortable and the physical examination will be unremarkable. Based on the benign clinical appearance, this may lead to an erroneous diagnosis of constipation or gastroenteritis. However, the cramping episodes usually occur every 15 to 30 minutes. When the pain occurs, the child may be difficult to examine. There may be audible peristaltic rushes, and a mass might be palpable anywhere in the abdomen or even visualized if the child is relatively thin (Fig. 39-2). The right lower abdominal quadrant may appear flat or empty (Dance’s sign) as the intussuscepted mass is pulled up. The mass is often curved because it is tethered by the blood vessels and mesentery on one side. On rectal examination, blood-stained mucus or blood may be encountered. The longer the duration of symptoms, the more likely the probability of identifying gross or occult blood. Palpation of the intussuscepted mass on bimanual examination is possible but rare.

Prolapse of the intussusceptum through the anus is a grave sign, particularly when the intussusceptum is ischemic. An ileocolic or colocolic intussusception can progress to the rectosigmoid and through the anus. Such a patient would undoubtedly exhibit signs

**Figure 39-2.** This 10-year-old boy has a palpable sausage-shaped mass (arrows) due to an intussusception.

of systemic illness. The greatest danger in a case of prolapse of the intussusceptum is that the examiner will misdiagnose the condition and attempt to reduce what is thought to be a rectal prolapse. Careful physical examination of the intussusceptum through the anus is mandatory to avoid this potentially life-threatening error in diagnosis. This is done by inserting a lubricated tongue blade along the side of the protruding mass before reduction is attempted. If the blade can be inserted more than 1 or 2 cm into the anus alongside of the mass, the diagnosis of intussusception should be considered. Rectal prolapse, while producing discomfort, is not generally accompanied by vomiting or signs of sepsis.

If the obstructive process worsens and bowel ischemia has occurred, dehydration, fever, tachycardia, and hypotension can develop in quick succession as a result of bacteremia and bowel perforation. In the absence of a rapid diagnosis, fluid resuscitation, and operation, a fatal outcome is likely.

## DIAGNOSIS

### Laboratory Studies

Although there are no specific laboratory studies that aid with the specific diagnosis of intussusception, as the process progresses there may be associated electrolyte abnormalities due to dehydration, anemia, and/or leukocytosis.

### Abdominal Radiography

In about half of cases, the diagnosis of intussusception can be suspected on plain flat and upright abdominal radiographs (Fig. 39-3). Suggestive radiographic abnormalities include an abdominal mass, abnormal distribution of gas and fecal contents, sparse large

**Figure 39-3.** Abdominal radiograph showing dilated loops of small bowel in the right lower quadrant and a soft tissue mass density in the vicinity of the transverse colon near the hepatic flexure (arrow).

bowel gas, and air-fluid levels in the presence of bowel obstruction.<sup>21</sup> The “target” sign or “coiled spring” sign denotes a cross-sectional appearance of the invaginated mesentery and bowel into the intussusciens, appearing as concentric lucencies on plain film. The “meniscus” sign is a crescent-shaped lucency in the colon outlining the distal end of the intussusception. However, plain films have limited value in confirming the diagnosis and cannot be used as the sole diagnostic test.<sup>22</sup>

### Ultrasonography

The use of abdominal ultrasound for the evaluation of intussusception was first described in 1977.<sup>23</sup> Since then, many institutions have adopted its use as a screening tool because of the lack of radiation exposure and decreased cost.<sup>24</sup> The intussusception is usually discovered in the right side of the abdomen. A transverse sonographic image of the bowel consists of alternating rings of low and high echogenicity representing the bowel wall and mesenteric fat within the intussusceptum. This characteristic finding has been referred to as a “target” or “doughnut” lesion (Fig. 39-4). The “pseudokidney” sign is seen on a longitudinal section and appears as superimposed hypoechoic and hyperechoic layers (Fig. 39-5). This pattern is similar to a sandwich and represents the edematous walls of the intussusceptum within the intussusciens. Ultrasonography can also guide the therapeutic

**Figure 39-4.** This transverse sonographic image shows the alternating rings of low and high echogenicity due to an intussusception. This finding has been called a “target” sign.

**Figure 39-5.** Sonogram showing the “pseudokidney” sign seen with intussusception on longitudinal section.

reduction of an intussusception by using a 10% meglumine iohalamate enema in a balanced salt solution or using sonographically guided pneumatic pressure.<sup>24,25</sup> Successful reduction results in a smaller “donut,” with an echogenic rim representing the edema of the terminal ileum and ileocecal valve. Equivocal findings using

this modality should mandate a conventional contrast or air enema.<sup>26</sup>

## Computed Tomography and Magnetic Resonance Imaging

Neither computed tomography (CT) nor magnetic resonance imaging (MRI) are routinely used in the evaluation of a patient with intussusception, although either may reveal possible pathologic causes for intussusception, such as a malignancy (i.e., lymphoma). The characteristic finding is a target or doughnut sign (invaginated bowel within the contiguous bowel loop) (Fig. 39-6). Transient small bowel intussusceptions that are discovered on CT or MRI are usually not clinically significant.<sup>27</sup> These “incidental” intussusceptions involve a small segment of bowel with no pathologic lead point. Repeat imaging usually demonstrates resolution of the intussusception. Radiographic or surgical treatment should be based on clinical findings in symptomatic patients.<sup>28</sup> Laparoscopy is an excellent means to evaluate these patients if surgical intervention is needed.

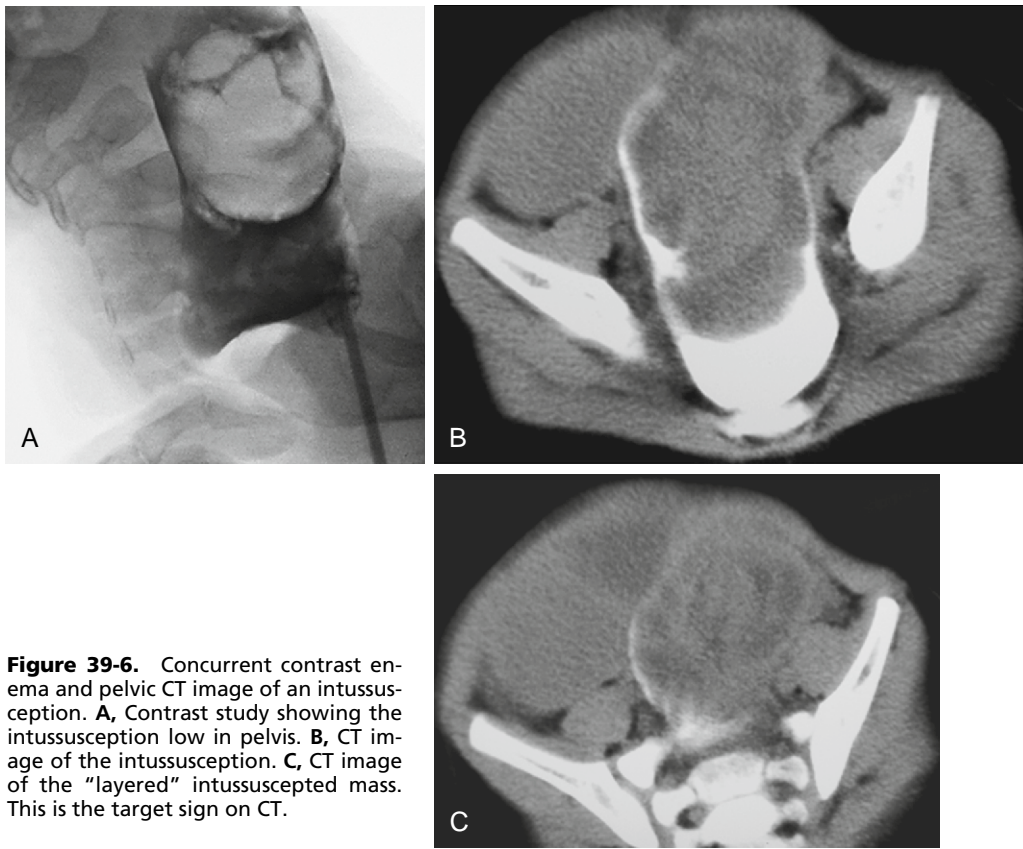

## NONOPERATIVE MANAGEMENT

If the diagnosis of intussusception is suspected, a nasogastric tube may be needed to decompress the stomach. Bowel rest and intravenous fluid resuscitation should be initiated. A complete blood cell count and serum electrolytes are obtained. An air or contrast enema is the study of choice for diagnosis and potential first-line treatment. The complications with hydrostatic or pneumatic reduction are minimal as long as certain guidelines are followed. Absolute contraindications to nonoperative reduction are intestinal perforation (free intra-abdominal air), peritonitis, or persistent hypotension. Findings of peritonitis or bowel perforation warrant surgical exploration.

## Hydrostatic Reduction

The methodology for hydrostatic reduction has not changed significantly since its first description in 1876.<sup>3</sup> Although hydrostatic reduction with barium under fluoroscopic guidance has been the historic method since the mid 1980s,<sup>22</sup> most pediatric centers use water-soluble isotonic contrast because of the potential hazard of barium peritonitis in patients with intestinal perforation.

A large, lubricated catheter is inserted into the rectum, and a seal is attempted by firmly taping the buttocks together. Balloon catheters are avoided by most radiologists owing to the risk of perforation and potential for a closed-loop obstruction. The “rule of threes” is commonly described, consisting of (1) hydrostatic reduction kept at a height of 3 feet above the patient and (2) no more than three attempts, with (3) each attempt no more than 3 minutes each. Under fluoroscopic evaluation, the contrast agent is observed until a concave filling defect is seen (Fig. 39-7). Occasionally, a curvilinear spiral pattern can be seen as the contrast

**Figure 39-6.** Concurrent contrast enema and pelvic CT image of an intussusception. **A**, Contrast study showing the intussusception low in pelvis. **B**, CT image of the intussusception. **C**, CT image of the “layered” intussuscepted mass. This is the target sign on CT.

medium surrounds the intussusceptum. Constant hydrostatic pressure is continued as long as reduction is occurring. Additional attempts can be repeated a second or third time.

Hydrostatic reduction is complete when the contrast medium freely flows through the ileocecal valve into the terminal ileum. Successful reduction in

uncomplicated patients is seen in about 85% of cases and ranges from 42% to 95%.<sup>29</sup> There is less success with long-segment intussusceptions,<sup>30</sup> patients with symptoms for more than 24 hours, and those with pathologic lesions. The advantages of nonoperative over operative reduction are decreased morbidity, cost, and length of hospitalization.

**Figure 39-7.** Fluoroscopic examination using isotonic contrast for hydrostatic reduction of intussusception. **A**, Intussusception (arrow) seen in midtransverse colon. **B**, Reduction has occurred to the hepatic flexure. **C**, Complete reduction with reflux of contrast medium into the terminal ileum. Note the edematous ileocecal valve (arrow).

## Pneumatic Reduction

Air reduction of intussusception was first described in 1897.<sup>31</sup> Pneumatic reduction gained popularity in the late 1980s, owing to the higher rates of successful reduction reported in large international series.<sup>32</sup> Success rates of reduction reported between 1980 and 1991 using hydrostatic techniques were 50% to 78% compared with 75% to 94% between 1986 and 1991 using pneumatic reduction.<sup>5</sup> Advocates of the air enema believe that the method is quicker and safer, is less messy, and decreases the exposure time to radiation.<sup>32</sup> The procedure is fluoroscopically monitored as air is insufflated into the rectum (Fig. 39-8). The maximum safe air pressure is 80 mm Hg for younger infants and 110 to 120 mm Hg for older infants. Carbon dioxide can be used instead of air because of the advantages of rapid reabsorption and less abdominal discomfort. Accurate pressure measurements are possible, and reduction rates are higher than with hydrostatic techniques.<sup>33</sup> Potential drawbacks of pneumatic reduction include the possibility of development of a tension pneumoperitoneum, poor visualization of lead points, and relatively

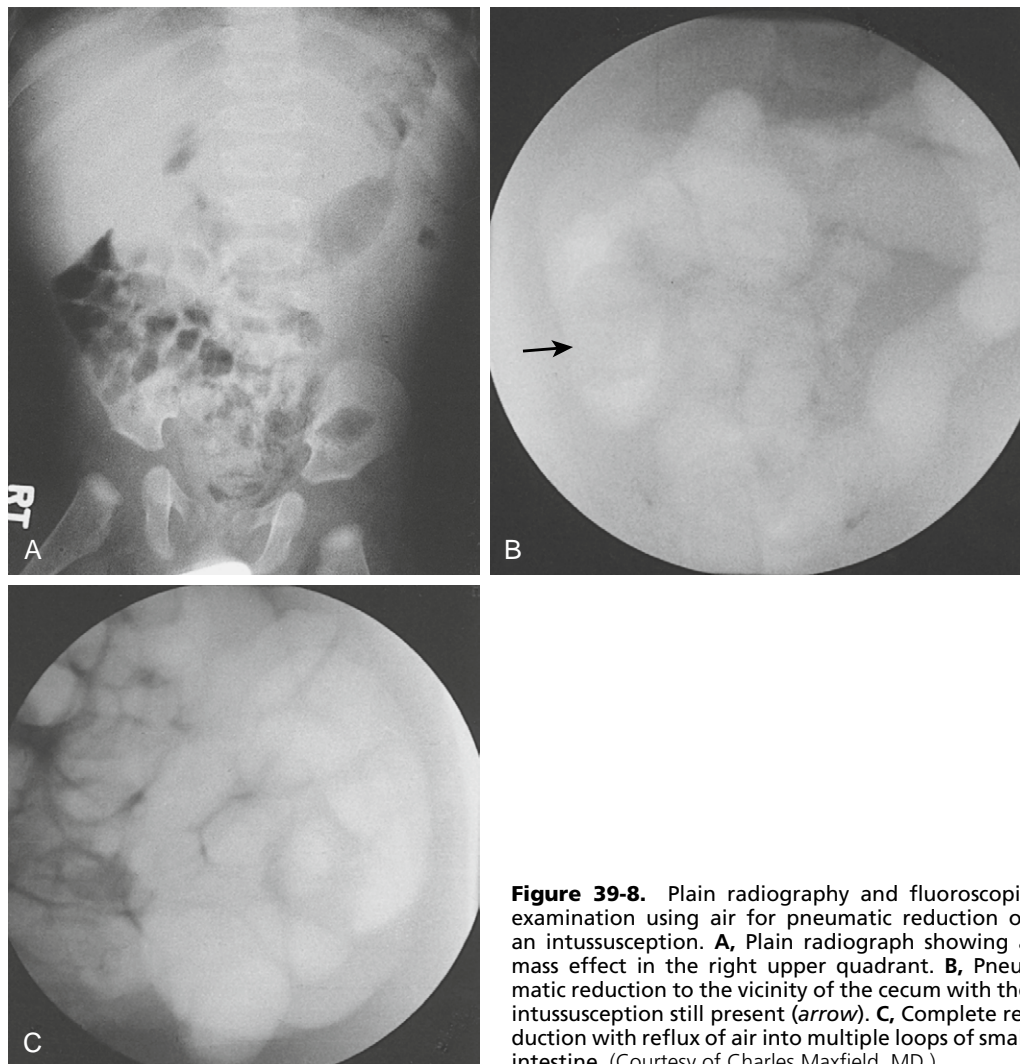

poor visualization of the intussusception and reduction process, resulting in false-positive reductions.<sup>33-35</sup> Rates of perforation range from 0.4% to 2.5%.<sup>36</sup>

Several studies have shown improved reduction rates by a second attempt after waiting between 30 minutes to 24 hours after the initial attempt.<sup>37-39</sup> However, the risks of the increasing radiation burden must be weighed against the risks of emergency surgery and anesthesia.<sup>40</sup> If nonoperative reduction is successful either by hydrostatic or pneumatic technique, the patient should be admitted for observation and should receive a short period of bowel rest and intravenous fluids. Any clinical signs of abdominal pain after reduction could be a sign of ischemic bowel or recurrent intussusception (see later).

## OPERATIVE TREATMENT

### Open Approach

Surgery is indicated when nonoperative reduction is unsuccessful or incomplete (Fig. 39-9), for signs of

**Figure 39-8.** Plain radiography and fluoroscopic examination using air for pneumatic reduction of an intussusception. **A**, Plain radiograph showing a mass effect in the right upper quadrant. **B**, Pneumatic reduction to the vicinity of the cecum with the intussusception still present (arrow). **C**, Complete reduction with reflux of air into multiple loops of small intestine. (Courtesy of Charles Maxfield, MD.)

**Figure 39-9.** Contrast enema view after hydrostatic reduction of an intussusception to the ileocecal junction. A persistent filling defect (arrow) is present without free reflux into the terminal ileum.

peritonitis, for the presence of a pathologic lead point, or for radiographic evidence of pneumoperitoneum. Preoperative preparation includes administration of broad-spectrum antibiotics, intravenous fluid resuscitation, and placement of a nasogastric tube for decompression.

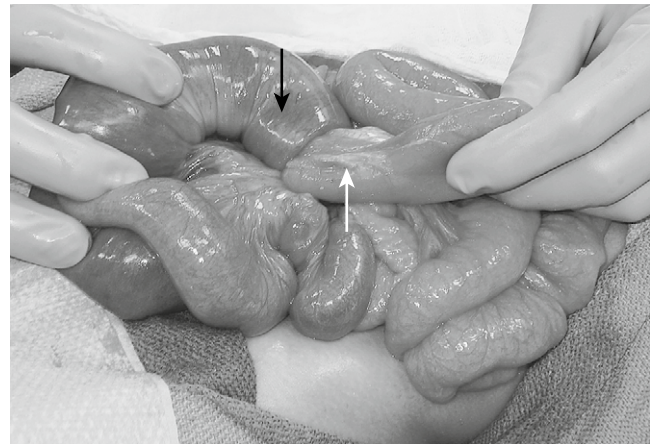

Open exploration of the abdomen and intestines has been traditionally performed through a right lower quadrant incision. Moderate serous ascites may be encountered owing to the obstructive lesion. Usually, the intussusception involves the cecum and terminal ileum, which can be delivered through the incision. Care must be taken to evaluate the extent of the intussusceptum before delivering it, because it can extend into the rectosigmoid region in severe cases. Extension of the incision is often required in such cases.

Once the leading edge of the intussusceptum is identified, it is gently manipulated back toward its normal position in the terminal ileum (Fig. 39-10). Excessive force or pulling is avoided to prevent injury or perforation of the bowel and subsequent contamination. Inability to manually reduce the intussusception, the finding of ischemic bowel, or identification of a pathologic lesion requires surgical resection and bowel anastomosis or diversion, depending on the condition of the bowel and child (see Figs. 39-1 and 39-11).

If surgical reduction is possible, the bowel is then evaluated for viability, perforation, or a pathologic

**Figure 39-10.** A right lower quadrant muscle-splitting incision allows delivery of the intussusception through the incision. Gentle and continuous massage from distal to proximal usually results in reduction of the intussusception.

**Figure 39-11.** This operative view shows an incompletely reduced intussusception with the intussusceptum (white arrow) telescoping into the intussuscipiens (black arrow). A pathologic lead point due to Hodgkin's lymphoma was found.

lead point (especially in children older than 2 years of age). Questionable ischemic bowel can be warmed with saline-soaked laparotomy pads and reevaluated by the coloration of the bowel, peristalsis, presence of Doppler signals, or Wood's lamp evaluation using fluorescein. After complete reduction of the intussusception, an incidental appendectomy is usually performed because the location of the abdominal scar is similar to an open appendectomy incision.

### Laparoscopic Approach

Initially, the use of laparoscopy in intussusception was strictly diagnostic and used in cases with equivocal radiographic studies or those with suspected

**Figure 39-12.** For laparoscopic reduction of an ileocolic intussusception, the small bowel (intussusceptum) is grasped with an atraumatic bowel clamp. It is best to completely grasp across the entire intussusceptum so that the bowel is not torn when attempting to distract it from the colon. A larger clamp (5 vs. 3 mm) is therefore often helpful. The cecum is then pushed away from the small bowel with an intestinal grasping forceps. (From Georgeson KE: Laparoscopic management of ileocolic intussusception. In Holcomb GW, Georgeson KE, Rothenberg SS [eds]: *Atlas of Pediatric Laparoscopy and Thoracoscopy*. Philadelphia, Elsevier Saunders, 2008, pp 71-73.)

pathologic lesions. Once the diagnosis was confirmed, the operation was converted to a laparotomy. Recent small studies have demonstrated laparoscopic reduction of intussusception with variable degrees of success.<sup>41-46</sup>

Various techniques have been reported, but a majority of minimally invasive approaches describe the use of three abdominal ports: one in the infraumbilical region with two other ports along the left side of the abdomen. Laparoscopic reduction is accomplished

by applying gentle pressure distal to the intussusceptum using atraumatic graspers. Although counterintuitive to the conventional open method, traction is usually required proximal to the intussusceptum to complete the reduction (Figs. 39-12 and 39-13). Careful inspection is then performed to evaluate for any signs of ischemia, necrosis, or perforation. If a resection is required, this can sometimes be accomplished by exteriorizing the bowel through the periumbilical incision. If this cannot be accomplished safely, the operation should be converted to an open laparotomy.

## RECURRENT INTUSSUSCEPTION

Recurrent intussusception has been described in 2% to 20% of cases (average about 5%), with about one third occurring within 24 hours and the majority within 6 months of the initial episode.<sup>7,47-49</sup> Recurrences usually have no defined lead point, and they are less likely to occur after surgical reduction or resection. Multiple recurrences can occur in the same patient. Success rates with enema reduction after one recurrence are comparable to those with the first episode and are better if the child did not previously require operative reduction. Patients tend to be seen earlier with recurrent intussusception, and they have fewer symptoms. Irritability and discomfort may be the only clues during the early stage of a recurrence.

An overriding concern in recurrent intussusception is occult malignancy, although multiple recurrences are not a contraindication to attempted radiologic reduction.<sup>48</sup> Unfortunately, the clinical findings or pattern of recurrence do not predict the presence of a pathologic lead point. A careful imaging search is mandatory, and ultrasonography has been recommended as the imaging study of choice.<sup>50</sup> Indications for operation include (1) irreducible recurrence, (2) clinical evidence to suggest a pathologic lead point, (3) documentation of a pathologic lead point by an imaging procedure, or

**Figure 39-13.** A, Ileoileal intussusception remaining after reduction of the ileum from the colon. B, The ileoileal intussusception has been completely reduced. Note the edema and induration in the wall of the small bowel in both photographs. (From Georgeson KE: Laparoscopic management of ileocolic intussusception. In Holcomb GW, Georgeson KE, Rothenberg SS [eds]: *Atlas of Pediatric Laparoscopy and Thoracoscopy*. Philadelphia, Elsevier Saunders, 2008, pp 71-73.)

(4) persistence of clinical symptoms after the completion of the enema.<sup>47</sup>

---

## POSTOPERATIVE INTUSSUSCEPTION

Intussusception accounts for 3% to 10% of cases of postoperative bowel obstruction during childhood and may occur after operations performed for a variety of conditions.<sup>51</sup> Thoracic and abdominal operations have been followed by latent intussusception. Because ileus

and adhesive obstruction more frequently come to mind as a cause for postoperative intestinal obstruction, these intussusceptions may not be diagnosed preoperatively, although ultrasonography has proved to be a successful diagnostic modality.<sup>51</sup> Most postoperative intussusceptions occur within a month of the initial procedure. An interval of about 10 days between initial operation and development of symptoms is average.<sup>52</sup> Most postoperative intussusceptions are ileoileal and respond to operative reduction without resection.<sup>51,52</sup>

# ALIMENTARY TRACT DUPLICATIONS

Scott J. Keckler, MD • George W. Holcomb III, MD, MBA

**A**limentary tract duplications are relatively rare congenital anomalies that may be found anywhere along the gastrointestinal tract from the mouth to the anus. If they are symptomatic, intestinal obstruction or bleeding can occur. Asymptomatic duplications can be discovered incidentally. Most duplications are benign conditions, but ectopic gastric mucosa and rare malignant degeneration remain secondary concerns. The majority of duplications are diagnosed by 2 years of age, but more are being diagnosed in utero with prenatal ultrasonography.

The surgical goal is to remove the duplication and prevent its recurrence. Duplications share a common vascular supply with the native alimentary tract, and simple resection is usually adequate. The management of thoracoabdominal or long tubular abdominal duplications can be challenging. Radical resections are rarely indicated and often not in the patient's best interest. After surgical resection, the prognosis is generally favorable, but the severity of the presenting illness and morbidity and mortality of any associated malformations will factor into the overall outcome.

## HISTORY

The first published report of alimentary tract duplication was by Calder in 1773, who described a duodenal duplication.<sup>1</sup> The first to use the term *duplication* was Reginald Fitz, who applied it to an omphalomesenteric duct remnant.<sup>2</sup> In the ensuing years, multiple terms such as *ileum duplex* and *enterogenous cyst* to describe these anomalies appeared in the literature. William Ladd applied the term *duplication of the alimentary tract* to a series of 10 patients that he described in 1937.<sup>3</sup> In this series, three common findings were noted regardless of location: a well-developed coat of smooth muscle, an epithelial lining, and attachment to the alimentary tract. This nomenclature was supported by the first large series to appear in the literature by Gross and associates in 1952.<sup>4</sup>

## EMBRYOLOGY

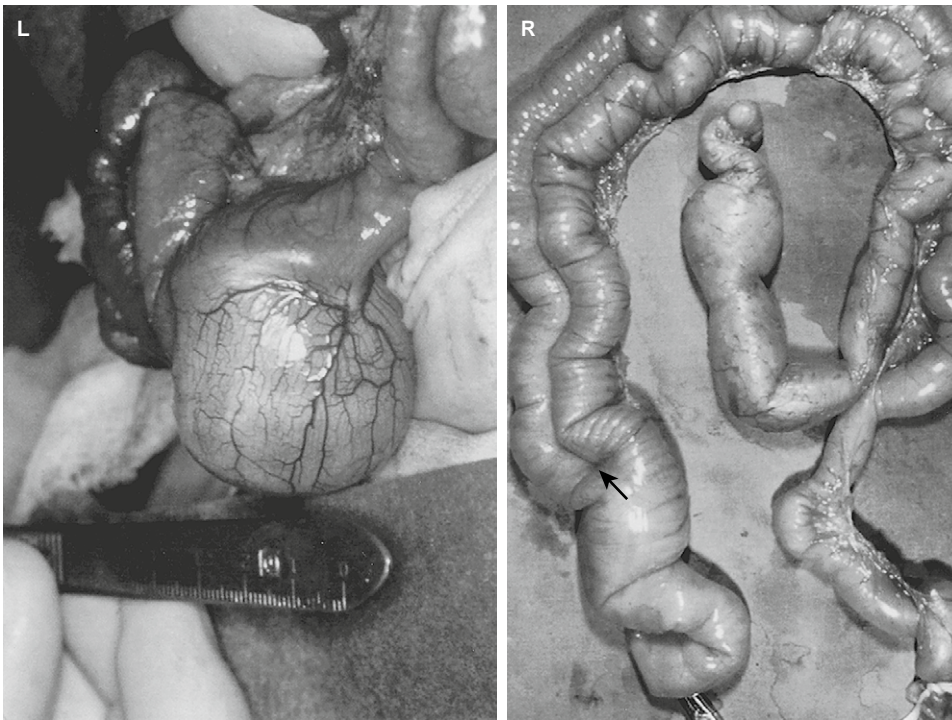

Alimentary tract duplications may be seen at any age but most commonly appear before age 2. Two types are seen: cystic or tubular. The incidence has been reported to be 1 in 4500 births.<sup>5</sup> Duplications are considered congenital malformations because they are thought to arise from disturbances in embryonic development.

Multiple theories have been proposed regarding the etiology of duplications. A persistent embryonic diverticulum from the developing alimentary tract was the first postulated theory.<sup>6</sup> Decades later, it was postulated that duplications resulted from aberrant recanalization of the alimentary tract lumen.<sup>7</sup> Also, the coincidence of colonic and genitourinary tract duplications and similar findings in conjoined twins led to the partial twinning theory.<sup>8,9</sup> The role of hypoxia in the development of fetal defects<sup>10</sup> was also applied to the development of alimentary tract duplications.<sup>11,12</sup> The association of enteric duplications and spinal anomalies led to the "split notochord" theory,<sup>13</sup> and the notochord has been recently shown to be involved in both foregut and hindgut malformations.<sup>14,15</sup>

Alimentary tract duplications are found in association with vertebral, spinal cord, and genitourinary anomalies in 30% to 50% of patients.<sup>4,16</sup> They have also been found in patients with malrotation and intestinal atresias.<sup>17</sup> All these findings suggest a multifactorial process for development and possibly different mechanisms depending on location. To date, no single unifying theory for their development has been described.

## CLINICAL PRESENTATION AND DIAGNOSIS

Alimentary tract duplications do not have a classic presentation but can manifest a variety of symptoms, including abdominal distention and/or pain, vomiting, bleeding, chronic respiratory complaints, or a painless abdominal mass. In general, symptoms are related to

**Figure 40-1.** Left, Most alimentary tract duplications are cystic. Right, A tubular duplication is seen. Note that the native bowel is bifurcated (arrow) into the tubular duplication and native intestine.

location, size, shape, and type of mucosa. The majority of patients (80%) present prior to 2 years of age, with over half (60%) seen before 6 months of age.<sup>17,18</sup> However, duplications may be found at any age from the fetus to the geriatric patient.<sup>19,20</sup> Of the two types, the vast majority are cystic, whereas a small minority are tubular (Fig. 40-1). The most common location is the jejunum/ileum, followed by the esophagus (Table 40-1). Histologically, most duplications are lined by the mucosa native to the lesion, but ectopic tissue is present in 25% to 30% of specimens.<sup>4,17</sup> The most common type of ectopic tissue is gastric followed by both exocrine and endocrine pancreatic tissue (Table 40-2).<sup>21</sup> However, any type of epithelial mucosa can be found. Peptic ulceration causing perforation or hemorrhage may occur in duplications with ectopic gastric mucosa (Fig. 40-2). In children, duplications are considered benign lesions, but malignancy has been detected in adults.<sup>22</sup>

## DIAGNOSIS OF SUSPECTED DUPLICATIONS

A variety of imaging studies are useful to make the diagnosis. Plain radiographs may demonstrate a posterior mediastinal mass, suggesting an esophageal duplication. Contrast studies may reveal a mass effect from the adjacent duplication or communication with the alimentary tract. In cases in which a combined thoracoabdominal duplication is suspected, computed tomography (CT) is beneficial. An enhancing rim of tissue surrounding a fluid-filled cyst is diagnostic of alimentary tract duplications. Ultrasonography is a noninvasive,

radiation-free modality for diagnosis of suspected duplications and is currently the most common imaging study for diagnosing small bowel duplications.<sup>23</sup> The typical sonographic appearance of duplications is an inner hyperechoic rim of mucosal-submucosal tissue and an outer hypoechoic muscular layer (Fig. 40-3).<sup>24</sup> Duplication cysts are being discovered in utero owing to the use of routine prenatal ultrasonography.<sup>25</sup> The presence of ectopic gastric mucosa may be discovered by technetium-99m (<sup>99m</sup>Tc) scintigraphy if there is a history of bleeding or anemia.<sup>26,27</sup> Suspected esophageal duplications with vertebral anomalies should be further investigated. CT myelography may be beneficial but is invasive. Magnetic resonance imaging (MRI) is less invasive but may require sedation or general anesthesia in young children.<sup>28</sup>

## CLASSIFICATION AND TREATMENT BY LOCATION

To better understand the variety of presentations and surgical management of alimentary tract duplications, they will be discussed according to their anatomic location. A compilation of the major case series from 16 institutions in the past 60 years is seen in Table 40-1.<sup>4,12,16-18,29-39</sup> Multiple duplications were found in approximately 8% of patients.

### Oropharyngeal Duplications

Oropharyngeal duplications are rare and account for 1% of all duplications. Most are asymptomatic, but they may present as feeding difficulties.<sup>36</sup> The most

**Figure 40-2.** Most intestinal bleeding from duplications is caused by tubular duplications with communication to the intestine. However, in this case, the bleeding was due to mucosal ulceration (*solid arrow*) secondary to an adjacent cystic duplication. (From Holcomb GW III, Gheissari A, O'Neill JA, et al: Surgical management of alimentary tract duplications. *Ann Surg* 209:167-174, 1989.)

common site is the floor of the mouth, and these duplications frequently contain gastric or colonic mucosa. Treatment involves an oral approach with resection of the cyst and reapproximation of the oral mucosa.<sup>40</sup>

## Esophageal Duplications

Approximately 20% of all duplications are esophageal. They may occur anywhere along the esophagus. Although duplications of the cervical esophagus are reported, the majority occur on the right side of the thoracic esophagus. Most esophageal duplications are cystic and do not share a muscular wall or communicate with the esophageal lumen. Extrinsic compression of the trachea may cause respiratory distress or pneumonia, or an incidental mass may be found on a chest radiograph. In older patients, dysphagia may occur. Esophageal duplication cysts should be in the differential diagnosis of any mediastinal mass. Because approximately half of esophageal duplications contain gastric mucosa, hematemesis or occult anemia may develop. Communication with the spinal column has been described in 20% of these patients.<sup>16</sup> Once suspected on chest radiography or esophagography, further imaging to clarify the anatomic details is usually warranted either with CT or MRI (Fig. 40-4). Because some esophageal duplications extend through the diaphragm, abdominal imaging may be necessary as well. Also, abdominal ultrasonography is a useful screening tool for intestinal duplications because 25% of patients with an esophageal duplication also had an intestinal duplication in the largest study published.<sup>17</sup> Historically, esophageal duplications limited to the thorax were excised through a right thoracotomy. However, owing to the benign nature of duplications, thoracoscopic excision leads to less morbidity and can usually be accomplished without significant complications.<sup>41-43</sup> Some authors have recommended against thoracoscopy if mediastinal

**Figure 40-3.** Ultrasonography is a frequent imaging modality for diagnosing abdominal duplications. **Left,** This ultrasound image shows a cystic mass (*arrow*) in an infant with symptoms of intestinal obstruction. **Right,** The laparoscopic view in this same patient shows a cystic duplication of the ileum.

**Figure 40-4.** This 16-year-old was found to have a posterior mediastinal mass on a chest radiograph. **Left,** CT scan shows the duplication (arrow) to be adjacent to the trachea and the esophagus. **Right,** View of the duplication as seen at thoracoscopy.

shift or lung compression is present,<sup>41</sup> but others have found that thoracoscopy can be performed safely after cyst decompression.<sup>43</sup>

### Thoracoabdominal Duplications

Extension of an esophageal duplication through the diaphragmatic hiatus into the abdomen is known as a thoracoabdominal duplication. These are uncommon and represent 3% of all duplications. The duplication has a variable length of intra-abdominal extension with connections to the stomach, duodenum, pancreas, and jejunum all being reported. Jejunal connections are the most common.<sup>16,17</sup> These duplications are all tubular, and a high percentage have ectopic gastric mucosa. As with isolated esophageal duplications, they may be asymptomatic. Likewise, symptomatic duplications will most often present as dyspnea or dysphagia. Hemorrhage and death from ectopic

gastric mucosa has been described.<sup>29</sup> The two largest series of thoracoabdominal duplications in the literature report an 88% incidence of vertebral anomalies in these patients.<sup>16,17</sup> This high association warrants further workup through either MRI or CT to exclude neuroenteric communication (Fig. 40-5). The current treatment is a one-stage combined thoracoabdominal approach for resection.

### Gastric Duplications

Gastric duplications account for about 8% of all duplications and usually become symptomatic in early childhood.<sup>17</sup> Unlike other duplications, a female predilection is seen.<sup>8,44</sup> Pain, hematemesis, melena, or anemia are the most frequent presenting symptoms. Gastric duplications are most often cystic and located along the greater curvature (Figs. 40-6 and 40-7), although there are reports of duplications along the

**Figure 40-5.** A 3-year-old was found to have a right paravertebral mass. **Left,** A large anterior defect in the vertebral bodies of the upper thoracic spine (arrow) is seen. **Middle,** This myelogram shows the filling defect caused by a neuroenteric cyst. **Right,** The contrast agent from the myelogram is seen in the neuroenteric cyst (upper arrow) with extension subdiaphragmatically (lower arrow) into the distal small intestine. (From Holcomb GW III, Gheissari A, O'Neill JA, et al: Surgical management of alimentary tract duplications. *Ann Surg* 209:167-174, 1989.)

**Figure 40-6.** A, This patient had nonbilious emesis and was found to have a mass effect on the antrum with extrinsic compression of the second portion of the duodenum on this contrast study. B, A gastric duplication (arrow) was found emanating from the inferior aspect of the greater curvature of the gastric antrum at operation. It was thought best to marsupialize the duplication, because a significant partial gastrectomy would be required to remove this lesion completely. C, The duplication has been marsupialized, and the mucosa (arrow) of the duplication lying on the common wall with the stomach is seen. D, The mucosa has been stripped, leaving intact the common wall between the duplication and the gastric antrum. (From Holcomb GW III, Gheissari A, O'Neill JA, et al: Surgical management of alimentary tract duplications. *Ann Surg* 209:167-174, 1989.)

**Figure 40-7.** A neonate was found to have pyloric atresia and underwent laparoscopic correction. At laparoscopy, a large gastric duplication (asterisk) was seen emanating from the greater curvature of the stomach. The duplication was excised and the greater curvature closed. The patient recovered uneventfully and did not develop any postoperative problems.

lesser curvature and the pylorus. Although the majority do not communicate with the lumen, if intraluminal communication is present, peptic ulceration with hemorrhage or perforation can occur.

Diagnostic evaluation is directed toward symptoms, with abdominal ultrasonography as the initial study.

Typically, the ultrasound image shows a duplication and differentiates it from pyloric stenosis.<sup>24</sup> Pancreatic pseudocysts or a choledochal cyst may be confused with a gastric duplication. Abdominal CT scan or an upper gastrointestinal series may be needed to further delineate the anatomy. All gastric duplications regardless of symptoms should be excised to prevent future gastrointestinal bleeding. Excision without violating the lumen is the preferred approach, but large or complex duplications may require partial gastrectomy. If this type of resection is considered too radical, then mucosal stripping of the common wall will prevent subsequent ulceration (see Fig. 40-6).<sup>17</sup> Adenocarcinoma has been reported in an adult with a gastric duplication.<sup>22</sup>

### Duodenal Duplications

Like gastric duplications, duodenal duplications are uncommon and account for about 6% of reported duplications.<sup>17</sup> Partial intestinal obstruction with emesis or gastrointestinal bleeding can be seen, but these lesions may also be asymptomatic. The presence of ectopic gastric mucosa has been reported at 13%.<sup>45</sup> Most duplications on the mesenteric side are found in the first or second portion of the duodenum. The majority are cystic, but tubular variants are occasionally seen.<sup>46</sup> The anatomic location of these duplications may obstruct the biliopancreatic ducts, causing jaundice or pancreatitis.

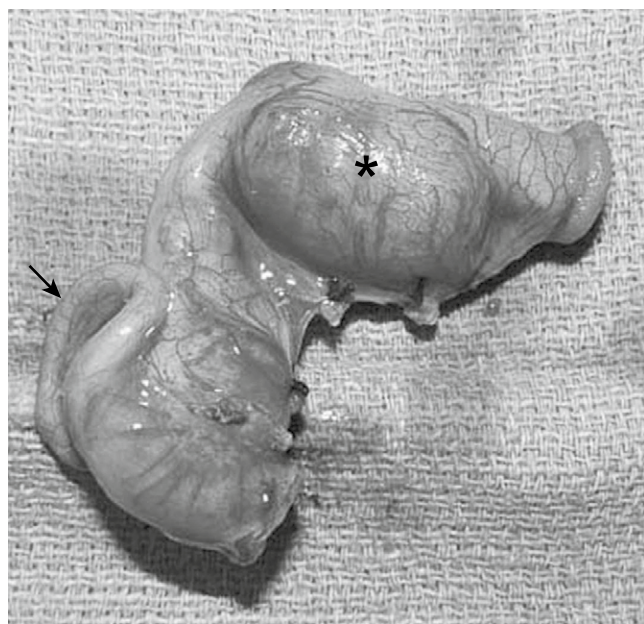

Abdominal ultrasonography or CT is the preferred imaging modality for these lesions. The location of duodenal duplications and their tenuous blood supply dictate the operative plan. Simple excision is preferred as long as the blood supply to the duodenum can be maintained. The intimate relationship to the biliopancreatic ducts may necessitate a Roux-en Y cystojejunostomy to preserve the blood supply.<sup>47</sup> If the duplication is large and contains gastric mucosa on frozen section, duodenal resection may be necessary to decrease the risk of future gastrointestinal hemorrhage.

### Pancreatic Duplications

The rarest form of alimentary tract duplications are pancreatic, with only 43 reported in the literature.<sup>48</sup> The most common presentation is abdominal pain (67%), followed by nausea/vomiting and a palpable abdominal mass. The radiologic workup is similar to gastric and duodenal duplications, with pancreatic duplications often mistaken for a pancreatic pseudocyst. Anatomically, the pancreatic head is the most common location (51%), with the remainder equally distributed in the body and tail. At operation, the presence of a smooth muscle lining on frozen section will distinguish pancreatic duplications from pseudocysts. Treatment ranges from cystectomy to more complex procedures, including cystojejunostomy, pancreaticoduodenectomy, or partial pancreatectomy, depending on the location.<sup>48</sup>

### Small Bowel Duplications

Small bowel duplications account for almost half of all reported duplications. They may be cystic or tubular, with the majority being cystic (Fig. 40-8).

**Figure 40-8.** This small bowel duplication (*asterisk*) was located in the terminal ileum and required removal of the terminal ileum as well as the cecum. Note the appendix (*arrow*) attached to the cecum. A primary anastomosis was performed.

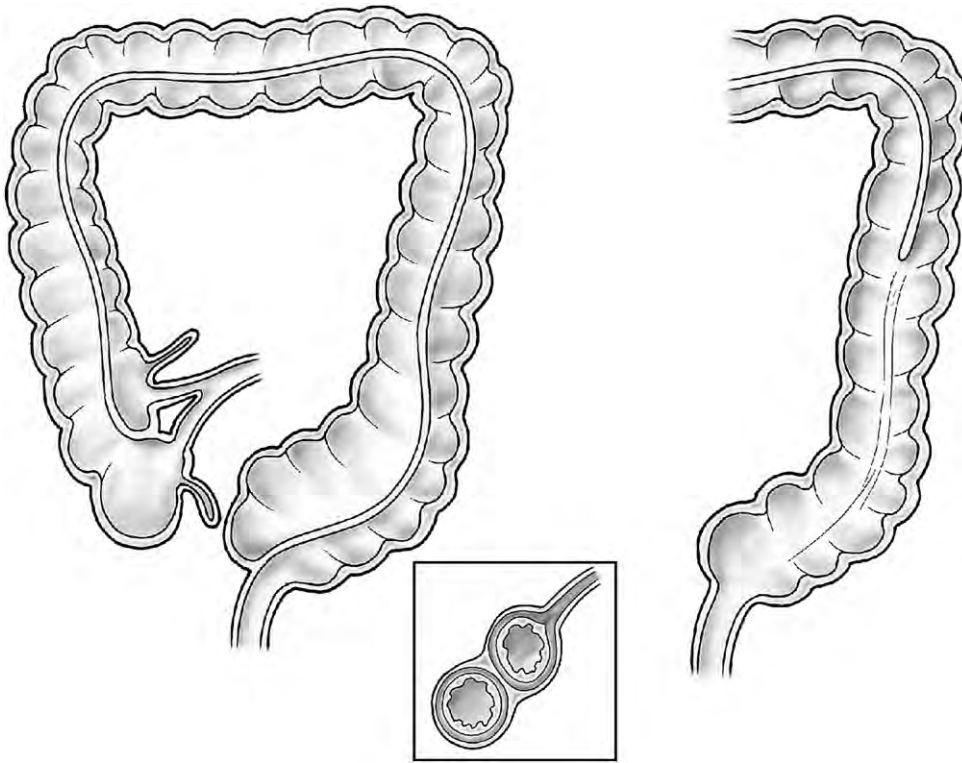

Tubular duplications vary in size from a few centimeters to the entire length of the bowel (Fig. 40-9). Small bowel duplications may be separate from the native bowel or share a common wall. They arise from the mesenteric side of the bowel and share a common blood supply. The most common location is the ileum (34%).<sup>16-18</sup>

Small bowel duplications are frequently seen in early childhood secondary to emesis, hematochezia, melena, anemia, or a palpable abdominal mass. The duplication may lead to volvulus, which is sometimes seen in neonates. In older children, intussusception is more common, with the duplication acting as the lead point.<sup>17</sup> Abdominal ultrasonography is usually the initial imaging study to evaluate these lesions. The presence of ectopic gastric mucosa is seen in 80% of tubular and 20% of cystic duplications.<sup>39</sup> This ectopic gastric mucosa may lead to ulceration and gastrointestinal bleeding or perforation. Also, such duplications can be mistaken for a Meckel's diverticulum on technetium scanning. Small bowel follow-through or CT scans are probably less helpful and lead to unnecessary radiation exposure. Recently, laparoscopy has been advocated for both diagnosis in uncertain cases as well as treatment, thereby eliminating open exploration and decreasing the length of postoperative hospitalization (see Fig. 40-3).<sup>39,49</sup>

Surgical management of small bowel duplications will vary because of the heterogeneity of these malformations. Small bowel resection with primary anastomosis is the usual approach. Infrequently, small cystic duplications can be treated with enucleation without sacrificing the native blood supply. Long tubular duplications may be more difficult to manage because of the intimate blood supply to the native bowel. Resections of large lengths of bowel will increase complications and can pose the risk of short gut syndrome. In this situation, mucosal stripping, sometimes through multiple enterotomies, will preserve bowel length and decrease the chance of ulceration and hemorrhage from the ectopic gastric mucosa.<sup>50</sup> Another approach is to anastomose the tubular duplication containing gastric mucosa to the stomach, allowing the gastric acid to drain and preserving bowel length.<sup>51</sup>

### Colonic Duplications

Colonic duplications account for approximately 15% of all duplications. Most occur in the cecum and are cystic. However, tubular duplications can also be found and will vary in length and complexity (see Fig. 40-9). Sometimes multiple tubular duplications are seen. Colonic duplications are found along the mesenteric border of the bowel. Large bowel obstruction secondary to compression, intussusception, and volvulus are the usual presenting symptoms. Because colonic duplications usually do not contain ectopic gastric mucosa, gastrointestinal bleeding is rare. However, a higher number of associated anomalies are present in patients with tubular colonic duplications. With total colonic tubular duplications, other duplicate structures such as bladder, vagina, and external genitalia are described,

**Figure 40-9.** Ileal and colonic tubular duplications vary in length and complexity. **Left,** The terminal ileum is seen to bifurcate into native colon and duplicated colon, which is medial to the native colon. In this scenario the duplicated colon ends blindly in the upper rectum. **Right,** In this drawing, the duplicated colon communicates with the native colon and forms a common descending colon.

supporting the partial twinning theory of embryogenesis.<sup>52,53</sup> The wide variety of tubular colonic duplications and associated anomalies has led some to state that no two are alike.<sup>54</sup> To better categorize tubular colonic duplications, a classification system has been described. Type I colonic duplications are limited to the alimentary tract, whereas type II duplications are associated with genital or urinary tract duplications.<sup>55</sup>

With colonic duplications, plain radiographs are usually nonspecific. Other studies including ultrasonography, CT, or contrast enema are usually ordered based on symptoms. A contrast enema may demonstrate a duplication and communication with the native colonic lumen, if present. Sometimes, colonic duplications are discovered at exploration for other reasons.

The treatment of colonic duplications will vary depending on the type and extent. Cystic duplications are managed with resection and anastomosis. Small cystic duplications can sometimes be enucleated. Tubular duplications are usually more challenging. For symptomatic tubular duplications, resection is preferred, if possible. If resection is considered too aggressive, a distal communication between the duplication and native colon can be created to relieve the obstruction. For large tubular duplications that are

asymptomatic and with a distal communication, conservative management with stool softeners is appropriate. Although rare, carcinoma has been reported in adults with both cystic and tubular colonic duplications, but this has not been reported in duplications with a distal colonic communication.<sup>22,56,57</sup> Because colonic duplications rarely contain ectopic gastric tissue, mucosal excision is usually not needed. Resection of a fistula tract to the bladder or uterus should be performed.

## Rectal Duplications

Rectal duplications account for approximately 6% of all duplications and are commonly found in the presacral space, posterior to the rectum (Fig. 40-10). A perirectal abscess may develop if a perineal fistula is present. Chronic constipation is commonly found in patients with rectal duplications because of the posterior mass effect. Digital rectal examination may be used to identify this presacral mass. Treatment will vary from marsupialization through a transanal approach, division of the septum between the duplication and rectum, or excision using a posterior sagittal approach. An initial colostomy may be needed in some patients.

**Figure 40-10.** **Left,** Radiograph of a neonate with abdominal distention and evidence of a pelvic mass. On rectal examination, a mass was palpable posterior to the rectum. **Middle,** A contrast study in which an 8-Fr Foley catheter was introduced into the rectum, and the balloon was inflated with air (*solid arrow*). Posterior to the rectum and compressing it is a rectal duplication with air (*dotted arrow*), indicating communication to the gastrointestinal tract. A colostomy was initially performed because of the rectal obstruction. **Right,** A barium enema was performed at age 6 months in this patient. On this lateral radiograph, filling of the posterior rectal mass is seen (*arrow*). (From Holcomb GW III, Gheissari A, O'Neill JA, et al: Surgical management of alimentary tract duplications. *Ann Surg* 209:167-174, 1989.)

# MECKEL'S DIVERTICULUM

Kurt P. Schropp, MD • Carissa L. Garey, MD

**M**eckel's diverticulum was first described by its namesake, the German anatomist Johann Meckel, in 1809. It is the most common congenital anomaly of the gastrointestinal tract and is a remnant of the vitelline (omphalomesenteric) duct. In utero, the vitelline duct connects the fetal gut to the yolk sac. The duct usually involutes during the fifth to sixth weeks of gestation. When the portion of the vitelline duct that is on the antimesenteric border of the ileum fails to regress, it forms a true diverticulum (Fig. 41-1). Its persistence may be present in a number of anatomic variations. These anomalies may be asymptomatic or the cause of a number of complications.

Although this malformation has been known for many years, controversies still persist, such as the best method for diagnosing a bleeding diverticulum and the proper treatment of an incidentally discovered malformation.

## INCIDENCE

Because the majority of patients who have a Meckel's diverticulum are asymptomatic, its true incidence is unknown. Most studies report the incidence to be around 2% of the general population, with an increased incidence in patients with certain congenital anomalies of the umbilicus (patent vitelline duct, omphalocele), alimentary tract, central nervous system, and cardiovascular system.<sup>1</sup> Overall, about 4% of patients with a Meckel's diverticulum become symptomatic, meaning that about 8 in 10,000 people will manifest complications.<sup>2</sup> The male-to-female complication rate ratio is about 3:1, and 50% to 60% of all cases of a symptomatic Meckel's diverticulum are discovered in the first 2 years of life.<sup>3</sup> Only about 15% of children initially seen with a symptomatic Meckel's diverticulum are older than 4 years of age.<sup>4</sup>

Heterotopic tissue is the cause of most of the complications, consisting mostly of gastric mucosa but less commonly of pancreatic, jejunal, or colonic tissue.<sup>3</sup> Symptomatic Meckel's diverticula have a 10-fold increased incidence of heterotopic tissue, but it

is estimated that only 50% to 60% of patients with ectopic tissue become symptomatic.<sup>5</sup>

## PATHOPHYSIOLOGY

A wide spectrum of omphalomesenteric abnormalities may be present, depending on the degree of involution of the vitelline duct (Fig. 41-2).<sup>6</sup> Anatomically, the classic description is that the Meckel's diverticulum is found on the antimesenteric border of the ileum 2 feet proximal to the ileocecal valve, 2 cm in diameter, 2 inches in length, and not attached to the abdominal wall. Bleeding secondary to heterotopic tissue is the most common complication. Occasionally, heterotopic tissue can act as a lead point for an intussusception, resulting in a bowel obstruction. Also, intestinal obstruction may be caused by a Meckel's diverticulum that is attached to the umbilicus by a mesodiverticular band. This may lead to a volvulus around the band and may be difficult to diagnose because the patient usually will not have undergone any previous abdominal

**Figure 41-1.** This laparoscopic view shows a long Meckel's diverticulum emanating from the antimesenteric border of the ileum. This is a true diverticulum and contains ectopic mucosa at the tip of the diverticulum (arrow).

**Figure 41-2.** A to F, Drawings illustrating Meckel's diverticulum and other remnants of the yolk sac. (From Moore KL: *The Developing Human*. Philadelphia, WB Saunders, 1988.)

operations and adhesive bowel obstruction is not high on the differential diagnosis. Similarly, a persistent vitelline artery, which is an end artery from the superior mesenteric artery, may cause obstruction and/or volvulus. Often this will cause a fibrous band from the base of the mesentery across the ileum and onto the diverticulum.

Because of the association of *Helicobacter pylori* and gastroduodenal ulceration, it had been suggested that the gastritis and ulceration/bleeding of Meckel's diverticula may be due to colonization with *H. pylori*. Eradicating the *H. pylori* potentially would decrease the bleeding associated with ectopic gastric tissue. Recently, however, studies have shown a very low colonization rate with *H. pylori* in children with Meckel's diverticulum.<sup>7,8</sup> These studies also concluded that the majority of symptomatic Meckel's diverticula do not have colonization. Therefore, *H. pylori* may incidentally colonize a Meckel's diverticulum and most likely has a minor role in pathophysiology.<sup>9</sup>

In a recent report about an asymptomatic Meckel's diverticulum in a patient with Beckwith-Wiedemann syndrome, nesidioblastosis was found in ectopic pancreatic tissue.<sup>10</sup> Moreover, being composed mostly of small bowel mucosa, the Meckel's diverticulum also may contain a wide variety of tumors, such as carcinoid, leiomyoma, gastrointestinal stromal tumor, angioma, and neurofibroma, which are often found incidentally but may be the cause of serious complications.

## CLINICAL PRESENTATION

The clinical presentation in symptomatic patients with a Meckel's diverticulum is quite varied and dependent on the configuration of the Meckel's diverticulum and whether it has ectopic tissue. The three main forms of

presentation are hemorrhage (40%-60%), obstruction (25%), and diverticulitis (10%-20%).<sup>3</sup> The classic presentation of a child with a bleeding Meckel's diverticulum is a preschool patient with painless rectal bleeding. This may consist of dark, tarry stools or red, gross blood if bleeding is heavy. The hemorrhage is episodic and usually ceases without treatment. Rarely will a child need immediate operation to control the bleeding. Sometimes the hemorrhage is insidious and not appreciated by the family. A young child with hemoglobin-positive stools and a chronic iron deficiency anemia must be investigated for a bleeding Meckel's diverticulum. The hemorrhage is often at the junction of the gastric and ileal mucosa. Hemorrhage can also originate on the mesenteric border of the ileum, especially with a short, wide-based diverticulum.

Patients seen with obstruction secondary to an intussusception usually have classic signs and symptoms of an idiopathic intussusception, including crampy abdominal pain, progressing to bilious vomiting and obstipation. They will often have currant-jelly stools. Patients with artery/band obstruction also demonstrate bilious vomiting and abdominal distention but may be in extremis if volvulus and ischemia develop. As mentioned earlier, the intussusception or obstruction is often diagnosed preoperatively but a Meckel's diverticulum is usually not the cause.

Patients with diverticulitis often have symptoms that resemble appendicitis. Periumbilical pain is usually the first presenting symptom. They usually do not have the same amount and intensity of nausea and vomiting as do children with appendicitis. Moreover, their point of maximal tenderness may migrate across the abdomen as the child moves. Many of these children have been previously hospitalized with similar symptoms but did not undergo exploration because the diagnosis of a Meckel's diverticulum was not entertained.

**Figure 41-3.** This neonate was born with an obvious patent omphalomesenteric duct. **A**, Meconium was seen to emanate from the stoma. **B**, A circumumbilical incision was made, and the duct (arrow) was dissected to its connection with the ileum. **C**, The duct was amputated from the ileum and the umbilical incision closed. The patient recovered uneventfully and has not developed any further problems.

Finally, a Meckel's diverticulum may be found in a number of less common, unusual presentations. A neonate can be found with an obvious patent vitelline duct (Fig. 41-3). Littre's hernia is an inguinal hernia with an incarcerated Meckel's diverticulum. It also can be incarcerated in a spigelian hernia,<sup>11</sup> be a cause of intra-abdominal hemorrhage,<sup>12</sup> or be a cystic mass.<sup>13</sup> Finally, it has been diagnosed in a neonate only 4 hours old.<sup>14</sup>

## DIAGNOSIS

The diagnosis of a symptomatic Meckel's diverticulum is dependent on the anatomic configuration of the diverticulum and its presentation, signs, and symptoms. Routine history and physical examination are probably the most important diagnostic methods. For example, patients with lower gastrointestinal bleeding need a complete description of the quality and frequency of the bloody stools. A nasogastric tube should be placed to help exclude gastric bleeding as the cause. Rectal examination, and occasionally lower endoscopy, is useful in identifying other causes of lower gastrointestinal bleeding, such as polyps and rectal tears. Radiologic examination may be helpful in diagnosing the complications of a Meckel's diverticulum, such as obstruction caused by the Meckel's diverticulum that has formed an intussusception or intestinal inflammation caused by Meckel's diverticulitis. However, of the three most common presentations, a bleeding diverticulum is probably most often diagnosed preoperatively by radiographic procedures.

Technetium-99m (<sup>99m</sup>Tc) pertechnetate scintigraphy of the abdomen is commonly used to help detect ectopic gastric tissue in a Meckel's diverticulum. Unfortunately, ectopic gastric mucosa also may be found in intestinal duplications and in the small bowel separate from a Meckel's diverticulum. The <sup>99m</sup>Tc pertechnetate

is secreted by the tubular gland cells of gastric mucosa. Therefore, any Meckel's diverticulum with ectopic gastric mucosa potentially may be diagnosed with scintigraphy. Unlike many other invasive and noninvasive tests for bleeding, an active hemorrhage is not a prerequisite for a positive diagnosis.

The scintigraphic study is fairly easily performed. If possible, the child should fast for 3 to 4 hours before the scan. Optimally, no barium studies should have been performed in the preceding 24 hours, nor should enemas or laxatives have been utilized. After the injection of the <sup>99m</sup>Tc pertechnetate, the only focal accumulation of tracer should be in the urinary tract or the stomach. A positive study is characterized by a focal tracer uptake that appears simultaneous with the stomach and increases in intensity over time (Fig. 41-4).<sup>15</sup> A number of causes of false-positive results may be found, including intussusception, inflammation of the bowel, intestinal duplication, an abnormal urinary collecting system, a hemangioma, or an arteriovenous malformation. False-negative scans are probably even more problematic. They may result from having only a small amount of gastric mucosa, residual barium from a previous study, or a Meckel's diverticulum that is low in the pelvis and obscured by the bladder.

Controversy exists as to the utility of pharmacologic enhancement of the isotope uptake to increase the accuracy of scintigraphy. The most commonly used medications for this purpose are pentagastrin and histamine-2 (H<sub>2</sub>) blockers. Pentagastrin enhancement works by stimulating acid production by parietal cells. H<sub>2</sub>-blocker enhancement works by decreasing the washout of pertechnetate from the gastric glands, thus enhancing the visualization of the scan. Because no conclusive evidence exists that pharmacologic enhancement clearly increases accuracy, many use these agents only when a study is inconclusive (not clearly positive or negative).

**Figure 41-4.** Technetium-99m pertechnetate scan of a patient with a Meckel's diverticulum. Note the blush (arrow) above the bladder. (Courtesy of Kyo Lee, MD.)

Even though the presence of ectopic gastric mucosa in a patient with a bleeding Meckel's diverticulum approaches 100%, the accuracy of  $^{99m}\text{Tc}$  scanning does not. The specificity of scintigraphy is probably about 95% or higher, but the sensitivity is significantly worse at around 60%. Therefore, a negative scan result does not necessarily exclude a bleeding Meckel's diverticulum. A number of authors advocate laparotomy, or more recently, laparoscopy, to exclude Meckel's diverticulum as the cause of bleeding in a patient with a negative scintigram but a high clinical suspicion of a bleeding Meckel's diverticulum.<sup>16</sup>

Some authors have touted the utility of angiography for a bleeding Meckel's diverticulum if high suspicion exists in the presence of a negative scintigram.<sup>17</sup> One difficulty with angiography, besides being very invasive, is that the ulcer must be actively bleeding for the study to be accurate.

A new, noninvasive diagnostic technique that may aid in the diagnosis of a bleeding Meckel's diverticulum is wireless capsule endoscopy.<sup>18</sup> With this study, the patient swallows a capsule and numerous pictures of the intestine are taken. Obscure gastrointestinal bleeding is the usual indication for this study. Data in the pediatric population are limited, but one study found relevant lesions in 60% of children with obscure bleeding that were not detectable with previous studies.<sup>19</sup> One limitation of this diagnostic tool is that it requires a child to swallow an 11 × 26-mm capsule. There is the option of delivering the capsule by endoscopy, but this makes the study more invasive. Complications such as delayed passage can also occur. A short course of corticosteroids and bowel preparation has been used to aid success in passage. Obstruction is another complication. In one study, 20% had delayed passage of the capsule and two patients had acute small bowel obstruction requiring surgical bowel resection for removal of the capsule.<sup>19</sup> There has been advancement with the recent invention of a capsule that will disintegrate within 40 hours. In conclusion, the current pediatric gastrointestinal community has recommended a role for capsule endoscopy in older children with obscure gastrointestinal bleeding.

The patient with a nonhemorrhaging Meckel's diverticulum will have a low incidence of heterotopic gastric mucosa. In this setting, scintigraphy will not be useful. Patients with obstruction secondary to an intussuscepted Meckel's diverticulum can often be diagnosed with an air enema. On occasion, the air enema will reduce the ileocolic portion of the intussusception and an unrecognized ileoileal component will remain. This component often will not be reducible with the enema. If it does reduce, it will often recur. Ultrasonography remains fairly reliable in skilled hands to diagnose the intussusception. It also may demonstrate an inflamed Meckel's diverticulum. Sometimes a combination of ultrasonography, computed tomography, and contrast enema may aid in the diagnosis of complicated, scintigraphy-negative Meckel's diverticulum.<sup>20</sup>

## TREATMENT

The treatment of a symptomatic Meckel's diverticulum begins with adequate resuscitation. If the patient presents initially with bleeding, adequate resuscitation to an appropriate hemoglobin level should be accomplished before operation.

Resection can be accomplished by either a simple diverticulectomy or by a partial ileal resection. This decision is based on the key principle of resecting all the ectopic tissue. Most authors believe that it is important to resect the ulcer, if present, caused by the gastric secretions. Because most narrow-based lesions have the gastric tissue at the tip, the ulcer is usually in the Meckel's diverticulum itself. A simple diverticulectomy by resecting transversely across the base would be appropriate in this setting. Conversely, some believe that resection of the ulcer is not necessary as long as all the gastric mucosa has been removed. If the diverticulum is wide based, then an increased chance exists the ectopic mucosa could be anywhere in the diverticulum. Therefore, an ileal resection should probably be performed.

For the past decade, most surgeons have advocated laparoscopy as the optimal approach for elective diverticulectomy for a bleeding Meckel's diverticulum. Multiple techniques have been described. The two primary techniques are laparoscopic intracorporeal and laparoscopic-assisted extracorporeal diverticulectomy.<sup>21</sup> The intracorporeal method utilizes an umbilical cannula large enough to allow a stapler (12 mm) and two additional 5-mm cannulas. These smaller cannulas are usually placed in the left upper and left lower abdominal quadrants, similar to port placement for laparoscopic appendectomy. Once the cecum is located, the ileocecal valve is identified and the small bowel can then be inspected in a retrograde fashion until the diverticulum is located. The decision can then be made whether a simple diverticulectomy or ileal resection is warranted. For diverticulectomy, a stapler is used to transect the Meckel's diverticulum at the base. Partial ileal resection can be accomplished intracorporeally by stapling across the ileum on

**Figure 41-5.** **A**, When diagnosed, Meckel's diverticulum can be managed either totally intracorporeally or exteriorized through the umbilical incision. **B** and **C**, The diverticulum and a small segment of the ileum just proximal and distal to the diverticulum were exteriorized through the umbilicus and the diverticulum was excised using the endoscopic stapler. The excision was done in an oblique direction to avoid narrowing the ileum at the site of the diverticulectomy.

either side of the diverticulum and then performing a stapled intracorporeal anastomosis. After removal from the abdomen in an endoscopic bag, the diverticulum should be opened to ensure that the ulcer is resected.

Because this procedure is often needed in infants and small children, adequate working space for endoscopic stapling is limited, and laparoscopic-assisted extracorporeal diverticulectomy is preferred by many surgeons.<sup>22</sup> This method also has the benefit of palpating the Meckel's diverticulum to determine ectopic tissue location, which assists in the decision for an ileal resection.<sup>23</sup> With the extracorporeal approach, a 10- to 12-mm cannula is inserted through an umbilical incision (Fig. 41-5). One additional smaller cannula is then inserted in the left lower quadrant. The Meckel's diverticulum is identified and exteriorized through the umbilical incision. Diverticulectomy or

ileal resection is then performed extracorporeally, and the bowel is then returned to the abdominal cavity.

Because the other presentations of Meckel's diverticulum often are found unexpectedly at operation, the feasibility of resection is determined on a case-by-case basis. For example, if an intussuscepted Meckel's diverticulum can be reduced, it may or may not be wise to staple across the base of the diverticulum, depending on the thickness of the base, the appearance of the intussusceptum itself, its ease of removal, and any damage that occurred because of the intussusception (Fig. 41-6).

Postoperatively, if the procedure is performed laparoscopically with simple diverticulectomy, the child may be fed almost immediately. If an ileal resection is needed, it is best to wait until bowel function returns before feeding is resumed.

**Figure 41-6.** A 4-year-old presented with an irreducible intussusception and required an operative reduction. **A**, Note the small bowel intussuscepted into the large bowel. **B**, After reduction of the ileum, a Meckel's diverticulum was found to be the lead point for the intussusception. **C**, The diverticulum was excised with an endoscopic stapler.

---

## CONTROVERSIES

The major controversy is whether to resect an incidentally discovered Meckel's diverticulum at operation for another indication. In adults, some evidence exists that more morbidity occurs with resection than does the risk that a complication will be found in the future from the diverticulum.<sup>24</sup> Others argue that, because

it is difficult to predict who will become symptomatic and because of the low incidence of surgical morbidity, no contraindication to removal exists.<sup>25</sup> If palpable gastric mucosa is noted in the tip and simple excision is feasible, it seems reasonable that the Meckel's diverticulum should be removed. In young children, because of a life-long potential for complications and the low morbidity with resection, an incidentally encountered Meckel's diverticulum probably should be resected.

# INFLAMMATORY BOWEL DISEASE AND INTESTINAL CANCER

Christopher R. Moir, MD

Children with inflammatory bowel disease (IBD) present with distinct clinical patterns that have important implications for surgical care. The overall incidence of IBD is four to six cases per 100,000 population.<sup>1,2</sup> Pediatric surgeons are becoming more involved because up to one third of patients who develop IBD experience their first symptom in childhood and surgical intervention occurs, on average, 2 years later.<sup>1,3,4</sup> Furthermore, operative treatment is more likely in Crohn's disease (CD), which is now twice as prevalent in children.<sup>5,6</sup>

Surgeons should be aware that up to 65% of children with IBD younger than age 8 present with pancolitis regardless of their eventual diagnosis.<sup>1,4,6</sup> Ulcerative colitis or indeterminate colitis is the most typical diagnosis in children between 3 and 5 years of age whereas CD becomes increasingly more prevalent after age 6, rising to a childhood peak at 15 years.<sup>1,7,8</sup> The diagnostic dilemma of pancolitis in the young child may not be sorted out until the mid-teens when the adult distribution pattern of CD is established.<sup>7,9</sup> To further cloud the situation, boys are now at higher risk than girls for CD by a ratio of 2:1, a reversal of the adult trend.<sup>4,6</sup> The surgeon evaluating a child with colitis must be aware that the disease location may change with age, which ultimately changes the choice of operation.<sup>10</sup>

The classic association of abdominal pain with CD is a less helpful differentiating factor in pediatric IBD. Many children with chronic ulcerative colitis (CUC) present with abdominal pain as the main complaint rather than rectal bleeding. Increased stool frequency and urgency are commonly seen as well.<sup>1,3,11</sup> Growth failure is often associated with CD but also occurs in CUC.<sup>3,12</sup>

A genetic predisposition is found in 12% to 44% of children depending on their age at presentation. The younger the child, the higher is the familial incidence of IBD.<sup>3,11,13</sup> Genetic polymorphism associated with colitis and familial disease is more frequent in pediatric-onset CD. This polymorphism in the NFκβ binding site

of the tumor necrosis factor-alpha (TNF-α) promoter is more strongly associated with colonic disease than ileal or small bowel involvement.<sup>14</sup> The latter is classically associated with *NOD2/CARD15* mutations.<sup>15</sup> These genetic findings may help explain the relatively high prevalence of colonic involvement in young children who have yet to be exposed to major environmental influences. The *NOD2/CARD15* mutations confer a more likely need for operation secondary to stricturing disease in older children and adults with longer exposure to environmental pathogens.<sup>15,16</sup>

## CROHN'S DISEASE

Whereas earlier versions of this textbook chapter started the discussion with CUC, it seems appropriate in this edition to begin with CD because it is the most prevalent form of childhood IBD owing to a marked increase in its incidence. CD affects children in both urban and rural settings and occurs in all minority groups and ethnicities. A child diagnosed with CD has a 78% probability of the need for operation within 20 years.<sup>17</sup> This risk is higher for ileocolic disease (92%). Approximately two thirds of patients with small bowel involvement and slightly less than 60% of patients with colonic disease will require operation. Pediatric surgeons planning the first operation should realize that 50% of their patients will return for another procedure.<sup>17,18</sup>

## Medical Therapy

Even though the incidence of CD is increasing and the probability of operation is a near certainty over time, the need for an early initial operation is decreasing. Improved responses to medical therapy and a general reluctance to proceed with operation in smaller children may explain this change.<sup>9,19</sup> Pediatric patients at higher risk for early surgical intervention include those with anti-*Saccharomyces cerevisiae* antibody (ASCA)-positive

disease, hypoalbuminemia, poor growth velocity, female gender, and stricture disease.<sup>20,21</sup> Interestingly, children with predominantly colonic CD and those on long-term therapy with aminosalicylates are less likely to undergo early operation.<sup>20</sup> In adults, smoking increases the risk for operation,<sup>22</sup> particularly in genetically susceptible individuals. On the other hand, prior appendectomy has been found to have a curiously protective effect.<sup>23</sup>

Enteral nutrition and corticosteroids are the mainstays of medical therapy for children with CD.<sup>24</sup> Nutritional therapy in children may avoid the growth delay and osteoporotic effects of corticosteroids while maintaining a more normal lifestyle and school attendance. With more palatable formulas and good compliance, enteral nutrition is associated with a reduction in inflammatory mediators and healing of CD lesions.<sup>25</sup> The best results have been obtained in the United Kingdom and in some European and Canadian centers. In the United States, enteral nutrition is used less frequently. Patient and physician noncompliance, variable insurer coverage, and frequent relapse are common reasons for a lack of widespread acceptance in the United States.<sup>26</sup>

The success of exclusive enteral nutrition therapy in children differs with the site of disease. Improvement is seen in 80% to 90% of children with primarily ileal or ileocolonic disease versus 50% of children with colitis. These findings may be related to a different genetic phenotype in patients with isolated Crohn's colitis and the interaction with colonic bacteria.<sup>27</sup>

Corticosteroid treatment remains an important induction therapy for children despite the well-known side effects. Milder cases may respond to mesalamine and antibiotics. Budesonide, a topically active corticosteroid with fewer systemic side effects, has also shown efficacy in children with ileocolonic disease. Unfortunately, these alternative therapies are effective for select subgroups only. Available data suggest a limited efficacy of mesalamine and related products in children with active disease and a limited ability to prevent postoperative recurrence.<sup>28</sup> Metronidazole and ciprofloxacin work best for patients presenting with perianal disease and can be useful for maintaining remission after operation as well.<sup>29</sup> Budesonide has been effective in adults who were previously corticosteroid dependent.<sup>30</sup>

Despite high initial response rates to systemic corticosteroids, a recent population-based study reported 58% of children remained corticosteroid dependent or required operation by 1 year. The response rates were similar for colonic and ileocolic disease, whereas small bowel disease was twice as likely to improve.<sup>31</sup> These recent data demonstrate the need for early implementation of second-line treatment strategies for children with CD. For example, early addition of azathioprine or mercaptopurine reduced the need for surgery and produced a 50% prolonged response in one study.<sup>31</sup> Oral tacrolimus also showed promise but did not produce long-term remission in another study.<sup>32</sup> A Danish population-based study of infliximab in children identified 71% with treatment benefit. This therapy was

associated with a 29% long-term response, whereas 42% were infliximab dependent. Twenty-five percent of children had no response. Forty-two percent of the children in this study had Crohn's colitis.<sup>33</sup>

## Indications for Operation

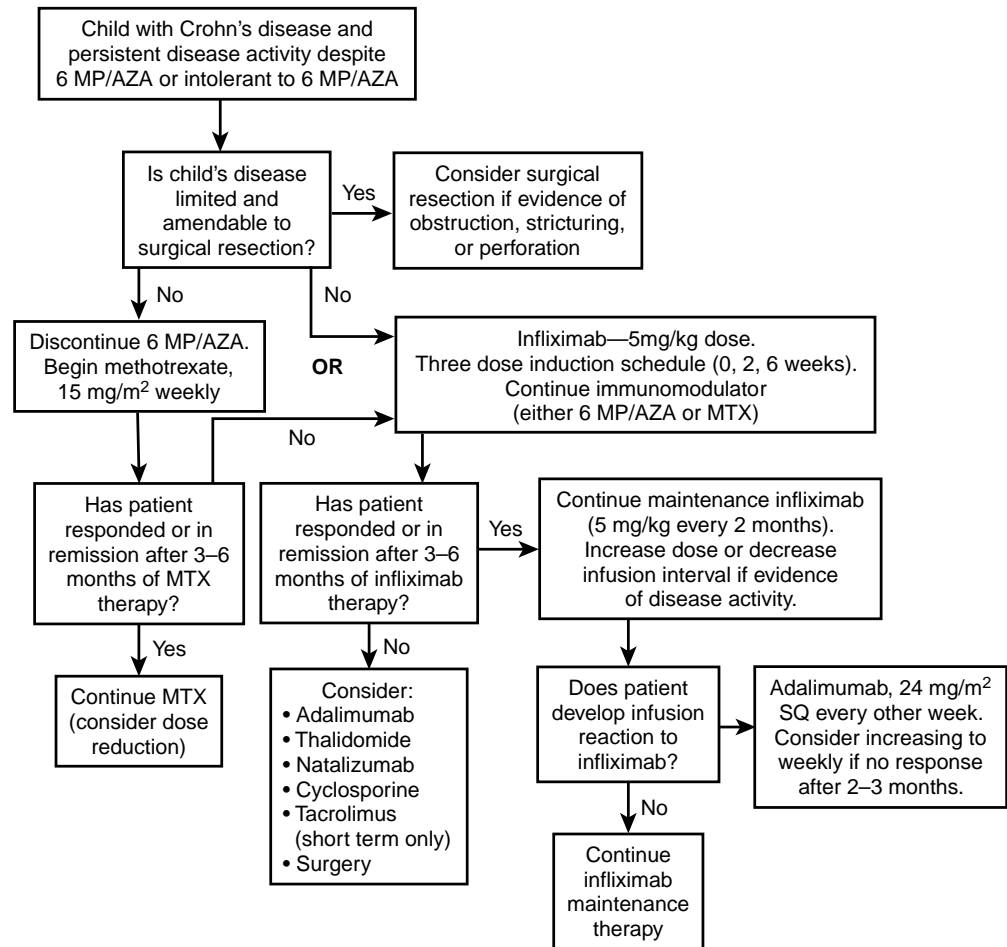

Refractory illness and complications of disease are the most common indications for operation in children with CD.<sup>34</sup> Strictures and local perforation/penetration are most commonly identified in children who present with small bowel and ileocolic disease.<sup>15</sup> Children with colonic CD do not often contract the common complications of abscess, perforation, or obstruction. In these patients, symptomatic disease and growth failure predominate.<sup>20</sup> Colonic strictures are the next most common indication and raise the possible spectre of colorectal carcinoma in patients with long-standing disease.<sup>35</sup>

Nearly 50% of children require their first operation to relieve refractory illness. The decision to operate represents a balance of medical and surgical factors designed to relieve symptoms and reduce treatment toxicity. Operative considerations include the site of disease, ease of resection, and the possibility of needing a stoma. The medical therapy of CD has evolved so rapidly that a treatment algorithm is proposed (Fig. 42-1).<sup>26</sup>

## Choice of Operation

The ability of the surgeon to select an appropriate operation and reduce recurrence risk in children with CD depends on specific patterns of disease. Isolated small bowel and localized ileocecal disease with clear proximal and distal margins present the least difficult surgical decision. Colonic disease is more complex. Children with significant ileal involvement will experience higher reoperation rates after right colectomy due to small bowel and anastomotic recurrence. Similarly, the presence of rectal ulceration portends recurrence and eventual proctocolectomy in patients undergoing an initial left colon or subtotal resection with reanastomosis. Anoperineal disease with rectal involvement is a particularly poor prognostic finding in children with colonic disease and is associated with the highest risk of permanent ileostomy.<sup>36-38</sup> Because most patients will have evidence of some forms of these conditions, operative judgment is very important.

A complete history and physical examination to detect perianal disease and the extent of small bowel and colon involvement is important. Before operation, a contrast study of the small intestine is needed to evaluate for proximal disease (Fig. 42-2). All patients should undergo upper gastrointestinal endoscopy and colonoscopy with ileal intubation and biopsy to determine the extent of ileal involvement. CT enterography and capsule endoscopy have shown promise in selected patients. However, a blinded four-way comparison of these techniques did not identify significant benefits of capsule endoscopy over CT enterography, small bowel follow-through studies, or endoscopy.<sup>39</sup>

**Figure 42-1.** This treatment algorithm for medical therapy for Crohn's disease is utilized at the Mayo Clinic in the child with persistent disease who is either intolerant to mercaptopurine/azathioprine (6MP/AZA) or has persistent disease with these medications. MTX, methotrexate.

The need for operative resection depends on the site of disease and age of the patient. In a population-based study of 1,936 patients in Sweden with 99% follow-up after 14.9 years, children were found to have the lowest incidence of operative therapy when compared with other age groups. Colorectal presentation had the lowest need for operation with a relative risk of 1.0. Small bowel or ileocecal CD had the highest relative risk of 3.2 whereas high intestinal and discontinuous ileal and colonic disease had intermediate surgical risks of 1.7 and

1.8, respectively.<sup>9</sup> The overall incidence of surgical recurrence was 33% at 5 years and 44% at 10 years. Again, small bowel and ileocolonic recurrences were more likely to need operation when compared with isolated colonic disease (1.5 and 1.8 vs. 1.0). Female gender and perianal disease also significantly increased the risk of recurrence in patients with colonic disease. Interestingly, diagnosis and an initial operation at a young age did not increase the risk of recurrence, nor was there a decrease in recurrence in the more recent years of the study.<sup>9</sup>

**Figure 42-2.** A, This upper gastrointestinal and small bowel follow-through contrast study shows a significant stricture (arrows) of the terminal ileum in a patient with persistent and symptomatic Crohn's disease despite medical therapy. B, The laparoscopic view shows active inflammation with creeping fat (arrows) along the terminal ileum in this patient.

**Figure 42-3.** **A**, The port placement for a patient undergoing a laparoscopic ileocolic resection is seen. A 12-mm port is placed in the umbilicus (arrow), and two 5-mm ports are introduced in the left lower abdomen and suprapubic area. **B**, The diseased small bowel has been exteriorized through the umbilicus for an extracorporeal resection and anastomosis. Note the inflamed bowel and creeping fat in the exteriorized portion of the small bowel. **C**, The appearance of the incisions after the laparoscopic ileocolic resection. The intestinal resection and anastomosis was performed extracorporeally through the umbilical incision.

### Ileocecal Resection

Pediatric surgeons most often perform ileocecal resections when operating for CD. This disease pattern is most likely to be associated with clear margins and an excellent disease-free interval. The need for a stoma is not likely, and postoperative complications are less likely than with colonic, pelvic, or long segment disease.

Laparoscopic-assisted surgery obviates the issue of where to make the incision.<sup>40</sup> Repeat laparoscopy is also feasible. The degree of obstruction, the presence of intraperitoneal adhesions, or a retroperitoneal, penetrating mass, along with the persistence of the surgeon, will determine the success of the laparoscopic approach. Intestinal reconstruction is accomplished using either an intracorporeal anastomosis or a laparoscopic-assisted technique with extraction of the bowel through one of the incisions for anastomosis or stricturoplasty (Fig. 42-3). In one small series, the laparoscopic approach resulted in longer recurrence-free intervals.<sup>41</sup> However, given consistent recurrence rates over time, it is possible that concomitant advances in

medical management may have decreased recurrence in the short term.

An important principle of CD surgery is to create a widely patent anastomosis. Patients with ileocolic resections are natural candidates for a stapled side-to-side anastomosis that can be twice as large as the end-to-end technique (Fig. 42-4). Studies of stapled versus hand-sewn anastomoses have shown improved recurrence-free intervals using the stapler.<sup>42,43</sup> A similar technique is now recommended for other small bowel anastomoses. Although such widely patent anastomoses may be expected to reflux colonic contents into the small bowel, whether this colonic reflux has a detrimental effect on growing children is unknown. Caution should be exercised in younger children in whom issues of growth and development are paramount.

### Small Intestine Surgery

Open or laparoscopic segmental resection is the standard approach to limited small intestine disease. The principles are identical to ileocecal resection. However,

**Figure 42-4.** Patients undergoing an ileocolic resection are ideal candidates for a stapled side-to-side anastomosis that can be twice as large as an end-to-end anastomosis. **A**, The mesentery is divided to visually normal bowel. **B**, The normal-appearing proximal ileum is then anastomosed to the normal-appearing ascending colon using a long linear stapler. **C**, The diseased ileocecal region is then resected. A second application of the stapler is utilized, if needed. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

**Figure 42-5.** This schematic depicts a Heineke-Mikulicz strictureplasty for a very short segment of active disease or for fibrotic strictures in a patient with multicentric Crohn's disease. The incision that transverses the stricture (A) is then closed in a vertical direction (B) to enlarge the intestinal lumen.

the opportunity for such procedures is less due to a decreased incidence of this disease pattern and the tendency for small intestinal disease to be multifocal.

Strictureplasty for active disease, as well as for fibrotic strictures, remains an excellent option for patients with multicentric activity. The length of the stricture and the noninflammatory nature of the obstruction are the two strongest factors determining success.<sup>44</sup> Such length-sparing procedures are particularly attractive for children with extensive disease and skip areas.<sup>45</sup> There are no data yet to support the relative contraindication of leaving persistent disease behind in developing children. Adverse effects on growth and the risk of malignancy have not been quantified.<sup>46,47</sup>

The strictureplasty technique resembles a Heineke-Mikulicz pyloroplasty (Fig. 42-5). The procedure is best suited for short fibrotic strictures less than 10 cm in length without surrounding inflammation and adjacent normal bowel.<sup>48</sup> The reoperative rate for strictureplasty approaches 25% and 30% at 5 and 10 years, respectively.<sup>49</sup> A meta-analysis suggests the Finney technique may have a lower recurrence rate.<sup>50</sup>

Most pediatric studies demonstrate improved growth velocity after resection of all disease.<sup>37,38,51</sup> The increased morbidity and recurrence rates of stricturoplasty suggest that selective use for isolated short segments is the best approach.<sup>44</sup>

### Colonic Resection

Because refractory disease is the main operative indication for Crohn's colitis, the decision to operate represents a balance between the effects of ongoing therapy and the consequences of resection. Crohn's colitis represents the highest risk for a permanent ileostomy. The 20-year risk of needing a stoma ranges from 14% to 44%.<sup>19,38</sup> This risk increases in children with significant rectal and perianal inflammation,<sup>37</sup> high pediatric CD activity index scores, and female gender.<sup>36,38,52</sup> On the other hand, a history of long-standing disease before operation may reduce this risk.<sup>20,38</sup> Data from large studies (that include adult patients) indicate that patients with colonic CD without major ileal or rectal involvement may experience similar success with bowel-sparing procedures as patients with isolated small bowel disease.<sup>36,53</sup> Furthermore,

there is insufficient evidence that infliximab or other immunotherapies have reduced the need for permanent stomas. However, these therapies do offer hope for temporary bowel-sparing procedures that may improve the quality of life.

### Segmental Resections

Segmental resections of the colon involve modifications of right and left hemicolectomies with primary reanastomosis. These procedures are ideal for laparoscopic-assisted mobilization, resection, and reanastomosis, depending on the degree of scarring and mesenteric mobility.<sup>54</sup> The affected portion of the colon is mobilized and resected to grossly normal margins. A primary ileocolonic or colocolonic anastomosis is then performed. However, long-term follow-up of children undergoing segmental colonic procedures report high recurrence rates, and a permanent ileostomy rate of 36% to 50%.<sup>55,56</sup> Despite nearly universal recurrence, 60% of pediatric surgeons surveyed in the United Kingdom favored segmental resection over total colectomy.<sup>57</sup> This optimism may be based on recent studies that indicate a trend toward decreased postoperative recurrence and increased salvage rates after colonic resections. Long-lasting remissions are most likely in patients with minimal or no anorectal disease.<sup>36,53,54</sup>

These results are similar to a large study of 84 patients undergoing segmental colonic resection.<sup>33</sup> In that study, with a follow-up of 9 years, 16% had a permanent ileostomy. The risk of colonic recurrence after segmental resection was 20% at 5 years and 35% at 10 years, substantially lower than a similar study from the Mayo Clinic (55%).<sup>58</sup> Of the 26 patients undergoing segmental resections, repeat resections were possible in 17 whereas colectomy with ileorectal anastomosis occurred in 5. The segmental colonic resections included 55% right-sided procedures and 40% left-sided operations and a combination of the two in 5%. The anastomotic leak rate was 7%, which is similar to other reports. Whether the resection margin is positive for disease has no effect on the leak rate or recurrence.<sup>36</sup>

Strictureplasty is not recommended for colonic involvement because of the cancer risk. Stricture

disease is difficult to survey, and biopsy specimens may not be representative.

### **Total Colectomy with Ileorectal Anastomosis**

For children with pancolonic disease, an ileorectal anastomosis is performed primarily or as a staged procedure depending on the indication for operation.<sup>34,51</sup> Emergent colectomy for life-threatening complications such as hemorrhage, sepsis, or perforation precludes immediate reconstruction. When an ileostomy is created, it is wise to leave a generous rectal stump. The bowel is usually divided with a stapler, preserving a portion of the sigmoid colon and rectum when possible. The proximal stapled end of rectum or sigmoid is attached to the anterior fascia for ease of identification 3 to 6 months later. Without significant attachment to the anterior abdominal wall, most stumps will retract well into the pelvis and require additional time for mobilization at the second operation.

When an ileorectal anastomosis is possible, less than 20% of patients with mild to moderate rectal disease progress to completion proctocolectomy.<sup>59</sup> Again, the significance of preexisting rectal or perianal disease is the highest predictor for failure.

There does not appear to be a linear relationship between the severity of disease and failure of the rectum, unless there is a significant lack of distensibility of the rectal wall.<sup>60</sup> Similarly, perianal involvement, if responsive to treatment, does not necessarily predict a poor outcome.<sup>37</sup> Significant ileal disease predicts a higher rate of recurrence, but the rectal failure is more related to the colonic disease rather than the small bowel involvement. Patients are able to undergo re-resection of the small bowel with repeat ileorectal anastomoses to preserve the intestinal tract.<sup>58</sup>

### **Ileal Pouch Anal Anastomosis**

Most patients with chronic CD undergoing an ileal pouch/anal anastomosis (IPAA) were initially misdiagnosed as having CUC or came to operation with the diagnosis of indeterminate colitis. There is a much higher rate of serious complications after this procedure. Families may expect repeat visits for anal dilation or control of perianal disease. Short-term success may not predict long-term outcome. Patients with indeterminate colitis may expect good functional outcome in 73% to 85% of cases compared with 89% for CUC.<sup>61</sup> Known CD patients have a failure rate of at least 45%.<sup>62</sup>

### **Proctocolectomy with End Ileostomy**

Complete removal of the colon and rectum with establishment of an end ileostomy carries the lowest rate of surgical recurrence in patients with Crohn's colitis.<sup>19</sup> Complications requiring surgery still occur at the stoma, but this option remains the best choice for patients with extensive colonic disease that involves the rectum and the anus. Perianal disease portends

a poor outcome for more limited colon resections.<sup>37</sup> Although families understand the prognosis, they may prefer a staged approach without a permanent ileostomy for as long as possible. In centers advocating bowel-sparing procedures, proctocolectomy with end ileostomy is performed as an initial procedure in approximately 20% of patients.<sup>36,53</sup>

Removal of the residual rectal stump via an abdominoperineal approach is reserved for patients with the most resistant disease.<sup>63</sup> Management of the perineal wound can be particularly problematic. A standard intersphincteric proctectomy is performed with a secure water-tight closure of the pelvic floor and placement of vascularized tissue, such as omentum. It is important to separate the remaining small bowel from the pelvic floor to reduce the possibility of perineal fistulas. The perineal wound is closed over a catheter irrigation system placed into the pelvis from the perineum. The catheter is passed through the ischio-rectal fossa and levator musculature to irrigate and drain the pelvis. The technical challenge of such procedures is surpassed only by the difficulty of caring for a nonhealing perineal wound. Multiple return visits for debridement, packing, and curettage may be necessary. Definitive closure with myocutaneous flaps can still have high recurrence rates.

### **Anorectal Disease**

Almost two thirds of patients with CD will develop perianal complications.<sup>64</sup> Most develop within 10 years of intestinal symptom onset, and 25% occur as the first sign of disease.<sup>65</sup> Symptoms are most pronounced in children whose colonic disease is anorectal. These children form a distinct genetic subtype identified on chromosome 5.<sup>66</sup>

The most common conditions are fistula-in-ano, anal fissures, and hypertrophy of the perianal skin.<sup>67</sup> These conditions combine to produce painful lesions that drain, bleed, and develop recurrent abscesses. Anal sphincter spasm complicates their presentation. Ongoing surveillance of symptoms is necessary for the early identification of surgical conditions. Perianal sepsis may progress to severe regional infection, including gangrene. Fortunately, complications are rare, because most interventions are performed in a timely fashion.<sup>68,69</sup>

Should there be a question of more extensive fistulization, magnetic resonance imaging is the investigation of choice. It is a highly sensitive (97%) and specific (100%) tool for detection of fistulas and quantification of surgical success.<sup>70</sup> Magnetic resonance fistulography is superior to endoanal ultrasonography but is more expensive and lacks the advantage of portability. The ultrasound probe can be utilized in the examination room, but the procedure can be quite painful.<sup>71</sup>

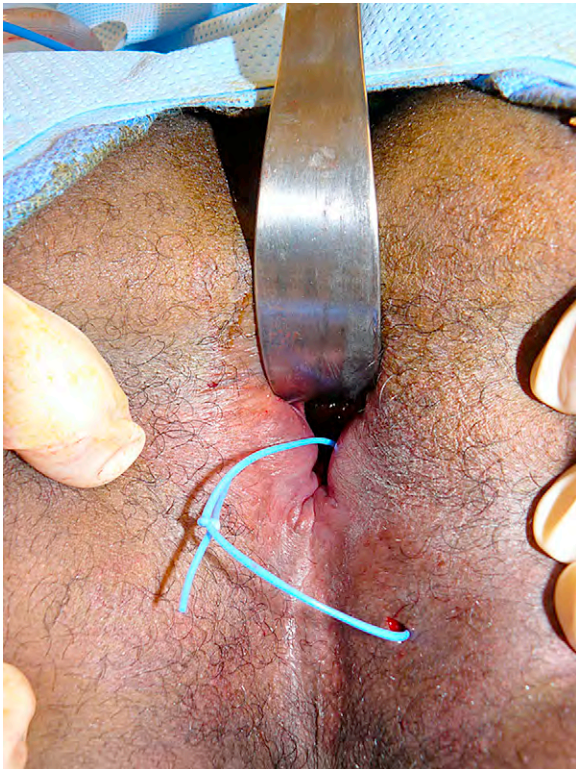

Examination and treatment is best performed under anesthesia. This allows for confirmation of the findings, endoscopy of the distal rectum, and identification of the internal fistulous openings. Drainage of abscesses and surgical debridement of chronic cavities are also important. In teenage girls with CD, a Bartholin cyst

should be diagnosed cautiously. Most vaginal or vulvar masses are the result of perianal fistulization rather than a separate disease process.

After the treatment has been established, local wound care remains an important part of symptom relief. Perianal hygiene with daily wound therapy, including debridement and application of barrier creams and ointments, is effective. Patients may purchase or create specialized cushions for sitting. Bowel management is also helpful for constipation or diarrhea.

A draining seton suture is effective for prevention of abscess and recurrent pain.<sup>67</sup> The goal is to produce a well-established draining tract without obstruction or sepsis. The seton is placed in a noncutting fashion using a soft silicon vessel loop or monofilament suture (Fig. 42-6). With the addition of immune and biologic therapy, the seton suture technique provides excellent control of disease and will lead to healing in most circumstances.<sup>72</sup>

Injection of “fibrin glue” into the remaining fistula tract has also been moderately successful.<sup>73</sup> The internal fistula opening may be sutured closed at the time of “fibrin glue” injection. There should be minimal to no granulation tissue left within the tract. Should a cavity persist, the seton suture technique affords the best chance for healing.

**Figure 42-6.** This teenager with refractory Crohn’s disease developed a perianal abscess that was quite painful. Examination under anesthesia confirmed the fistula and underlying abscess that was drained. A soft, noncutting silicon vessel loop (seton) was then placed. This technique allows excellent control of the perianal disease and leads to healing in most circumstances.

Fistulotomy is the definitive procedure for a persistent anal fistula. Healing occurs in 73% to 81% of patients with low fistulas laid open in the traditional fashion.<sup>68</sup> The risk of incontinence and poor wound healing is high in children with a transsphincteric or complex fistula. If there has been a good response to medical therapy, advancement flaps may be a reasonable consideration. Rectal mucosal flaps preserve continence and provide healing in 64% to 71% of patients with transsphincteric abscesses. In this setting, ileostomy is often required for healing.<sup>67,74</sup>

Rectovaginal fistulas may also be cured with advancement flaps. In one study, healing was successful in 54% of patients.<sup>75</sup> After reoperation, the success rate increased to 60% during follow-up of 5 years. A transvaginal approach is recommended for those with persistent rectal disease. Success rates of 90% may be achieved with this approach in patients with controlled disease.<sup>67</sup> Rectal dissection is also successful when the disease has improved after fecal diversion. Cutaneous advancement flaps for persistent mucosal disease have also been advocated. Under the best of circumstances, a 70% healing rate may be possible.<sup>76</sup>

## Recurrent Crohn’s Disease

Recurrence at the anastomosis is a feature of the disease process rather than the presence of microscopic residual disease at the margins. Grossly negative resection margins are all that is necessary for an initial success.<sup>51,77</sup> Symptomatic recurrence is usually preceded by a long interval of subclinical disease at the resection margin. Symptom onset can be expected to occur earlier for patients with diffuse intestinal disease, perianal CD, and those who had postoperative surgical complications.<sup>78</sup> At least 85% of surgical patients have histologic evidence of recurrence by 3 years after surgery. The high prevalence of microscopic disease does not mean all postoperative patients will develop endoscopically obvious lesions, nor does endoscopic recurrence necessarily mean reoperation is imminent. Most studies report 10-year reoperative rates of approximately 50% for ileocolic disease and 45% each for isolated colonic or small bowel CD.<sup>17,37</sup>

Initial perforation developing from CD represents a group that is at high risk for perforation again. The absolute risk of recurrence is similar to obstructing CD.<sup>79</sup> Older adolescents who smoke represent another high-risk group.

Indications for reoperation are based on the intensity of symptoms, treatment toxicity, and interference with quality of life.

## Subfertility

Subfertility was thought to be a complication of the underlying disease. Recent studies have shown a stronger correlation to operative sequelae rather than the disease process itself.<sup>80</sup> Perianal disease, dyspareunia, and the risk of incontinence may reduce the desire for intercourse. Tubal factors are also extremely

important. There is evidence that fertility may be reduced by as much as 80% to 90% after ileoanal procedures. The most important factors are the location of the dissection and the development of pelvic sepsis. Patients with polyposis or those undergoing appendectomy for uncomplicated appendicitis do not share the same tubal infertility risks as patients undergoing deep pelvic procedures for CD or CUC. Although colon resection and ileorectal anastomosis for CD remain an excellent operation, care should be taken to reperitonealize the pelvis and protect the fallopian tubes from damage.<sup>81-83</sup>

## CHRONIC ULCERATIVE COLITIS

The surgical options for children with CUC are well studied, and the expectation for disease eradication is high. Complete surgical resection leaves little chance of recurrence unless some disease has been left behind. Segmental resection of the most involved portion of the colon is not recommended. In general, more limited forms of CUC respond well to medication whereas those with refractory pancolitis require proctocolectomy.

Optimal surgical management of pediatric patients includes restoration of bowel function after removal of the colon and rectum.<sup>84-86</sup> Significant postoperative complications and pouch failures still occur in patients treated in high volume centers. Nevertheless, children do well despite the high morbidity.<sup>87</sup>

The timing of operation is a balance between the risk of ongoing disease and the risk of complications associated with proctocolectomy. Laparoscopic procedures have the potential to improve outcome by reducing perioperative morbidity and improving social adaptation important to developing teenagers.<sup>88</sup> Questions concerning the patient's quality of life are paramount. Because the long-term results of pouch function and the effects of the operation on the patient's life are uncertain, families and their physicians may be hesitant to risk the possibility of the need for a permanent ileostomy.

### Medical Therapy

In contrast to CD, the incidence and presentation of CUC in childhood is stable. Population studies identify 1 child per 100,000 with disease, compared with CD, which is 2 to 4/100,000.<sup>5,6,89</sup> As noted previously, a higher proportion of children with CD now present with pancolitis. The colonic predilection for CD means a child with pancolitis undergoing an ileoanal procedure could have CD.<sup>4,10</sup> These issues and the differentiating factors have been discussed previously.

The need for surgery for CUC is much less than with CD. Less than half of affected patients will require colectomy during their lifetime. The increased incidence of pancolitis in childhood produces relatively more treatment resistance, but durable remissions and good medical control is still possible. The introduction of TNF- $\alpha$  inhibitors is the latest alternative to surgery. Despite

these advances, early involvement of the surgical team to discuss the surgical options and outcomes is important for an informed decision by the parents.

CUC is a cyclic disease characterized by flares and remission. Aminosalicylates and corticosteroids are the foundation of therapy. Immune modulation with azathioprine, mercaptopurine, and cyclosporine form a second line of therapy that is augmented by the TNF inhibitors infliximab and adalimumab.<sup>90</sup> Surgical therapy is needed in patients whose disease is resistant to these medications.

Further investigation into genetic and environmental factors may produce innovative new therapies. The high rate of familial disease with IBD in children makes this population ideal for future study of gene-targeted therapy. Environmental factors also play a role, especially the bacterial environment and the unusually protective association of appendectomy. The reproducible correlation of tobacco use and IBD is not only of great interest to parents, but may figure prominently in amelioration of pouchitis.<sup>91-93</sup>

### Indications for Operation

Refractory disease, defined as treatment resistance or the inability to wean from corticosteroids, is the most common indication for operation. Children are particularly sensitive to long-term corticosteroid therapy. Not only are there implications for growth and development, but bone mineralization and the risk of fracture are important considerations for the active child.<sup>3</sup> Middle and high school adolescents are acutely aware of their social limitations and look to surgery to restore a more normal life. Preoperative discussions center on the expected quality of life and psychosocial issues associated with bowel functional outcome.

In contrast to adults, acute-onset, unremitting, fulminant colitis is a presentation more common in children.<sup>4,6</sup> Most of these desperately ill children require urgent colectomy and ileostomy. Pouch reconstruction is deferred for several months. The consistent occurrence of this pattern suggests a genetic or immune etiology. Other indications for operation include medication toxicity, growth retardation, and carcinoma prophylaxis. Quality of life instruments may help guide surgical decision-making.

Before operation, children are evaluated for the presence of toxic colitis, anemia, hypoalbuminemia, elevated C-reactive protein levels, and coagulopathic states.<sup>94-96</sup> Correction of mild abnormalities should not preclude complete reconstruction, but seriously ill children should have a staged procedure. Recent data from adult studies suggest a deleterious effect of infliximab on pouch healing.<sup>97</sup> A delay in constructing the pouch is suggested when infliximab has been administered within 2 months of operation.

Mechanical bowel preparation is beneficial when possible. Perioperative intravenous antibiotics are administered within 1 hour of surgery and continued postoperatively at the surgeon's discretion. Preoperative oral (luminal) antibiotics are no longer necessary.

Patients who are corticosteroid dependent require a “steroid prep” that includes a high initial bolus of intravenous corticosteroids followed by a postoperative taper over several weeks or months. When truncal obesity precludes safe pouch construction, weight reduction is discussed as a postoperative bridge to successful restoration of function. Laparoscopy is size independent and recommended in such patients.<sup>94</sup> Currently, many centers utilize a laparoscopic-assisted approach.<sup>98</sup> Preoperative evaluation of the child’s abdomen helps determine whether a Pfannenstiel or periumbilical incision is most appropriate for specimen removal and pouch construction.

## Choice of Operation

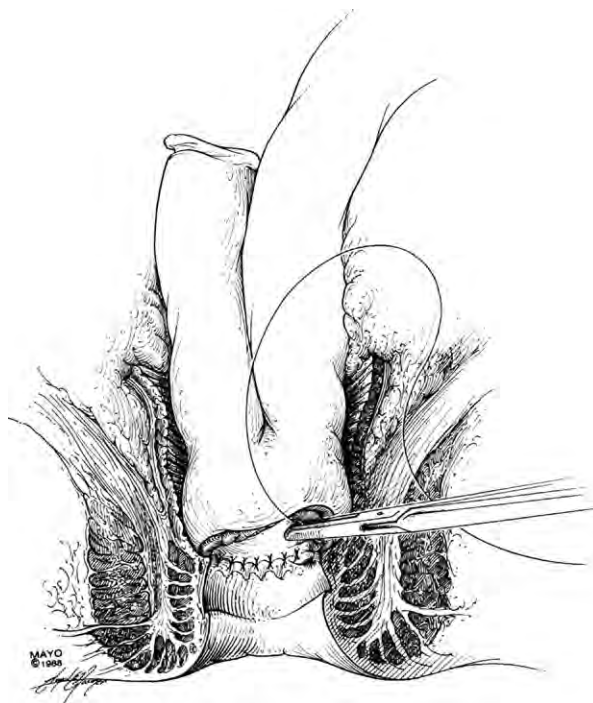

The colectomy may be accomplished laparoscopically, be laparoscopically-assisted, or via an open approach. The reconstruction can occur in one, two, or three stages, and with or without a variety of pouches that are stapled or hand sewn to the anus. These choices reflect the need to tailor the operative approach to the individual needs of the patient.

For children with severe refractory disease, laparoscopic colectomy and end ileostomy is a good option. The colon is removed through the ileostomy or umbilical cannula site. Newer intracorporeal ligating devices have reduced the amount of mesenteric manipulation, limiting the risk of bleeding or perforation in critically ill children. Postoperative recovery is still prolonged owing to the patient’s condition, but the procedure is effective and safe. The ensuing months allow for recovery, tapering of corticosteroid therapy, and differentiation from Crohn’s disease. Later, ileal pouch construction may be performed without an ileostomy provided there are no technical concerns, such as bleeding or tension on the anastomosis. Three-stage procedures have become less common but remain an option for some patients undergoing emergent colectomy.<sup>99</sup>

Colectomy and immediate reconstruction is possible for most children with stable, but corticosteroid-dependent disease. A diverting loop ileostomy is usually performed, followed by ileostomy closure 6 to 8 weeks later as the final procedure. Despite the relatively short time with a stoma, teens may be concerned about returning to school and may want to prolong the decision for the initial colectomy. Ironically, any delay in operation may actually increase the need for a stoma because the corticosteroid doses may need to be increased concomitantly.

An informed family may present for operation at an earlier stage of disease to avoid the need for ileostomy. Although such an approach is possible in highly selected patients with low corticosteroid exposure and normal nutritional parameters, single-stage procedures should be unusual. An anastomotic leak and pelvic sepsis are too high a risk in most children.<sup>88,98,100</sup>

Although the double-stapled ileoanal anastomosis is the standard technique for adults and older adolescents undergoing reconstruction,<sup>99-101</sup> there is a short segment of involved mucosa that requires surveillance. Small children may require a hand-sewn

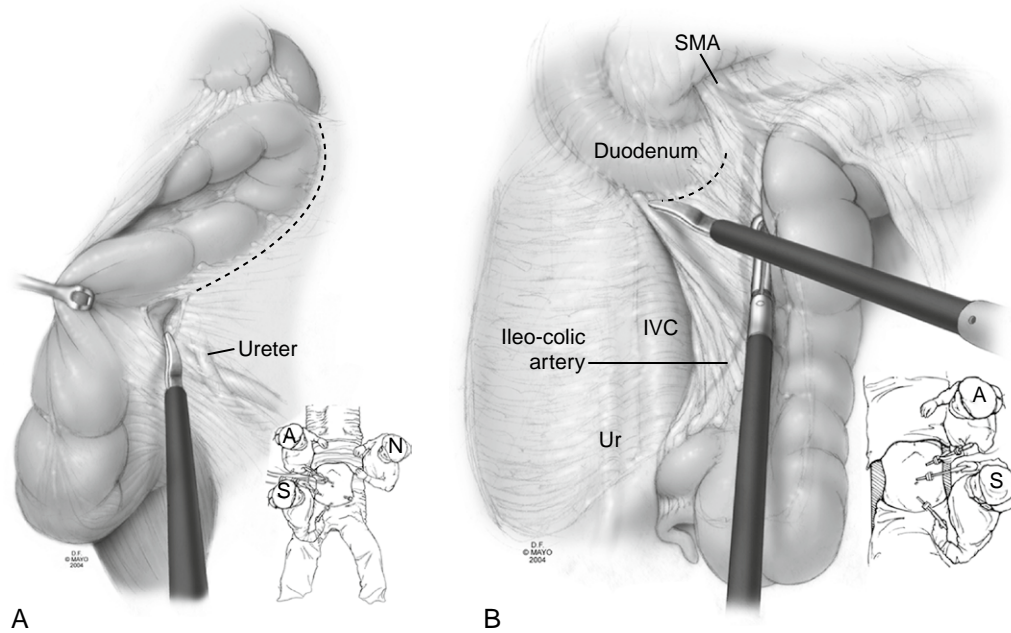

**Figure 42-7.** In small patients, the double-stapled ileoanal anastomosis using the endoscopic circular stapler may not be possible. Also, some surgeons prefer the hand-sewn ileoanal anastomosis. The rectal mucosectomy begins approximately 5 mm above the dentate line and continues proximally to the completed pelvic dissection. The J-pouch is then pulled through the muscle cuff and anastomosed to the anal mucosa, just above the dentate line with interrupted sutures. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

anastomosis with similar concerns for retained islands of mucosa and the later development of cuff adenocarcinoma (Fig. 42-7).<sup>102</sup> Pediatric surgeons caring for children with Hirschsprung’s disease have extensive experience with mucosectomy and hand-sewn coloanal anastomosis. It is expected that this experience will help reduce this risk in children.

Not all children require an ileal pouch. The success of straight ileoanal procedures is a testimony to the tremendous long-term adaptability of children.<sup>94,103</sup> Relatively equivalent stool frequencies are achieved with fewer reports of pouchitis. The postoperative time necessary to achieve a reasonable stool frequency is significantly longer than in those children with pouch construction. Therefore, ileal J-pouches have become the standard technique for reconstruction in children. Other methods, such as the S-, W-, and lateral pouches, have also been utilized in leading pediatric centers.<sup>96</sup> Whereas each has its advocates and may be necessary in certain situations, the J-pouch is the easiest to construct and can be performed laparoscopically.<sup>91,98,99,104</sup>

## Laparoscopic Technique

The laparoscopic approach utilizes a standard laparoscopic total abdominal colectomy followed by a laparoscopic proctectomy. The patient is positioned in a low lithotomy position and prepared for synchronous

**Figure 42-8.** In a child undergoing a laparoscopic colectomy and ileoanal anastomosis at the same setting, the patient is placed in a low lithotomy position and prepared for synchronous abdominal and perineal procedures. **A**, For mobilization of the upper rectum and left colon, the surgeon (S) can stand along the patient's right lower abdomen (see *inset*) or between the patient's legs. The left lateral peritoneal attachments are then divided sharply, taking care not to injure the left ureter. **B**, For mobilization of the right colon, a similar technique is employed. The *inset* show the surgeon (S) and assistant (A) positioned along the patient's left side. Again, the location of the right ureter is important. N, scrub nurse. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

abdominal and perineal procedures. The initial cannula is placed in the umbilicus. After diagnostic laparoscopy, three additional ports are inserted under direct vision. If desired by the surgeon, the cannula sites can be situated such that they are incorporated within a future Pfannenstiel incision, depending on the body habitus of the patient. The stoma site should be marked preoperatively by the enterostomal therapist. The left and right lateral peritoneal attachments of the colon are mobilized, and mesenteric windows are created (Fig. 42-8). The omentum is preserved by entering the lesser sac and freeing the anterior attachments from the transverse colon. The mesocolon is then divided intracorporeally (Fig. 42-9). In older children, the proctectomy can be completely performed laparoscopically, with division of the rectum just above the level of the levator complex using a roticulating laparoscopic stapler. In younger or smaller children, when the pelvis is too narrow or too small to allow for the insertion of a roticulating stapler down to the level of the levators, the rectum can be divided at a location that will allow for a stapled transection. In a three-stage procedure, the specimen is removed through the ileostomy site and an end stoma is created. For a two-stage operation, the remainder of the laparoscopic dissection is completed distal to the level of the levator complex and the rectum is everted out through the anus. After everting the rectum out the anus, the rectum is divided externally using a standard stapler. The small anal cuff is then inverted back into the pelvis. The colon and rectum are removed either transanally or through an enlarged umbilical incision, or at the site of the

**Figure 42-9.** Once the right and left peritoneal attachments are incised, mesenteric windows are created for application of the stapler, as seen in this schematic. Other devices such as the ultrasonic scalpel and Ligasure can also be used, especially in patients with a thin mesentery. Again, it is often advantageous for the surgeon (S) to stand between the patient's legs or along the patient's left side as shown in the *inset*. A, assistant. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

**Figure 42-10.** The double-stapled technique for the pouch/anal anastomosis has shown similar results as the hand-sewn technique. **A**, The anvil has been placed into the pouch and is being brought close to the circular stapler, which has been introduced through the anus. **B**, The anus and pouch have been approximated and the circled, stapled anastomosis performed (*inset*). There is usually about a 5-mm to 1-cm cuff of native rectal mucosa remaining that requires lifetime surveillance. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

protecting ileostomy. The J-pouch is created using a stapled technique through an enlarged umbilical incision, the ileostomy site, or a low suprapubic incision. The J-pouch can be stapled to the anal cuff using an appropriately sized circular endoscopic stapler or hand sewn, depending on surgeon preference (Fig. 42-10). A diverting loop ileostomy is created and exteriorized at one of the port sites in the right lower quadrant.

The laparoscopic approach using a circular endoscopic stapler for creation of the pouch/anal anastomosis has shown similar results as the hand-sewn technique. However, in one report, the double-staple technique resulted in less night-time soiling and produced better postproctectomy anal resting pressures.<sup>105</sup>

On occasion, some children have insufficient mesenteric length to safely perform an ileoanal anastomosis. Sufficient length can be measured by stretching the folded terminal ileum over the pubis. An adequate length is reliably predicted if the terminal ileum extends beyond the inferior margin of the symphysis. Body habitus and the influence of corticosteroids can predispose patients to mesenteric infiltration and edema. Also, uncontrolled disease activity may temporarily shorten the mesentery by reducing elasticity and increasing fragility. In these circumstances, it is usually best not to perform the ileoanal anastomosis at the time of the colectomy.

Several options are available for patients without adequate mesenteric length for primary pull-through.

A straight ileoanal anastomosis has acceptable long-term functional results in children. Storage capacity is limited but improves over the ensuing years to provide a good quality of life.<sup>94</sup> Creation of an S-pouch is an alternative to the use of a J-pouch in selected patients. However, prior experience with S-pouch creation and an understanding of the optimal length of the efferent limb is essential for good results.<sup>106</sup>

Some patients will have already undergone a rectal mucosectomy before discovering the ileum will not reach the anus. An ileostomy is then created at the first stage. At the second stage, reoperation is more difficult owing to scarring in the muscle cuff. The pelvic dissection can be aided by inserting a dilator through the anus to identify the top of the muscle cuff. The cuff is then opened farther and expanded to allow passage of the pouch. It is usually necessary to split the muscle cuff posteriorly. It is important to preserve the deep pelvic nerves by staying within the cuff. If the scarring is too intense, partial cuff resection can be performed transabdominally beginning at the distal extent of the prior dissection.

After the operation, total parenteral nutrition is continued, especially for children who had fulminant colitis preoperatively. Once a diet is tolerated, antibiotics are discontinued and the corticosteroid dosage is tapered. Ileostomy dysfunction is common. Problems include prolapse, stenosis, and bleeding. Preoperative counseling is suggested for children concerned about returning to school with a stoma. Most children are

capable of engaging in school activities and sports within 3 to 4 weeks of the operation, but are reluctant to do so. Contact with peers who have undergone operations for CUC is helpful.

## Postoperative Course

There is a persistently high (30%-66%) incidence of perioperative complications.<sup>107</sup> Infection, obstruction, and ileoanal anastomotic strictures predominate along with the temporary, but sometimes acute, complications associated with the ileostomy. The practice of at-home anal dilation is difficult in children with chronic disease. Many opt for outpatient procedures under sedation.

Long-term complications center on the high rate of pouchitis and chronic problems with the ileoanal anastomosis.

### Pouchitis

Pouchitis is a nonspecific mucosal inflammation that develops in 26% to 47% of children postoperatively. The incidence increases with longer follow-up.<sup>86,107</sup> Each episode is characterized by increased stool frequency, night-time incontinence, pain, urgency, and bleeding. Extraintestinal symptoms include arthralgias and erythema nodosum. Pouchitis is not life threatening nor is it usually life limiting. However, the symptoms represent the perception of return of disease. Patients feel ill, and their quality of life is affected.<sup>108-110</sup>

Treatment is directed at identifying causative factors and symptom relief. Patients with persistent disease should be investigated for anal stricture, retained rectal mucosa, small volume pouch, medication-induced irritability, and CD.<sup>70</sup> These conditions require a different therapeutic approach than idiopathic pouchitis.<sup>104,111</sup> Children without risk factors usually respond to oral antibiotics, and symptomatic improvement is generally seen within 12 to 24 hours of therapy with oral metronidazole or ciprofloxacin. A gradual reduction in the dose is possible within days of treatment.

Chronic pouchitis is controlled with low-dose antibiotics that may be alternated on a weekly or monthly schedule. Amoxicillin and vancomycin have also been successful. Probiotics and other measures have been tried for pouchitis, but their effectiveness remains in question.<sup>112</sup> Investigation of lifestyle and over-the-counter medication usage is important when treating pouchitis. Smoking, caffeine use, stress, and nonsteroidal anti-inflammatory drugs contribute to pouch irritability.

Approximately 10% of ileoanal procedures fail secondary to severe pouchitis that is resistant to medical therapy,<sup>113</sup> and pouch excision may be necessary. Chronic antibiotic use has been tried in an attempt to avoid a permanent stoma. The long-term effects of years of low-dose antimicrobial agents in children have not been established. Dysplasia in chronically inflamed pouches has also been raised as a concern for children who have a long life expectancy. A relatively short-term follow-up study did not identify problems.<sup>114</sup>

## Functional Outcome

Pediatric studies have identified lower incontinence rates and less frequent stooling than is seen in most adult studies.<sup>85</sup> Also, children score well when evaluated for functional outcomes, including night-time continence, completeness of defecation, and the lack of dietary restrictions. Importantly, the presence of postoperative surgical complications has not been shown to have a negative effect on functional outcome.<sup>5,108</sup> The two most common negative outcomes identified were chronic pouchitis and night-time incontinence.

Randomized trials investigating the laparoscopic approach in adults have demonstrated similar efficacy and safety compared with the open operation. These techniques have also been applied to children. Laparoscopic and laparoscopic-assisted proctocolectomy with ileal pouch/anal anastomosis (IPAA) began in the late 1990s. Preliminary data suggest functional outcomes are similar to those with the open approach.<sup>85</sup>

### Quality of Life

A patient's quality of life after a major surgical procedure can be measured and correlates with bowel functional outcomes. A study of children undergoing IPAA procedures at our institution revealed normal assessment scores despite major surgery and change in bowel function.<sup>86</sup> Pouchitis and night-time stooling correlated with lower quality of life scores. Parental anxiety regarding their child's ongoing health remained higher than U.S. norms, reflecting a higher level of parental concern for the child's well-being. This anxiety did not dissipate over time.

### Effect of Aging

Families often wonder if the good functional outcomes found in children will decline with age. A recent 15-year follow-up study has shown durable pouch function without a decline in continence or quality of life.<sup>115</sup> Follow-up studies in children will continue to be important for evaluating the real incidence of pouch failure and long-term quality of life.

## Reoperation

The risk of pouch-related failure increases with time to approximately 10% at 10 years.<sup>113</sup> Technical complications with pouch construction and the ileoanal anastomosis are the most common reason for a poor outcome.<sup>116</sup> Early pelvic or anastomotic sepsis increases the failure rate by a factor of 5.<sup>108</sup> A pouch/anal anastomotic stricture can result in urgency, frequent bowel movements, inability to fully evacuate, night-time incontinence, and poor sleep. These secondary symptoms directly correlate with a poor quality of life.<sup>86,100</sup>

The risk of sepsis after ileoanal procedures decreases with increased surgeon experience. Identification of the complication before ileostomy closure

allows for antibiotic management and percutaneous drainage of an abscess. Occasionally, multiple local procedures are necessary before stoma closure. Once eradicated, long-term pouch success rates are similar to those in patients who did not develop pelvic sepsis (92%).<sup>108</sup> Patients with severe infection requiring abdominal reoperation for infection control have a guarded outlook. More than 50% will lose their pouch, and fewer than one third have good long-term function. Similarly, 30% of patients with extensive anastomotic dehiscence have long-term failure, despite reoperation.<sup>116</sup> Fortunately, most of the anastomotic disruptions are localized, and minor revisions allow good long-term results.

Patients have reverted to ileostomy to avoid the ongoing symptoms of stool frequency, bleeding, mucus discharge, urgency, night-time incontinence, and extra-intestinal manifestations such as arthralgias and erythema nodosum. Prompt treatment will usually ameliorate these symptoms. Treatment resistance usually leads to a diagnostic workup for CD.

Intra-abdominal conditions above the level of the pouch are a rare cause of failure. Patients may have kinking at the small bowel/pouch interface or present with intermittent small bowel obstruction secondary to adhesions. Both of these conditions produce abdominal distention, cramping, and poor pouch evacuation. The difference in these symptoms from the usual pouch-associated symptoms of urgency and incontinence helps the surgeon differentiate these diagnoses.

When complications from the IPAA procedure become chronic, the quality of life for the patient is poor. Frequent defecation and loss of night-time control seriously impair the abilities of the adolescent or young adult to attend school or embark on a professional career.<sup>86</sup> These problems eventually outweigh the stigmas of an ileostomy. When surveyed, patients with permanent ileostomies still prefer a restorative pull-through, but have quality of life indicators similar to those without an ileostomy. It is helpful to set goals for therapy and establish a time line for re-evaluation. Although not ideal, an ileostomy remains an excellent long-term solution for patients with chronic problems after colectomy.<sup>108,113</sup>

### Subfertility and Pregnancy

Studies have demonstrated decreased fertility in patients after proctocolectomy and IPAA.<sup>82,83</sup> Reperitonealization of the pelvis at the time of pouch construction is recommended to prevent entrapment of the fallopian tubes and ovaries. Pregnancy and vaginal delivery are possible and recommended for women after pouch procedures without serious pouch- or anastomosis-related complications. One review showed no difference in birth weight, pregnancy, or delivery complications before or after IPAA procedures.<sup>117</sup> However, there was a higher rate of planned cesarean sections and day-time stool frequency.

## Indeterminate Colitis

Indeterminate colitis is a distinct clinical and pathologic entity diagnosed in 5% to 15% of patients requiring surgery for IBD. With long follow-up, these patients gradually differentiate into ulcerative colitis or Crohn's categories.<sup>118</sup> Also, there is greater morbidity after an IPAA procedure in patients with the diagnosis of indeterminate colitis. Adults with indeterminate colitis have a higher rate of serious postoperative complications (20%)<sup>119</sup> than those with CUC (3.5%-10%), but still less than patients with CD (35%).<sup>108</sup> The long-term success of IPAA for indeterminate colitis is 73% to 85% compared with 89% for CUC. These results make a fairly good case for IPAA in the setting of indeterminate colitis.<sup>61</sup> However, indeterminate colitis patients with features favoring CD may benefit from delayed IPAA 6 to 12 months after colectomy. Operative decisions are based on the age of the child, severity of disease, and the urgency of the operation. Surgeons who see a child younger than age 8 years with indeterminate colitis should proceed cautiously before full reconstruction.

## INTESTINAL CANCER

### Secondary Intestinal Cancer

Hematologic malignancy is the most common childhood cancer and is the most common cancer of the gastrointestinal tract as well. Small bowel lymphomas and colonic tumors, such as Burkitt's lymphoma of the ileocecal region, comprise 75% to 80% of intestinal malignancies in children. Two reports describing 82 pediatric gastrointestinal malignancies identified lymphoma as the only small bowel tumor and Burkitt's lymphoma as the major colonic tumor.<sup>120,121</sup> In these reviews, the remaining tumors were colorectal carcinoma and gastric sarcomas. Although appendiceal carcinoid was more common than lymphoma, carcinoma, or sarcoma, it was alternatively classified as benign or malignant and excluded in these reviews. Surgical therapy for lymphoma, when necessary, involves tissue diagnosis and treatment of complications such as perforation, obstruction, or stricture. With Burkitt's lymphoma, resection of all gross disease in the abdomen (intestine and mesentery) results in a limited chemotherapy regimen (6 weeks compared with 6 months) in the current Children's Oncology Group protocol.

### Primary Intestinal Cancer

#### *Adenocarcinoma*

Colon cancer is the third most common cause of cancer-related deaths in adults. In children, the disease remains rare. Primary adenocarcinoma of the colon does occur in young adults, but most have a familial link or other special features. Pediatric surgeons are

most concerned with prevention of this fatal condition. Surgery for children with familial polyposis syndromes is the most visible example of this approach. Other conditions that may require prophylactic resection include chronically active IBD (CUC and CD) and inherited colorectal cancer (hereditary nonpolyposis colorectal cancer [HNPCC] or Lynch syndrome). The genetics of these disorders are known, and some cases overlap. Mutations are found in the adenomatous polyposis coli (*APC*) tumor suppressor gene in the autosomal dominant form of polyposis and in the *MYH* repair gene for the recessive version. The *MYH* defect promotes somatic mutations in the tumor *APC* gene. Nonpolyposis cancer patients have mutations in the DNA mismatch repair genes, especially *MSH2*, *MLH1*, and *PMS2*.<sup>122-124</sup> Screening of children with a family history of early-onset colorectal cancer could uncover defects that lead to prophylactic colon resection. Because the entire colon mucosa is at risk, the best available procedure is total proctocolectomy with IPAA.

Children who progress from dysplasia to colorectal cancer tend to present with a late stage of disease and with the more aggressive subtypes (mucinous or poorly differentiated adenocarcinoma). In a recent small review of seven children from Italy, the overall survival at 5 years was 23%, despite the fact that it was possible to achieve total gross resection in 5 of 7 patients.<sup>125</sup> Only one patient is currently disease free.

Because there are not enough pediatric cases for separate clinical studies, treatment of pediatric colorectal cancer is based on adult clinical trials. The surgical principles of complete resection with clear margins and a wide regional node dissection apply. Most children receive postoperative chemotherapy. Neoadjuvant chemotherapy may salvage some unresectable tumors. Major chemotherapeutic agents include 5-fluorouracil, oxaliplatin, and irinotecan. Targeted therapies with bevacizumab and cetuximab are under investigation.<sup>126</sup> If possible, early screening of children from families with known colorectal malignancies may improve current results. Unfortunately, the poor prognosis in children continues to be based on an advanced stage of disease and the inability to achieve a complete resection.

Small bowel adenocarcinoma is so rare in children that only a few case reports exist.<sup>127</sup> Celiac disease in childhood has been reported to result in small intestine cancer or non-Hodgkin's lymphoma later in life.<sup>128</sup>

### ***Inflammatory Bowel Disease***

The risk of colorectal cancer with CUC is an indication for colectomy when the disease has been active for more than 10 years. The commonly quoted figure is an annual increase in cancer risk of 0.5% to 1% per year after 8 to 10 years of pancolitis.<sup>129</sup> A meta-analysis in children who developed CUC reported higher overall probabilities of cancer, which has been estimated at 5.5% at 10 years, 11% at 20 years, and 16% at 30 years.<sup>130</sup> Population-based estimates identify colon cancers arising two to three times more frequently in CUC patients.<sup>131,132</sup> These data influence surgical

decision-making for families considering colectomy and IPAA during the teenage years. If colectomy is deferred, colonoscopic surveillance is mandatory. Patients at higher risk for developing colorectal cancer include those diagnosed at an early age and those with a family history of colon cancer, with findings of inflammatory pseudopolyps or strictures, or with the presence of sclerosing cholangitis.<sup>130</sup> In addition, removal of the colon does not completely remove the risk of disease. A stapled anastomosis preserves transitional mucosa that may later become dysplastic.<sup>133</sup> A hand-sewn anastomosis reduces this concern, but there are case reports of cancer developing in the retained rectal mucosa on the muscle cuff.<sup>103</sup>

The risk of adenocarcinoma developing in CD patients is less than in those with CUC or indeterminate colitis. In 1251 patients with CD followed in Stockholm County, Sweden, the cancer risk was 1.15 times higher than the general population.<sup>134</sup> This increase was mainly in small intestine cancer with a standardized morbidity ratio over 15. Patients with CD are also at higher risk for developing other intestinal malignancies, particularly lymphoma. Persistent perianal disease could predispose to squamous cell carcinoma as well.<sup>135,136</sup>

### ***Familial Polyposis Syndromes***

A summary of the childhood polyposis syndromes is found in Tables 42-1 and 42-2. Adenomatous polyps are by definition dysplastic and have a distinct propensity for malignant degeneration. The sheer number of polyps (sometimes in the thousands) combined with a long duration of illness leads to inevitable malignancy. Large polyps are more prone to malignant degeneration than smaller ones. Most children have tubular adenomatous polyps smaller than 1 cm, with a reassuring low cancer risk of less than 5%. Once the polyps advance beyond 2 cm, the risk of cancer increases to 35%. Villous architecture is even more concerning, with a malignant risk of over 50% in 2-cm polyps.<sup>137</sup>

Most children with polyps are asymptomatic. The average age at discovery of nonfamilial polyposis coli is 29 years, but earlier identification occurs when children develop mucus in their stools, blood per rectum, frequency, and change in bowel habit. Generally, when the family history is known, children present to the surgeon for colectomy at an early age. Although treatment is suggested by symptoms, the symptoms themselves are rarely severe enough to warrant colectomy. Rather, it is the cancer risk that is of most concern. The average age at cancer development is 39 years, but this varies by family, depending on the specific *APC* gene mutation within affected family members. Children who have more than 1000 colon polyps can be expected to have a higher risk of early cancer. There are case reports of children as young as 5 and 9 years old developing adenocarcinoma.<sup>138,139</sup> A recent worldwide survey of selected polyposis registries identified 14 patients with cancer younger than 20 years, leading to a calculated risk of 1/471 pediatric cases.<sup>124</sup>

Syndrome	Gene Defect	Population Frequency	Gastrointestinal Cancer Risk	Defining Features
Common juvenile polyps	Unknown	1:50-1:100 (1%-2% of children)	None known	Hamartoma
Juvenile polyposis	<i>SMAD4</i> (18q21.1) <i>PTEN</i> Autosomal dominant	1:100,000	Up to 50%	50-200 hamartomas; 5- to 50-mm diameter
Peutz-Jeghers syndrome	<i>LKB1</i> (19p13.3) Autosomal dominant	1:120,000	20%-40%	Muscle polyp core, mucocutaneous pigment
Familial adenomatous polyposis	<i>APC</i> (5q21) Autosomal dominant or spontaneous mutation	1:5,000-1:17,000	100%	Adenomatous polyps in colon and small bowel

The timing of operation is based on symptoms, the risk of cancer, and the expected outcome. The prophylactic nature of the operation has prompted some families and physicians to consider waiting until the child is old enough to participate in the decision. Such an approach may be possible in patients with late-onset disease and a low polyp burden, but may not be advisable in younger children with larger numbers of polyps of significant size.

Essential investigations before operation include genetic or biologic confirmation of the diagnosis, obtained by gene testing and colonoscopic biopsy. The presence of desmoid tumors in the family should prompt a search in the child as well. The most common locations for desmoid tumors are the truncal muscle or the mesentery. When desmoid tumors are found preoperatively, the risk of postoperative recurrence is high and must be weighed against the preventative nature of an operation. A more cautious approach is suggested for these patients, especially when the polyp load is small and the risk of cancer is low. Treatment of desmoids remains difficult, although newer chemotherapeutic agents offer optimism.

Surgical management in children with familial adenomatous polyposis (FAP) is aimed at removal of all polyp-bearing tissue combined with preservation of continent gastrointestinal function. This is accomplished by a standard proctocolectomy and IPAA, as discussed previously. Long-term complications, such as pouchitis, are much less common in patients with FAP. Functional outcome data demonstrate excellent

pouch function with the stool frequency averaging three to four per day. There is usually no night-time stooling or incontinence. Children rate their quality of life as equal to that of their peers.

Subtotal colectomy with ileorectostomy is an alternative to total proctocolectomy. Candidates for this procedure recognize the need for life-time surveillance of the remaining rectal mucosa. Endoscopy and polypectomy may be reasonable alternatives for patients with attenuated forms of the syndrome (AFAP) and a low polyp burden that typically spares the rectum. Preservation of the rectum is useful in children with nonadenomatous polyps and those with a contraindication to the proctocolectomy and IPAA such as children with pelvic abnormalities that preclude surgery or perineal disorders of continence that affect outcome.

## Other Intestinal Malignancies

### *Carcinoid Tumor*

A carcinoid tumor is most often diagnosed at or following an appendectomy. The estimated incidence of such an event is 2 to 5/1000 operations.<sup>140</sup> Carcinoid tumors are the next most common intestinal tumor after lymphoma.<sup>120</sup> The indolent behavior of these small tumors suggests they should be classified as benign in most circumstances. Appendiceal carcinoids are usually found at the distal tip of the appendix but can occur anywhere along its course (Fig. 42-11).

Syndrome	Germline Mutation	Cancer Risk	Clinical Features
Familial adenomatous polyposis (FAP)	<i>APC</i>	100% by age 40 yr	CHRPE, desmoid tumors, thyroid and liver cancer risk
Gardner's syndrome	<i>APC</i>	Same as FAP	Osteomas, lipomas, sebaceous cysts, dental lesions, desmoids
FAP-related Turcot's syndrome	<i>APC</i>	Same as FAP	Medulloblastomas
Attenuated FAP	<i>APC</i>	70% by age 65 yr	<100 right-sided colon and fundic polyps, exclude <i>MYH</i> mutation

CHRPE, congenital hypertrophy of retinal pigment epithelium.

**Figure 42-11.** This 14 year old girl presented with acute appendicitis and underwent laparoscopic appendectomy. Histologic examination of the appendix revealed a carcinoid tumor in the mid-portion of the appendix. The tumor was less than 2 cm in size. **A**, A low power view shows the nests of tumor cells (solid arrows) invading the muscularis mucosa. The normal appendiceal glands are noted by the dotted arrow. **B**, A higher power view shows the solid islands of uniform oval to polygonal tumor cells with minimal pleomorphism. Mitotic figures are not seen.

The usual location does not account for the relatively high incidence of appendicitis. The tumor can infiltrate the appendiceal wall and mesenteric fat, creating significant concern for regional nodal and distant metastasis. The carcinoid syndrome is not seen until hepatic implantation has occurred and has not been reported in childhood. Malignant carcinoid tumors are slow-growing, slow-spreading lesions without meaningful cure rates until decades have passed.

Longitudinal follow-up of appendiceal carcinoid tumors found in children has shown that appendectomy is curative for all tumors less than 2 cm in diameter. Very little data are available for larger tumors. Traditional teaching suggests patients with larger tumors should undergo right hemicolectomy and regional mesenteric node excision. A combined review of 124 children identified only 7 patients with 2-cm tumors.<sup>140</sup> Of the 4 undergoing hemicolectomy, one tumor recurred. The three who had appendectomy alone have remained free of disease. In our experience, we have found that lesions larger than 2 cm may be safely resected by appendectomy alone.<sup>141</sup> However, it is difficult to draw conclusions from such limited data on a tumor known to take decades to reappear.

Tumor invasion into the periappendiceal fat or vessels has also been considered an indication for hemicolectomy. In adults, metastatic disease is observed more frequently when these characteristics are found.<sup>142</sup> However, the pediatric data do not necessarily support this conclusion because no recurrence was noted in 16 patients with tumor margins outside the wall.<sup>141</sup> An exception should probably be made for lesions near the base of the appendix where wide local excision is not possible.

Laboratory and radiologic studies are usually unremarkable and are not helpful in the decision for hemicolectomy. Unless hepatic metastases are already established, serum and urine markers for serotonin metabolites will be negative. Similarly, chromogranin

A levels will be normal. Octreotide scans may be more sensitive for metastatic disease and can be confirmed by magnetic resonance imaging of the liver for larger lesions.<sup>143</sup> Carcinoid tumors may occur elsewhere in the gastrointestinal tract in children, most commonly in the terminal ileum. These tumors tend to have a higher malignant potential and should be excised with a wide margin of mesentery, including the lymph nodes. Carcinoids of the colon and rectum have not been described in children.<sup>141</sup>

### Gastrointestinal Stromal Tumor

Gastrointestinal stromal tumors (GISTs) have emerged from obscurity as a rare, but leading cause of pediatric intestinal malignancies. Once thought to be leiomyomas or sarcomas, electron microscopy and immunohistochemistry have identified an overlap of muscle and neural elements inconsistent with a smooth muscle tumor. CD34 was found to be positive. Later, KIT tyrosine kinase became the phenotypic marker for this tumor. Recent studies have also identified a less common but causative role for platelet-derived growth factor receptor A (PDGFRA) mutation.<sup>144</sup> These features suggest a common stem cell origin with the interstitial cells of Cajal (ICC).

Pediatric GISTs tend to express fewer KIT and PDGFRA mutations than adults, have a higher female predominance, and may be associated with pulmonary chordomas and paragangliomas. The majority of pediatric GISTs are found in the stomach. Small bowel and colorectal locations are rare. Tumors in these locations have a worse prognosis than those in the stomach.

GIST behavior varies by size, location, and mitotic index. The risk of complications, such as local recurrence and regional spread, is stratified by these indicators into low, medium, and high risk. Surgical resection remains the best form of therapy. Even low-risk tumors may recur at the margins, mandating a cancer operation for every GIST tumor regardless of

risk assignment. The typical pattern begins with local recurrence, followed by serosal spread and hematogenous liver metastasis. Distant disease is late, and lymphatic spread is not characteristic.

Low-risk tumors have excellent survival, but late recurrences are still possible. High-risk GISTs recur

early and spread indiscriminately throughout the abdomen. Chemotherapy has been disappointing, but therapy targeting KIT activation and the downstream effects may yet hold promise. Early results are promising despite the lower expression of KIT in children.<sup>145</sup>

# APPENDICITIS

Shawn D. St. Peter, MD

Over 70,000 cases of appendicitis are seen in children in the United States each year, making it the most common acute surgical condition.<sup>1,2</sup> A lifetime risk of appendicitis has been estimated at 8.7% for boys and 6.7% for girls.<sup>3</sup> The age-specific incidence progresses from extremely low in the neonatal period to a peak incidence between ages 12 and 18 years. Although the disease is common enough to make familial predisposition difficult to identify, there are data to suggest a higher family risk in children who suffer appendicitis before 6 years of age.<sup>4</sup>

## NATURAL HISTORY

Appendicitis is simply a version of diverticulitis in which the appendix represents a long, true diverticulum with a narrow lumen. Inflammation of the appendix is initiated as the result of an obstructive process within the lumen. This was initially demonstrated in an experimental model 70 years ago.<sup>5</sup> The offending mechanism obstructing the lumen can be lymphoid hyperplasia, inspissated fecal matter, a foreign body, or parasites. There is a temporal relationship aligning the incidence of appendicitis with the development of submucosal lymphoid follicles at and near the base of the appendix. These collections of reactive immune cells are sparse at birth but increase with age to a peak in adolescents followed by a sharp decline after age 30.<sup>6</sup> An epidemiologic association between fecaliths and appendicitis is seen in developed countries with a high consumption of low-fiber diets where both are more common than in developing nations with high-fiber diets.<sup>7</sup>

After appendiceal obstruction, intraluminal pressure increases from the accumulation of undrained mucus and contained bacterial proliferation. This pressure progresses until lymphatic and venous drainage are impaired, directly resulting in local edema. If untreated, this congestion will limit arterial inflow and thereby limit cellular substrate exchange. This results in impaired tissue integrity to the end point of necrosis with subsequent perforation. However, luminal obstruction is not always found on histologic

examination, in which case the obstruction may be physiologic or static and not mechanical. Alternatively, the tissue may be locally inflamed as the result of a noxious inciting agent. *Yersinia*, *Salmonella*, and *Shigella* and viruses such as mumps virus, coxsackievirus B, and adenovirus have been implicated in appendicitis.<sup>8,9</sup> In children with cystic fibrosis, painful distention of the appendix may develop from abnormal production of mucus without inflammation.<sup>10</sup> Appendicitis in neonates is rare and warrants evaluation for cystic fibrosis as well as Hirschsprung's disease.<sup>11</sup> Neonatal appendicitis also can be indistinguishable from focal necrotizing enterocolitis confined to the appendix.<sup>12</sup>

Although the natural history of untreated appendicitis is usually perforation and abscess development, this course is not assured because resolution without treatment can occur.<sup>13</sup> Early inflammation that does not progress to perforation appears to be the mechanism behind the clinical phenomena of relapsing or chronic appendicitis.<sup>14</sup> When the disease does progress to perforation, the patient will present with peritoneal irritation. If the presentation is further delayed, the patient may present with an abscess. Young children have less ability to understand or articulate their developing symptomatology compared with adolescents. Therefore, they more commonly present with perforation. Perforation rates have been reported to be as high as 82% in children younger than 5 years and nearly 100% of 1-year olds.<sup>15</sup> However, all perforation rates reported in the literature must be viewed with caution because these rates are reported without a consistent definition of perforation. This accounts for the wide range of 20% to 76% perforation rates reported from 30 pediatric hospitals in the United States.<sup>16</sup>

Delays in presentation or diagnosis causing elevated perforation rates have been documented to occur for reasons other than age. Children with perforation are much more likely to have been initially referred to a pediatrician rather than a surgeon.<sup>17</sup> It would logically follow that patients who do not have good access to medical care would be more likely to present with perforation. In adults, lack of insurance or financial coverage status has been shown to be related to an increase in perforation.<sup>18</sup> In children, a review of a national

database reports perforation disproportionately affects minority children with a 24% to 38% higher rate of rupture than white children, adjusting for age and gender.<sup>19</sup> A separate database review also found the rate of rupture in school-aged children was associated with race and lack of health insurance.<sup>20</sup> Encouragingly, a more recent single institution study found no relation to race or financial status.<sup>21</sup>

## CLINICAL PRESENTATION

The clinical course of appendicitis in its simplest and classic presentation begins with anorexia and vague periumbilical pain. This pain is of visceral origin and is referred to the common dermatome of the 8th to 10th thoracic dorsal ganglia, which results in the periumbilical pain. It is important to remember that inflammation of any midgut derivative will cause similar symptoms. The description of periumbilical pain migrating to the right lower quadrant is not a true migration of the pain nor is it migration of the inflammatory source. Localization occurs when the inflammation of the appendix progresses to irritate the peritoneum, which has potent somatic sensation. More typically, nausea leading to vomiting follows the onset of pain, but this is not a reliable finding in children. Diarrhea is more commonly seen with perforated appendicitis but is also more common in infants and toddlers, which may direct the diagnosis toward gastroenteritis.<sup>22</sup> In general, gastroenteritis is more likely with a history of repeated episodes of vomiting and diarrhea starting at a similar time or preceding the onset of pain, particularly when the abdominal pain is the minor symptom, is not localized, and is without focal tenderness on examination.

The most discrete physical finding is tenderness, exhibited by the objective demonstration of pain such as wincing, moving, or flexing on gentle pressure applied in the right lower quadrant near McBurney's point. This point was originally described as "one and a half to two inches from the anterior superior iliac process along a line drawn from the process to the umbilicus."<sup>23</sup> If the patient is under the influence of narcotic analgesia at the time of examination, tenderness in the right lower quadrant is considerably of more concern for appendicitis. Narcotic analgesics improve the level of comfort but do not change the inflammatory focus, which may still be tender on palpation. However, a negative examination done on a patient on analgesics does not exclude appendicitis.

The search for rebound tenderness, by deep palpation with abrupt removal of pressure, is inherently uncomfortable for the patient and is a poor indicator of peritonitis and should be avoided. Gentle pressure applied to the left side of the abdomen or placing a hand in the center of the abdomen with mild shaking of the abdomen will elicit tenderness in the setting of peritonitis. If these maneuvers precipitate sharp pain in the right lower quadrant, acute appendicitis is extremely likely. A palpable mass in the right lower abdomen is difficult or impossible to identify in the

patient with guarding or rigidity. (This mass often becomes evident on the operating table after anesthesia has been induced.) It is important to remember that localized symptoms depend on peritoneal irritation that is detectable by examination. Therefore, obesity, a retrocecal appendix, or a medial appendix walled off by omentum, mesentery, or small intestine may never localize and the patient may maintain vague symptoms. One or more of these factors are often present in patients who present with perforation or abscess.

Examination of a crying, resistant child can be difficult. This requires patience, deflection of the child's attention, and/or a reassuring parent. However, sedation may be necessary. Despite previous dogma, a rectal examination is a traumatizing and nonspecific adjunct that is unlikely to contribute to the evaluation.<sup>24</sup> Even in the setting of a suspected pelvic abscess or ovarian pathologic process, these diagnoses cannot be affirmed without imaging. Bowel sounds are also quite nonspecific but may be absent with perforation compared with being hyperactive with gastroenteritis.

Fever is common and is usually low grade in acute appendicitis. However, a lack of documented fever does little to exclude the disease. High fever is more common after appendiceal rupture due to the inflammatory response of peritoneal contamination. A patient with high fever and no peritoneal signs is less likely to have appendicitis and should alert the physician toward a viral infection or urinary tract condition.

Serum studies are generally not very sensitive nor specific for appendicitis. A mild elevation of the leukocyte count (11,000 to 16,000/mm<sup>3</sup>) is the most common finding. A markedly elevated leukocyte count suggests perforation or another diagnosis. A case-control series has shown that patients with perforated appendicitis have, on average, a significantly higher leukocyte count than those with acute appendicitis.<sup>25</sup> This series also found that the leukocyte differential count showing neutrophilia and lymphopenia were both fairly predictive of appendicitis. However, a normal leukocyte count does not exclude appendicitis.

The urine is usually free of bacteria, whereas a few or moderate number of red or white blood cells are common because the inflammation may affect the ureter or bladder. Because patients are often dehydrated, a concentrated urine is expected with ketones from decreased oral intake and the release of insulin-antagonizing inflammatory mediators. Serum electrolytes, liver enzymes, and liver function studies are usually normal. C-reactive protein is usually increased and becomes markedly elevated with perforation.<sup>26,27</sup> However, this finding is less reliable in children compared with adults, and no studies have yet demonstrated C-reactive protein to be superior to the leukocyte count. As with a leukocyte count, a normal C-reactive protein does not exclude appendicitis, even when combined with a normal leukocyte count.<sup>28</sup> Therefore, C-reactive protein is not routinely measured.<sup>27,29</sup>

Whereas the aforementioned clinical picture represents the most common manifestation of appendicitis,

it must be recognized that children often present with wide deviations from the classic picture, which makes a confident diagnosis often unlikely without imaging. Moreover, the location of the appendix is not consistent, owing to the variation in the position of the cecum. The appendix can be in the right upper abdomen if the patient has an incomplete rotation. Likewise, if the patient has untreated nonrotation, the appendix could lie anywhere in the abdomen. Because there are commonly one or more components of the presentation not consistent with appendicitis, several groups have attempted to apply clinical scoring systems utilizing elements of the history, physical examination, and laboratory studies to quantitate the sum of the clinical features that are consistent with the diagnosis. One series found scoring to be rather accurate,<sup>30</sup> whereas others have found their overall sensitivity and specificity to be only modest with little advantage over experienced clinical judgment.<sup>31,32</sup> Recently, a scoring system was used to stratify which patients should have surgical consultation (high score), proceed to imaging (moderate score), or be discharged (low score).<sup>32</sup> This is the most applicable use of a scoring system because imaging has become an important adjunct in patients with unclear symptoms.

## RADIOLOGIC IMAGING

Misdiagnosis can lead to an extremely prolonged delay in treatment due to family reassurance from the first caregiver interaction, which may delay them from seeking further care. This results in an increase in morbidity from advanced disease. Epidemiologic data have shown the risk of a missed diagnosis in children to be higher in hospitals with a volume of less than one pediatric appendectomy per week.<sup>33</sup> Parents should be encouraged to take their children to pediatric hospitals for abdominal pain when possible. Historically, negative appendectomy rates of 10% to 20% were not only considered appropriate but advisable to minimize the number of patients with a missed diagnosis. More recently, some authors have questioned this philosophy, citing the risk and expense of an avoidable operation.<sup>34</sup> Diagnostic imaging is necessary if physicians are going to balance minimizing the risk of negative appendectomy and the risk of a missed diagnosis. Currently, data from children's hospitals demonstrate extremely low negative appendectomy rates with the use of diagnostic imaging.<sup>16,35</sup>

Plain films may demonstrate a fecalith in 5% to 15% of patients.<sup>36-38</sup> However, these studies are extremely nonspecific and almost never serve as the determinant for operation. Therefore, they fruitlessly consume time and resources and are not recommended unless bowel obstruction, or free peritoneal air is suspected.<sup>39</sup>

Ultrasonography offers the advantages of being an efficient bedside technique that is noninvasive, requires no contrast, and emits no radiation. Graded compression ultrasonography is performed by placing pressure on the transducer to displace bowel loops and

identify the appendix. The pressure is adequate if the psoas muscle and the iliac vessels are identified, which assure the range of view is posterior to the appendix. The common signs of appendicitis include a fluid-filled, noncompressible appendix, a diameter greater than 6 mm, appendicolith, periappendiceal or pericecal fluid, and increased periappendiceal echogenicity caused by inflammation.<sup>40,41</sup> Results from multiple pediatric series totaling more than 5000 patients have documented that the sensitivity of ultrasonography ranges from 78% to 94% and the specificity ranges from 89% to 98%.<sup>42-50</sup> However, ultrasonography is operator dependent. Thus, the published results must be interpreted relative to local experience and expertise with this imaging modality. The effectiveness of ultrasonography is hindered by abdominal wall thickness and fat, which accounts for the generally inferior results reported in the adult literature.<sup>51-56</sup> Causes of false-positive results include a normal large appendix, the psoas muscle being mistaken for the appendix, and inspissated stool. A false-negative study can result from a retrocecal appendix, perforated appendix, gas-filled appendix, involvement of only the tip, and, most importantly, the inability to visualize the appendix.<sup>37,40</sup> Whereas a normal appendix must be visualized to exclude appendicitis, ultrasonography is not typically efficacious in identifying the normal appendix, because early reports showed only 10% to 50% of normal appendices could be identified in children.<sup>37,40</sup> However, as with other modalities, appendicitis is effectively excluded by the inability to identify the appendix in combination with the identification of a pathologic process that explains the symptoms.<sup>57</sup> Furthermore, recent data from a large series employing upward graded compression, posterior manual compression, left oblique lateral decubitus position, and a low frequency convex transducer, demonstrated that nearly all appendices could be identified with over 98% accuracy for diagnosing appendicitis.<sup>58</sup> Another recent report in 50 patients using contrast-enhanced power Doppler ultrasound imaging demonstrated similar accuracy.<sup>59</sup>

Computed tomography (CT) provides a complete three-dimensional image of the entire abdomen and pelvis, is not operator dependent, and is extremely accurate. Although there is some overlap in the ranges of sensitivity and specificity reported for CT with the ranges reported for ultrasonography, most series report both sensitivity and specificity around 95% or greater for CT.<sup>33,43,53,60-66</sup> These data are difficult to interpret because of the range in sample sizes, quality of patient selection for imaging, and institutional variation in technology and expertise. Therefore, more insight is gained by examining intrainstitutional comparative series between US and CT, which have almost universally found CT to be significantly more accurate than ultrasonography.<sup>33,43,53,60,62,67</sup> There are, however, several concerns with CT. Some protocols require a delay in the emergency department for contrast agent administration, and the smaller children may require sedation. Radiation has become a growing concern with the wide application of CT. It has been estimated that a complete abdominal CT is equivalent to 25.7 months of natural background radiation exposure.<sup>68</sup>

The risk of radiation-induced malignancy from a CT scan decreases with age.<sup>69</sup> The lifetime risk of a fatal radiation-induced malignancy is estimated at 0.18% for a 1-year-old child. Stated another way, one malignancy would result from a CT scan done on 555 one-year-old patients, whereas about twice as many 15-year-olds would need to be scanned to equal that risk. Although this risk may appear miniscule, it is important information when evaluating a patient with the classic symptoms of appendicitis.

Magnetic resonance imaging (MRI) is an intriguing nonradiation alternative to CT and is extremely accurate in diagnosing appendicitis.<sup>70</sup> The current version of this technology makes it impractical for widespread application, but future generations of scanners could allow this technology to be the initial imaging study.

Radionuclide-labeled white blood cell scans have been employed, but the reported diagnostic capacity appears to offer little advantage over the aforementioned modalities and they have the disadvantage of being more cumbersome to obtain.<sup>71</sup>

Imaging is invaluable in the evaluation of children with abdominal pain, allowing for an accurate diagnosis, avoiding unnecessary operations, and decreasing the risk of a repeat presentation with perforation. Perhaps the most important contribution of imaging is the ability to pinpoint an alternative diagnosis that entirely redirects therapy.<sup>19,37,40,72</sup>

## DIFFERENTIAL DIAGNOSIS

In the patients with lower abdominal pain, the workup toward a diagnosis of appendicitis must also consider the alternative possible causes. Causes of acute right lower quadrant pain that is indistinguishable from appendicitis without laboratory or imaging studies include a tubo-ovarian pathologic process, Crohn's disease, mesenteric adenitis, cecal diverticulitis, Meckel's diverticulitis, constipation, viral gastroenteritis, and regional bacterial enteritis (*Yersinia* and *Campylobacter*, particularly). Lower abdominal pain or vague nonfocal pain can result from a urinary tract infection, kidney stone, ureteropelvic junction obstruction, uterine pathologic process, right lower lobe pneumonia, sigmoid diverticulitis, cholecystitis, pancreatitis, gastroenteritis, vasculitis, bowel obstruction, and malignancy (lymphoma). The most common diagnosis made in the presence of missed appendicitis has been reported to be gastroenteritis.<sup>17</sup> Although many of these conditions may seem easily distinguished from appendicitis, they all possess a spectrum of presentation that overlaps the possible symptoms of appendicitis.

## TREATMENT

### Medical Management

The treatment of appendicitis begins with intravenous fluids and antibiotics. The antibiotic regimen must provide broad-spectrum coverage of enteric organisms.

In simple, acute appendicitis, a single dose of antibiotics is adequate preoperative coverage. After appendectomy, patients with acute appendicitis are usually discharged within 24 hours. Current evidence suggests that an additional dose of antibiotics after appendectomy is not necessary or recommended.<sup>73,74</sup>

The patients with perforated appendicitis will require antibiotic therapy postoperatively until clinical resolution has occurred. The antibiotic regimen employed in this situation has traditionally been triple-antibiotic therapy (ampicillin, gentamicin, and clindamycin), which is still practiced in many pediatric surgery centers despite several reports of simpler antibiotic regimens.<sup>75-77</sup> Monotherapy with piperacillin/tazobactam for intra-abdominal infections has recently been shown to be equally efficacious as traditional triple-antibiotic therapy.<sup>75,76</sup> Similarly, cefotaxime, a third-generation cephalosporin, has been shown to be equal to the monotherapy schedule of piperacillin/tazobactam in children with complicated perforated appendicitis when combined with metronidazole.<sup>77</sup> Monotherapy has the disadvantage of being costly and requires three to four doses per day.

The financial charges to the patient are inseparably linked to the dosing schedule. This impact of decreased dosing on antibiotic expenses has been emphasized by several authors.<sup>78-82</sup> In several studies, a decrease in expense has been shown with once-daily dosing of ceftriaxone compared with broad-spectrum monotherapeutic agents in the penicillin and cephalosporin families.<sup>80-87</sup> A retrospective comparative study found once-daily dosing with ceftriaxone and metronidazole was as effective as traditional triple-antibiotic therapy with cost benefits.<sup>88</sup> This was confirmed in a prospective, randomized trial.<sup>89</sup> Therefore, current best evidence suggests once-a-day dosing with ceftriaxone at 50 mg/kg/day and with metronidazole at 30 mg/kg/day provides the simplest and least expensive regimen.

The length of time required for antibiotic treatment or the mode of delivery for perforated appendicitis has yet to be delineated. A multicenter case-control study suggests that the patient who is clinically well by postoperative day 3 is unlikely to develop an abscess.<sup>90</sup> A retrospective comparative series found early transition to oral antibiotics as effective as a prolonged course of intravenous antibiotics.<sup>91</sup> However, prospective trials will be required to clarify this issue.

### Surgical Management

A discussion of the surgical management of appendicitis must be separated into the three distinct categories of disease at presentation. These categories are those with appendicitis with no evidence of perforation, those with perforated appendicitis, and those with a well-defined abscess.

#### Acute Appendicitis

Acute, nonperforated appendicitis is cured with prompt appendectomy, which is the rationale for why an early operation has always been the standard of

care. We now understand that, as a version of diverticulitis, acute appendicitis can be treated effectively to the point of disease resolution and hospital discharge with antibiotics alone.<sup>92-94</sup> This fact has been proven by large prospective, randomized trials in adults comparing antibiotics alone to appendectomy for appendicitis.<sup>94,95</sup> Therefore, once antibiotics have been initiated, the operation is not an emergency or even necessary in the immediate setting. Appendectomy in the middle of the night is no longer justified.<sup>92-94,96-98</sup> Not only is the operation elective once antibiotic therapy has been initiated, this information may be useful in easing family anxiety during the time they await surgical intervention.

### *Perforated Appendicitis*

Appendectomy for perforated appendicitis is currently a topic of debate. There are three general strategies possible for this situation: antibiotics only, antibiotics followed by interval appendectomy, and appendectomy on presentation.

The logic of treating initially with antibiotics is to avoid a difficult operation in the presence of severe inflammation that obliterates the normal anatomy and creates dense adherence of the surrounding structures. Once the infection is controlled with antibiotics, allowing an operation to be more simple and safe, the decision becomes whether to perform the appendectomy. Those who do not perform appendectomy believe there is a low risk of recurrent appendicitis, which short-term data suggest are 8% to 14%.<sup>99,100</sup> However, not only is there short-term follow-up in these studies, these are retrospective reviews of patients already treated, meaning they were specifically selected for this management. It would be expected that a prospective application of antibiotics alone to all patients with evidence of perforation on CT would yield a much higher failure rate. Furthermore, all pediatric follow-up data, even to age 18, is relatively short term considering the current life expectancy is nearly 80 years. Therefore, it is impossible to estimate the lifetime risk of leaving the appendix in situ as these patients mature through adulthood because we do not know what the recurrence curves would look like decade by decade. However, assuming a stable rate, and assuming the current series are accurate in estimating the short-term risk of recurrence at 1% to 3% per year, this is an unfavorable prognosis when the typical pediatric patient has 60 to 80 years of expected life remaining.

Some authors have noted a high rate of pathologic findings in interval appendectomy specimens.<sup>101,102</sup> These cases augment the concern over the lifetime risk of not performing the appendectomy. In addition, most pediatric surgeons perform the interval appendectomy in patients who were initially managed medically. A survey of the American Pediatric Surgical Association (APSA) found that 86% of the responders perform interval appendectomy routinely after nonoperative management of perforated appendicitis.<sup>103</sup>

Regarding nonoperative management of perforated appendicitis, one group found a high failure rate in

patients with more than 15% band forms in the differential white cell count on presentation.<sup>104</sup> Another group found failure was more common when an appendicolith was present on imaging.<sup>105</sup> Others have found that evidence of disease or contamination beyond the right lower quadrant on imaging is a predictor of failure.<sup>106</sup> Finally, when choosing among treatment options, the surgeon should remember that some cases are difficult to categorize accurately as perforated or nonperforated preoperatively.

Although the logic of antibiotic therapy first is to avoid a difficult and potentially dangerous operation, most experienced surgeons can perform this operation safely through a minimally invasive approach. Laparoscopic appendectomy has been shown to be reliably feasible and safe in both children and adults who present with a phlegmonous mass in the right lower quadrant.<sup>107,108</sup>

In the discussion about whether to perform an operation, the most important factor is deciding if the patient has a perforation. The presence or absence of perforation cannot be accurately predicted by preoperative imaging, but not all patients will have preoperative imaging performed. In these cases, perforation is diagnosed intraoperatively. This is another source of controversy. Surgeons polled with photographs have extreme incongruence on which patients would be considered to have a perforation.<sup>109</sup> Furthermore, a survey of APSA members demonstrated the majority of members reported that they based their practice approaches on their individual preferences.<sup>110</sup> Because surgeons do not agree on what constitutes perforation, and because each surgeon holds his or her own opinion, this means almost all of the data published on the topic of perforated appendicitis must be viewed with caution because we do not know the composition of the study populations. In reality, a definition of perforation is not as important as the ability to identify which patients possess a high risk of developing a postoperative abscess. Emerging prospective evidence suggests defining perforation as an identifiable hole in the appendix or as a fecalith in the abdomen clearly separates high-risk from low-risk patients.<sup>111</sup> Moreover, this distinction prevents overtreating patients with purulent disease who actually have a good prognosis from the outset.

### *Abscess on Presentation*

Patients presenting with a well-defined abscess that is identified on imaging are clinically challenging. Historically, the operations were difficult and required large incisions with high morbidity. Treatment of the abscess with percutaneous drainage with or without drain placement (Fig. 43-1), followed by interval appendectomy when the inflammation has resolved, allows for a less morbid operation. This approach was initially described over 25 years ago and has become an important part of contemporary practice.<sup>103,112-116</sup> However, the advancement of laparoscopic skills has also allowed the operation to be performed with minimal morbidity. There are no concurrent comparative

**Figure 43-1.** This patient presented with perforated appendicitis and a well-defined abscess. She underwent initial nonoperative management (abscess drainage, antibiotics) followed by a laparoscopic interval appendectomy 10 weeks later. These CT scans show the large pelvic abscess (asterisk, **A**) followed by needle placement (arrow, **B**), and drainage with a percutaneous drain (arrow, **C**). The drainage resulted in resolution of the abscess.

data available describing how the patients with percutaneous drainage fare in comparison to a cohort undergoing early operation. The practice of percutaneous drainage with interval appendectomy also carries the risk of complications and employs considerable medical resources.<sup>117</sup> Furthermore, there are no data available on the stress of the medical burden placed on the families treated with a long medical course involving antibiotics, drainage, and a long wait for the interval operation. This topic is an important one to address with a prospective trial, which is currently underway.<sup>118</sup>

Regardless of whether the abscess is drained under radiologic guidance or is opened at operation, culture of the fluid has not been shown to be helpful.<sup>119,120</sup> One study demonstrated that children whose treatment followed the cultures did somewhat worse than those whose fluid was not cultured.<sup>120</sup> In addition, peritoneal lavage with saline or antibiotic solution has never been shown to reduce the incidence of postoperative abscess.<sup>121</sup> Similarly, the use of drains has not proved useful except in cases of walled-off abscess cavities.<sup>122,123</sup> Injection of bupivacaine into the wound

has been shown to reduce postoperative pain significantly in a randomized controlled trial in children.<sup>124</sup>

### The Laparoscopic Approach

The traditional method of appendectomy was a muscle-splitting, right lower quadrant incision. Laparoscopic appendectomy typically involves a camera site at the umbilicus with two additional working ports (Fig. 43-2). During the initial experience with laparoscopy for perforated appendicitis, some authors found a higher postoperative abscess rate than had been seen with the open operation.<sup>125-127</sup> However, this literature also suffers from the lack of a substantive definition of perforation. Alternatively, this finding may have been the result of the early experience with laparoscopy.

Since the last edition of this book, there has been a plethora of evidence from around the world documenting no difference in intra-abdominal abscess risk between the open and laparoscopic approaches.<sup>128-146</sup> This evidence includes a multitude of level 1, 2, and 3 studies, including multiple prospective trials,

**Figure 43-2.** **A**, Port positions for a laparoscopic appendectomy. Typically three cannulas are used, with the endoscopic stapler introduced through the 12-mm umbilical port. The appendix is removed through this site as well. **B**, Postoperative appearance.

meta-analyses, and large multi-institutional comparative series from several countries. This is important because the risk of postoperative abscess was the potential justification for the open approach.

Laparoscopy possesses several advantages. This approach effectively removes the concern for wound infections, which has been a formidable problem in some patients with the open operation. The wound infection rate is substantially lower with laparoscopy owing to the small incisions and protection of the tissues by the cannulas.<sup>128-132,135,136,142-144,146,147</sup> When a wound infection occurs with laparoscopy, the morbidity is quite minimal owing to the size of the incision.<sup>89</sup> This effect is amplified in obese patients in whom the laparoscopic incision size remains the same but the open operation requires a much larger incision that results in the contamination of an abundance of poorly vascularized subcutaneous tissues.<sup>148,149</sup> Also, the length of hospitalization has been repeatedly shown to be shorter with laparoscopy.<sup>129,130,132-137,140-145,147</sup> Laparoscopy has been shown to allow for an earlier return to full activity in several studies, including an earlier return to sports and work.<sup>141,142,144,145,147</sup>

One prospective, randomized trial documented a superior quality of life at 2 weeks after laparoscopic appendectomy compared with the open operation.<sup>137</sup> A large database study involving 43,757 patients found a lower rate of gastrointestinal complications and overall complications with laparoscopy.<sup>143</sup> Similarly, the laparoscopic operation has also been shown to reduce the rate of postoperative adhesive small bowel obstruction.<sup>150</sup> Multiple authors have expressed the point that laparoscopy offers the substantial advantage of allowing excellent visualization of the entire abdominal cavity, removing therapeutic concerns of an alternative diagnosis.<sup>132-134,141,144,147,151</sup> The most recent Cochrane review concluded that laparoscopy should be the primary approach for suspected appendicitis, if available.<sup>147</sup>

The concern about laparoscopy requiring longer operative time is becoming dated. As with the early experience of all laparoscopic operations, it is likely that a longer operating time was the result of surgeons comparing an approach they were beginning to apply against one they had practiced for decades. Several recent comparative studies, including two prospective, randomized trials, have failed to show laparoscopy as

taking longer.<sup>130,136,138,139,141</sup> The most recent meta-analysis found no difference in operative time.<sup>136</sup> One prospective trial in patients with acute appendicitis and another large comparative series in patients with perforated appendicitis found the laparoscopic approach to have a shorter operating time.<sup>130,138</sup> Most of the early studies documenting longer operating times for laparoscopy were reporting operating times of over 1 hour. The recent studies report times of less than 50 minutes. In the most recent prospective, randomized trial in children with perforated appendicitis, who all underwent laparoscopic appendectomy, the mean operating time was 44 minutes, with many cases requiring 30 minutes or less.<sup>89</sup> If these times are found in the setting of perforation, a straightforward appendectomy can easily be done in 20 minutes with good laparoscopic experience.

In spite of the fact that appendicitis is the most common acute surgical condition in children, there are many unresolved management issues that will require prospective studies to delineate.

### Technique

The patient is placed supine on the operating table, and the abdomen is prepped widely. A 12-mm cannula is introduced through an umbilical incision, and pneumoperitoneum is established. Diagnostic laparoscopy is then performed. Two 5-mm ports are then placed, one in the left midabdomen and one in the left suprapubic area (see Fig. 43-2). A 5-mm 45-degree telescope is introduced through the umbilical port, and the two 5-mm ports are the working ports until introduction of the stapler. Once the appendix is identified, a window is made in the mesoappendix. At this point, the telescope is rotated from the umbilical port to the left midabdominal port and an endoscopic stapler is inserted through the 12-mm umbilical cannula. Usually, the appendix is ligated and divided first (Fig. 43-3), followed by ligation and division of the mesoappendix. On occasion, however, it may be more expedient to ligate the mesoappendix first.

If the appendix can be delivered through the cannula, an endoscopic bag is not used. However, so as not to drag the appendix through the umbilical incision, an endoscopic bag is utilized if the appendix is too large for the cannula.

**Figure 43-3.** A, Initially, a window is made in the mesoappendix. B, Usually, the appendix is ligated and divided with the stapler first, followed by ligation/division of the mesoappendix.

For perforated appendicitis, the port positions remain the same. However, the purulent material is evacuated in the pelvis and suprahepatic areas. Interloop abscesses are also lysed and opened if they have developed. Drains are not routinely utilized for advanced disease.

Our experience with laparoscopic appendectomy over the past 8 years has been previously

reported.<sup>88,89,111,150,152,153</sup> Our conversion rate is less than 1%. We have found a less than 1% postoperative abscess rate in patients with acute appendicitis and a 20% postoperative abscess rate if perforation has occurred.<sup>89,111</sup>

# BILIARY TRACT DISORDERS AND PORTAL HYPERTENSION

Atsuyuki Yamataka, MD, PhD • Yoshifumi Kato, MD, PhD • Takeshi Miyano, MD, PhD

## BILIARY ATRESIA

Biliary atresia is a relatively rare obstructive condition of the bile ducts causing neonatal jaundice. The etiology is unknown but is the result of a progressive obliterative process of variable extent. Reliable incidence figures are available from Europe (1 in 18,000 live births), France (1 in 19,500 live births), the United Kingdom and Ireland (1 in 16,700 live births), Sweden (1 in 14,000 live births), and Japan (1 in 9640 live births),<sup>1-6</sup> but the highest recorded incidence is in French Polynesia (1 in 3124 live births).<sup>7</sup> No significant seasonal variation or clustering appears. In most large series, a slight female preponderance is found.

In the late 1950s, Morio Kasai reported the presence of patent microscopic biliary channels at the porta hepatis in young infants with biliary atresia. He postulated that by exposing these channels through radical excision of the atretic extrahepatic biliary remnants, then effective drainage of bile could be possible in some cases, especially if such surgery was performed within 8 weeks of birth. Although the Kasai portoenterostomy has become accepted as the standard initial operation for biliary atresia, this disease remains the foremost indication for liver transplantation in infants and children.

## History

Biliary atresia appeared as a distinct disease entity in the *Edinburgh Medical Journal* in 1891.<sup>8</sup> In 1916, the concepts of “correctable” and “noncorrectable” types of disease were introduced after a comprehensive review of all reported cases.<sup>9</sup> Successful surgical treatment for the correctable type was reported for the first time in 1928.<sup>10</sup> However, over the next 3 decades there were only a few long-term survivors, all of whom had the favorable correctable type.<sup>11,12</sup>

For the majority with “noncorrectable” type disease, a number of procedures designed to relieve

biliary obstruction, including impalement of the liver with metal tubes, incisions into the hilum with a cardiac valvulotome, partial hepatectomy to create biliary fistulas, and lymphatic drainage through the thoracic duct were developed.<sup>13-17</sup> Despite occasional hopeful reports, all techniques failed to provide adequate biliary decompression. Timing of surgical intervention was controversial, with some surgeons recommending that all infants with obstructive jaundice undergo early diagnostic laparotomy and cholangiography to identify those with correctable variants, whereas others concluded that early age was a contraindication for surgical treatment.<sup>18,19</sup> This latter group emphasized that neonatal hepatitis could be worsened by surgical intervention and recommended that surgical procedures should be postponed until at least 4 months of age. The argument for early surgical correction also was weakened by reports describing “spontaneous” cure.<sup>20,21</sup> Finally, second-look surgical exploration became recommended because of a rather mystical belief that a totally fibrotic extrahepatic ductal system might subsequently become patent.<sup>22</sup>

In 1959, the now common Kasai hepatic portoenterostomy procedure was reported for the first time and ended a long, hopeless era for patients with the noncorrectable-type disease.<sup>23</sup> Kasai’s original report was in Japanese and received little attention until it was published in English in 1968.<sup>24</sup> Although effective bile drainage could be achieved after portoenterostomy in about 50% of patients, early surgical repair was crucial and needed to be performed before the age of 2 months. Conversely, effective bile drainage was observed in only 7% if correction was performed after the age of 4 months.<sup>25</sup> The portoenterostomy procedure gradually gained popularity in the United States during the 1970s. In the 1990 report of the Biliary Atresia Registry, more than 90% of infants with biliary atresia had undergone the procedure.<sup>26</sup>

## Etiology and Pathogenesis

Despite intensive interest and investigation, the cause of biliary atresia remains unknown. Two different forms are described.<sup>27</sup> In syndromic biliary atresia (also known as the embryonic type), associated congenital anomalies are found, such as an interrupted inferior vena cava, preduodenal portal vein, intestinal malrotation, situs inversus, cardiac defects, and polysplenia. In this variety, which accounts for 10% to 20% of all cases, biliary atresia is likely to be due to a developmental insult occurring during differentiation of the hepatic diverticulum from the foregut of the embryo. A possible relation between syndromic biliary atresia and maternal diabetes has been reported.<sup>28</sup> Nonsyndromic biliary atresia (also known as the perinatal type) may have its origins later in gestation and may have a different clinical course, with biliary obstruction being progressive.

No ideal animal model exists for biliary atresia, a fact that has slowed the understanding of its pathogenesis. Various etiologic mechanisms have been postulated, including intrauterine or perinatal viral infection, genetic mutation, abnormal ductal plate remodeling, vascular or metabolic insult to the developing biliary tree, pancreaticobiliary ductal malunion, and immunologically mediated inflammation. Recent observations would suggest that biliary atresia is not a single disease entity. Some infants even have pigmented stools at birth.

Reovirus type 3 infection, rotavirus, cytomegalovirus (CMV), papillomavirus, and Epstein-Barr virus have all been proposed as possible etiologic agents, but conclusive evidence is lacking. CMV infection has been found in 4 of 10 patients with biliary atresia, and reovirus infection has been found in the livers of up to 55% of biliary atresia patients versus 10% to 20% in a control group.<sup>29,30</sup> Reovirus type 3 can cause an inflammatory cholangiopathy in recently weaned mice, but the condition is not progressive and the animals recover. The identification of viruses in children with biliary atresia is inconsistent in the literature, and several viruses have been used to create animal models that may be valuable for assessing the pathogenesis and treatment of biliary atresia.

Generally, biliary atresia is not considered an inherited disorder. However, genetic mutations that result in defective morphogenesis may be important in syndromic biliary atresia. Transgenic mice with a recessive deletion of the *inversin* gene have situs inversus and an interrupted extrahepatic biliary tree.<sup>27,31</sup> Mutations of the *CFCl* gene, which is involved in left-right axis determination in humans, have recently been identified in a few patients with syndromic biliary atresia.<sup>32</sup> The importance of the macrophage migration inhibitory factor (MIF) gene, which is a pleiotropic lymphocyte and macrophage cytokine in biliary atresia pathogenesis, has also been reported.<sup>33</sup> Other studies have identified abnormalities in laterality genes in a small number of subjects with biliary atresia, including the transcription factor *ZIC3*.<sup>34</sup> A high incidence of polymorphic variants in the *jagged-1*, *keratin-8*,

and *keratin-18* genes have been reported in a series of 18 children with biliary atresia.<sup>35,36</sup> Taken together, the increased incidence of nonhepatic anomalies in children with biliary atresia and genetic mutations reported in subsets of patients with laterality defects suggest that multiple genes are involved, each affecting a small number of patients.

Intrahepatic bile ducts are derived from primitive hepatocytes that form a sleeve (the ductal plate) around intrahepatic portal vein branches and associated mesenchyme in early gestation. Remodeling of the ductal plate in fetal life results in the formation of the intrahepatic biliary system. This is supported by similarities in cytokeratin immunostaining between biliary ductules in biliary atresia and normal first-trimester fetal bile ducts.<sup>37</sup> These findings suggest that nonsyndromic biliary atresia might be caused by a failure of bile duct remodeling at the hepatic hilum, with persistence of fetal bile ducts poorly supported by mesenchyme.

Several studies have investigated whether bile duct epithelial cells are susceptible to an immune/inflammatory attack because of abnormal expression of human leukocyte antigen (HLA) antigens or intracellular adhesion molecules on their surfaces.<sup>38,39</sup> A greater than threefold increase in HLA-B12 antigen is found in patients with biliary atresia compared with controls, particularly in those with no associated malformations and increased incidence of haplotypes A9-B5 and A28-B35.<sup>40</sup> Aberrant expression of class II HLA-DR antigens on biliary epithelial cells and damaged hepatocytes in patients with biliary atresia may render these tissues more susceptible to immune-mediated damage by cytotoxic T cells or locally released cytokines.<sup>41</sup> Increased expression of intercellular adhesion molecule-1 (ICAM-1) is noted on bile duct epithelium in patients with biliary atresia, a finding that may play a role in immune-mediated damage.<sup>39</sup> Strong expression of ICAM-1 also has been found on proliferating bile ductules, endothelial cells, and hepatocytes in biliary atresia.<sup>42</sup> A direct relationship exists between the degree of ductular expression of ICAM-1 and disease severity, suggesting that ICAM-1 might be important in the development of cirrhosis.

More recently, interest has focused on co-stimulatory molecules. Two processes are involved in the activation of T lymphocytes by antigen-presenting cells (APCs). One relates to the expression of major histocompatibility complex class II molecules, which interact directly with T-cell receptors. The other depends on the expression of B7 antigens on APCs and provides the second (co-stimulatory) signal to T lymphocytes through CD28.<sup>43</sup> In postoperative biliary atresia patients with good liver function, co-stimulatory antigens (B7-1, B7-2, and CD40) are expressed only on bile duct epithelial cells, whereas in patients with failing livers these markers are found on the surfaces of Kupffer cells, dendritic cells, and sinusoidal endothelial cells and in the cytoplasm of hepatocytes.<sup>44</sup> This suggests that the biliary epithelium and hepatocytes in biliary atresia are susceptible to immune recognition and destruction. Agents that block or prevent co-stimulatory pathways might offer a new therapeutic

approach to controlling liver damage. Two studies performed comprehensive molecular and cellular surveys of liver biopsies and found a proinflammatory gene expression signature, with increased activation of interferon- $\gamma$ , osteopontin, tumor necrosis factor- $\alpha$ , and other inflammatory mediators.<sup>45,46</sup> These studies may prove to be instrumental in dissecting the molecular networks responsible for the proinflammatory response and autoimmunity thought to be involved in the pathogenesis of biliary atresia. However, none of these mechanisms appears to be mutually exclusive. Moreover, it is not clear which signs and symptoms are primary and which are secondary. One current hypothesis is that the etiology of nonsyndromic biliary atresia is due to a viral or other toxic insult to the bile duct epithelium that induces the expression of new antigens on the surfaces of biliary epithelial cells.<sup>47</sup> Coupled with a genetically predetermined susceptibility that is mediated via histocompatibility antigens, these neoantigens are recognized by circulating T lymphocytes, resulting in a cell-mediated, immune, fibrosclerosing bile duct injury.

### Classification and Histopathology

Although the term *biliary atresia* implies a static process with complete obstruction or absence of bile ducts, it is more a dynamic process of progressive bile duct obliteration and sclerosis. The areas that are affected and the degrees of fibrosis are variable and presumably

**Figure 44-1.** Morphologic classification of biliary atresia based on macroscopic and cholangiographic findings. Type I, occlusion of common bile duct; type IIa, obliteration of common hepatic duct; type IIb, obliteration of common bile duct, hepatic and cystic ducts, with cystic dilatation of ducts at the porta hepatis, and no gallbladder involvement; type III, obliteration of common, hepatic, and cystic ducts without anastomosable ducts at porta hepatis. (From Lefkowitz JH, et al: Biliary atresia. *Mayo Clin Proc* 73:99, 1998.)

reflect different sites of primary involvement by an as yet unknown cause.

The disease can be classified by using macroscopic appearance and cholangiography findings according to three main categories: (1) main type, (2) subtypes according to the pattern of distal bile ducts, and (3) subgroups according to the pattern of hilar hepatic radicles. Types I, II, and III are defined as atresia at the site of the common bile duct (CBD), at the site of the hepatic duct, and up to the porta hepatis, respectively. Most patients have type III. Cystic dilatation at the distal end of a patent duct is seen in some cases of type I biliary atresia (Fig. 44-1). Of the subtypes, patent distal ducts through the gallbladder to the duodenum are seen in 20% and atretic distal ducts are seen in 62% of cases. In these subgroups, a patent duct that can be anastomosed to the intestine at the porta hepatis is present in 5% of cases (i.e., “correctable” type). In more than 90% of cases, however, no normal ductal structures are seen at the porta hepatis (i.e., “noncorrectable” type).<sup>48</sup>

Early in the course of biliary atresia, the liver is enlarged, firm, and green. The gallbladder may be small and filled with white mucus, or it may be completely atretic (Fig. 44-2). Microscopically, the biliary tracts contain inflammatory and fibrous cells surrounding miniscule ducts that are probably remnants of the original embryonic duct system. The liver parenchyma is fibrotic and shows signs of cholestasis. Proliferation of biliary neoductules is seen (Fig. 44-3). This process develops into end-stage cirrhosis if good drainage cannot be achieved. These early changes are often nonspecific and may be confused with neonatal hepatitis and metabolic disease.

It is generally accepted that the pathologic changes seen in biliary atresia are panductal, affecting the intrahepatic biliary tree as well as the extrahepatic bile duct system. Moreover, the intrahepatic bile ducts can be narrowed, distorted in configuration, or irregular in shape.<sup>49-51</sup> However, some authors believe that secondary damage occurs only to the extrahepatic biliary system as a result of obliteration of extrahepatic bile ducts during development of the liver.<sup>52</sup> This

**Figure 44-2.** Type III biliary atresia with an enlarged, firm, green liver and hypoplastic small gallbladder was found in this infant.

**Figure 44-3.** Photomicrograph of the portal tract of the liver in a 60-day-old infant with biliary atresia. Ductal plate malformation can be seen in the center of the portal space with portal fibrosis. Note ductal metaplasia of hepatocytes (Azan stain,  $\times 100$ ).

theory is strongly supported by the fact that outcome is better if corrective surgery is performed early. In any case, the intrahepatic biliary tree is important not only pathologically but also clinically. The degree of damage that is present in the intrahepatic biliary system is actually responsible for much of the morbidity after hepatic portoenterostomy. Ductal proliferation includes ductal plate malformations, such as a disturbance of adequate remodeling of the ductal plate as well as ductular metaplasia of hepatocytes.<sup>53</sup> Paucity or absence of intralobular bile ducts along with architectural disturbances, even in jaundice-free infants after successful hepatic portoenterostomy, has been observed by some investigators.<sup>54</sup> The nature and fate of the intrahepatic biliary involvement is still a subject of great controversy.

## Diagnosis

The cardinal signs and symptoms of biliary atresia are jaundice, clay-colored stools, and hepatomegaly. However, meconium staining is normal in most patients. In the neonatal period, feces are yellowish or light yellowish in more than half of patients.<sup>55</sup> The newborn's urine becomes dark brown. Although the neonates are active, and their growth is usually normal for the first few months, anemia, malnutrition, and growth retardation develop gradually because of malabsorption of fat-soluble vitamins. In this period, jaundice that persists beyond 2 weeks should no longer be considered physiologic, particularly if the elevation in bilirubin is mainly in the direct fraction. Neonatal hepatitis and interlobular biliary hypoplasia are most likely to be confused with biliary atresia. Conventional liver function tests alone are useless for establishing a definitive diagnosis of biliary atresia.

A number of diagnostic protocols have been published, but the emphasis must always be on early diagnosis (Table 44-1).<sup>56,57</sup> For definitive diagnosis of biliary atresia, further investigations, including special biochemical studies, tests to confirm the patency of

**Table 44-1** Clinical Findings and Examination for Diagnosis of Biliary Atresia

### Routine Examinations

Consistency of the liver  
Conventional liver function tests, including test for  $\gamma$ -glutamyl transpeptidase  
Coagulation times (PT, aPTT)

### Special Examinations

Special biochemical studies  
Hepatitis A, B, C serologic studies  
TORCH titers  
 $\alpha_1$ -Antitrypsin level  
Serum lipoprotein-X  
Serum bile acid  
Confirmation of patency of extrahepatic bile ducts  
Duodenal fluid aspiration  
Ultrasonography  
Hepatobiliary scintigraphy  
Endoscopic retrograde cholangiopancreatography  
Near-infrared reflectance spectroscopy  
Needle biopsy of the liver for histopathologic studies  
Laparoscopy  
Surgical cholangiography

PT, prothrombin time; aPTT, activated partial thromboplastin time; TORCH, toxoplasmosis, other viruses, rubella, cytomegalovirus, and herpes simplex virus.

the extrahepatic bile ducts, and needle biopsy of the liver are often required. Several authors consider liver biopsy to be the most reliable test for establishing the diagnosis.<sup>58,59</sup> Serum lipoprotein-X is positive in all patients with biliary atresia, although it also is positive in 20% to 40% of patients with neonatal hepatitis. Serum bile acid levels increase in infants with cholestatic disease, but both the total bile acid level and the ratio of chenodeoxycholic acid to cholic acid have no value for differentiating biliary atresia from other cholestatic diseases.<sup>60</sup> Hyaluronic acid, which has been considered as a serum marker for liver function, has been reported to be a biochemical marker for evaluating infants with biliary atresia.<sup>61</sup> Duodenal fluid aspiration is recommended as an easy, noninvasive, and rapid test because biliary atresia can be excluded if typical yellow bilirubin-stained fluid is aspirated.<sup>62</sup> Hepatobiliary scintigraphy with technetium-labeled agents is widely used for differentiating biliary atresia from other cholestatic diseases. In biliary atresia, nucleotide uptake by hepatocytes is rapid but excretion into the bowel is absent, even on delayed images. In hepatocellular jaundice, isotope uptake is delayed owing to parenchymal disease and excretion into the intestine may or may not be demonstrated.

Ultrasonography, a safe and noninvasive test, should be performed in all jaundiced infants. Hepatobiliary ultrasonography will exclude other surgical causes of jaundice such as choledochal cyst and inspissated bile. In biliary atresia, the intrahepatic ducts are not dilated on ultrasonography because they are affected by the

**Figure 44-4.** Ultrasonography shows a well-defined triangular area of high echogenicity at the porta hepatis, corresponding to fibrotic ductal remnants (the “triangular cord” sign).

inflammatory process. Various sonographic features have been targeted in an attempt to distinguish biliary atresia from other causes of conjugated hyperbilirubinemia in infants.<sup>63-67</sup> In biliary atresia, the gallbladder is small, shrunken, and noncontractile and there is increased echogenicity of the liver. The presence of other associated anomalies of the polysplenia syndrome is pathognomonic of biliary atresia.<sup>68</sup> Differentiation from choledochal cyst and type I biliary atresia also is rapid and simple with ultrasonography.<sup>69</sup> Irrespective of interobserver variation, failure to visualize the CBD is not diagnostic of biliary atresia, because a patent distal CBD can be found in up to 20% of biliary atresia cases. However, an absent gallbladder or one with an irregular outline is suggestive of biliary atresia.<sup>67</sup> In some cases, a well-defined triangular area of high reflectivity is seen at the porta hepatis, corresponding to fibrotic ductal remnants (the “triangular cord” sign) (Fig. 44-4).<sup>64,65</sup>

Nonvisualization of the fetal gallbladder may indicate abnormalities ranging from gallbladder agenesis to biliary atresia.<sup>70</sup> Amniotic fluid digestive enzymes, which are synthesized by the biliary epithelium, gradually decrease until 24 weeks of gestation. Because it is no longer possible to differentiate between abnormally low and physiologically low levels of the enzymes after 24 weeks of gestation, the prenatal diagnosis of biliary atresia is very difficult.<sup>71</sup>

Most patients with biliary atresia can be correctly diagnosed by using an appropriate combination of the investigations just listed. However, to differentiate accurately among biliary atresia, biliary hypoplasia, and severe neonatal hepatitis, cholangiography is usually required.

Recently, laparoscopy-assisted cholangiography has been used to accurately display the anatomic structure of the biliary tree with minimal surgical intervention.<sup>72</sup> Percutaneous cholecystocholangiography has also been considered as a useful option to prevent unnecessary laparotomy in infants whose cholestasis is caused by diseases other than biliary atresia.<sup>73</sup>

## Treatment

### Preoperative Management

Daily doses of vitamin K are usually given for several days before operation. The bowel should be prepared with oral kanamycin. Oral feeding is discontinued 24 to 48 hours before surgical intervention, and glycerin enemas are given. Preoperative broad-spectrum antibiotics are administered preoperatively.

### Surgical Technique

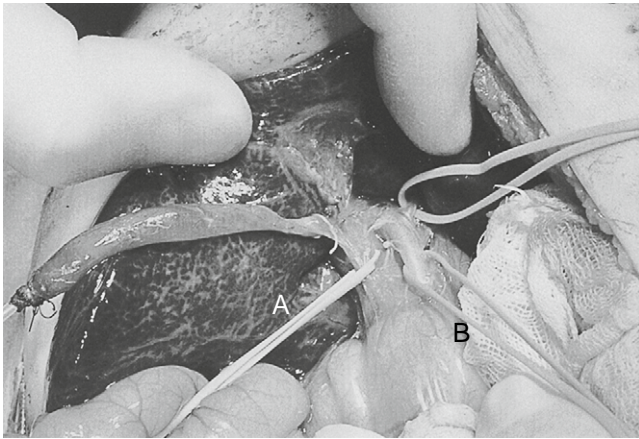

#### HEPATIC PORTOENTEROSTOMY

The patient is placed supine on an operating table with facilities for intraoperative cholangiography. An extended right subcostal incision, dividing the muscle layers, is used to expose the inferior margin of the liver. After division of the falciform and triangular ligaments, the liver is delivered from the abdominal cavity. This procedure provides an excellent operative field for dissection of the porta hepatis. Cholangiography is needed to determine if biliary atresia is present and the correct anatomy (Fig. 44-5). The fundus of the gallbladder is mobilized from the liver bed, and a 4- to 6-Fr feeding tube is passed into the gallbladder through a small incision. If bile is detected on aspiration of the gallbladder, a small amount of contrast material is injected.

Unless normal anatomy of the intrahepatic biliary system is seen, a hepatic portoenterostomy should be performed.<sup>24,74</sup> At some point, a liver biopsy is performed on the right lobe to obtain histopathologic data for prognostic purposes.<sup>75-77</sup> To begin the portoenterostomy, the cystic artery is ligated and divided and the gallbladder is dissected from the liver bed. The mobilized gallbladder is used as a guide for locating the fibrous remnant of the CBD. After the caudal end of the CBD is ligated and divided at the upper border of the duodenum, the cephalad portion of the CBD with the gallbladder attached is dissected

**Figure 44-5.** Intraoperative cholangiogram, type III biliary atresia. Note the almost atretic common bile duct (arrow).

**Figure 44-6.** Type III biliary atresia. The vessel loops are around the atretic common bile duct (A) and hepatic artery (B).

cephalad above the bifurcation of the portal vein. The portal vein and the hepatic arteries are exposed along their entire course. For better portal dissection, the right and left hepatic arteries and the right and left portal branches are individually encircled by vessel loops (Fig. 44-6). The fine veins extending between the portal vein and the base of the portal fibrous mass are carefully ligated and divided. After dissecting up to the right and left portal vein branches, the portal fibrous mass is transected at its border with the liver. Transection can be performed very accurately by using scissors or a scalpel. The liver parenchyma should be avoided to prevent obstruction of the remnant bile duct by scar tissue. For use during the portoenterostomy anastomosis, 5-0 absorbable sutures are usually placed in the liver surface of the posterior side of the remnant fibrous mass before transection. It is important to have enough distance between these sutures and the remnant fibrous mass. Bleeding points are controlled by packing with gauze. Diathermy electrocautery is not used because it can cause damage to the remnant bile ducts (Fig. 44-7). Intraoperative histopathology of the transected portal fibrous plate is important. If openings of microscopic bile duct structures are present at the transected surface, additional transection of the portal fibrous mass should be performed. A 30- to 40-cm Roux loop is prepared by transecting the jejunum 15 to 25 cm downstream from the ligament of Treitz (Fig. 44-8). The distal end may be oversewn or left open and is passed in a retrocolic position to the hepatic hilum. Small bowel continuity is established with an end-to-side enteroenterostomy. The hepatic portoenterostomy is performed in an end-to-side or end-to-end fashion using interrupted 5-0 sutures. Using the previously placed 5-0 sutures, the posterior anastomosis is performed first. The anterior margin of the jejunum is then sutured to the surface of the liver. There should be adequate separation between the anterior margin and the remnant fibrous mass. A small drain is positioned in the foramen of Winslow through a separate stab incision in the right abdominal wall and the incision is closed.

## HEPATICENTEROSTOMY

In “correctable” biliary atresia, a Roux-en-Y hepaticojejunostomy is usually performed. Although a wide and deep portal dissection is not required, excision of the patent CBD to the liver hilum is needed. Any cyst-like structure should be excised and must not be used for anastomosis to the intestine. Failure to remove all abnormal duct tissue results in an anastomotic stricture and cholangitis.<sup>78</sup>

## REPEATED HEPATIC PORTOENTEROSTOMY

Pediatric surgeons have reached a consensus about repeated hepatic portoenterostomies.<sup>79</sup> Bile drainage after reoperation is significant only in patients with good bile excretion after the initial surgery.<sup>80</sup> Because liver transplantation is a treatment option, repeated hepatic portoenterostomy should be considered only in patients in whom good bile flow suddenly ceases.

## MINIMALLY INVASIVE SURGERY

The first laparoscopic Kasai procedure was described in 2002, and there have been few other reports.<sup>81</sup> One reason for the lack of information on minimally invasive surgery for this condition may be related to the difficult nature of the procedure, the apparent increased incidence of postoperative complications, and the worse early clinical outcome.<sup>82</sup> At the 2007 International Pediatric Endosurgery Group meeting in Buenos Aires, a consensus panel of experts in biliary atresia surgery and minimally invasive surgery concluded that minimally invasive surgery should not be utilized for this operation at this time because the results are not as good.

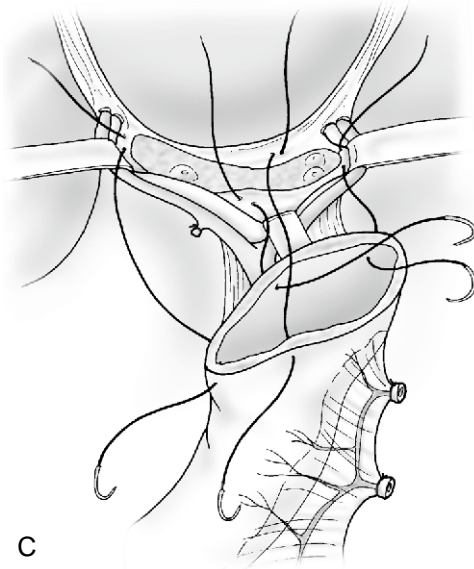

## Postoperative Management

Patients are given oxygen and intravenous fluids, and nasogastric tube drainage is used. Broad-spectrum antibiotics are continued postoperatively to prevent cholangitis. Corticosteroids are also given intravenously or orally. Some studies have reported improved outcomes with high-dose corticosteroid therapy after a Kasai procedure and the effectiveness of standardized protocols that include corticosteroids.<sup>83</sup> Both antibiotic and corticosteroid use are largely empirical but corticosteroids are used both for their choleric effect and to decrease scarring at the anastomosis site.<sup>84,85</sup> Ursodeoxycholic acid may be useful in augmenting bile flow, but only in the presence of patent bile ductules. Fat-soluble vitamins (A, D, E, and K) and formula feeds enriched with medium-chain triglycerides are also used.

## Complications

### CHOLANGITIS

Cholangitis is the most frequent complication occurring after portoenterostomy and occurs most commonly during the first 2 years. Approximately 40% of infants are affected. All conduits become colonized within a month of surgery. Cholestasis is the main risk

**Figure 44-7.** The portoenterostomy operation. **A**, Photograph of the initial mobilization of the gallbladder and atretic bile ducts and dissection/exposure of the porta hepatis. After the common bile duct remnants are severed from the duodenal side, the proximal end is pulled up and the portal bile duct remnants are freed from underlying structures. The portal vein and hepatic artery are encircled with vessel loops. Several small vessel branches between the portal vein to the fibrous remnants can be identified and should be divided between ligatures. **B**, The portal bile duct remnants must be dissected 5 or 6 mm proximal to the anterior branch of the right hepatic artery on the right side and to the umbilical point of the left portal vein on the left side. After completion of the portal dissection, the portal bile duct remnants should be transected at the site of the line that has been drawn. **C**, The end of the Roux-en-Y limb is anastomosed around the transected end of the portal bile duct remnants. Sutures should not be placed into the transected surface of the bile duct remnant because minute bile ducts may be present. (B and C from O'Neill JA, Rowe MI, Grosfeld JL, et al: *Pediatric Surgery*, 5th ed. St. Louis, Mosby-Year Book, 1998, vol 2, p 1471.)

factor for cholangitis, and all patients with biliary atresia have very small ducts.

Cholangitis presents initially as fever, decreased quantity and quality of bile, elevations in serum bilirubin, and a variety of signs associated with any infection. Nonetheless, prompt treatment is necessary because recurring attacks cause progressive liver damage. After initial blood cultures, broad-spectrum antibiotics with good gram-negative coverage are started and a favorable response is usually prompt. If stools become acholic, a pulse of corticosteroids is useful. To decrease the risk for cholangitis, Roux-en-Y biliary reconstruction has been modified by various maneuvers, including lengthening the Roux-en-Y limb from 50 to 70 cm, total diversion of the biliary conduit, intestinal valve formation, and the use of a physiologic intestinal valve.<sup>86-90</sup> An intussusception-type intestinal valve may be associated with a lower incidence of

cholangitis. Stomas complicate liver transplantation, which may be required later. At this time, the anti-reflux intussusception valve may be the modification of choice. A gallbladder conduit is not recommended when the lumen of the patent duct is narrow or when pancreaticobiliary anomalies are demonstrated on cholangiography.

#### CESSATION OF BILE FLOW

Loss of fecal bile pigment in a patient with a well-functioning portoenterostomy is an ominous sign. Prompt re-establishment of bile flow is imperative to avoid liver damage. Parents should be encouraged to report changes in stool color or signs of cholangitis. If cessation of bile flow occurs, a pulse of corticosteroids is tried because corticosteroids both augment bile flow and reduce inflammation.<sup>84,85</sup> If bile flow is re-established, then the corticosteroid dosage is reduced.

If bile flow is not re-established, corticosteroids are stopped. If bile flow was initially good, it is reasonable to consider reoperation. However, multiple attempts at reoperation are not useful and increase the technical difficulties for subsequent transplantation.

### PORTAL HYPERTENSION

Portal hypertension is common after portoenterostomy, even in infants with good bile flow. The basic inflammatory process affecting the extrahepatic ducts also damages the intrahepatic branches, albeit at variable rates. Continuing fibrosis has been demonstrated in some children despite successful portoenterostomy.<sup>91</sup> Clinical manifestations of portal hypertension include esophageal variceal hemorrhage, hypersplenism, and ascites (Fig. 44-9). Of special note is the finding that, over time, the susceptibility to complications of portal hypertension seems to decrease, resulting in reduced frequency and severity of variceal bleeding. This observation is difficult to explain and may be related to improvement in hepatic histology or the development of spontaneous portosystemic shunts. In any case, this general observation justifies a nonsurgical approach to the management of portal hypertension, as long as hepatic function is preserved (i.e., the patient remains anicteric with no coagulopathy and normal serum albumin level). In the presence of poor hepatic function, however, complications of portal hypertension are an indication for liver transplantation.

**Figure 44-8.** A 40-cm Roux-en-Y loop is prepared by transecting the jejunum 20 to 30 cm downstream from the ligament of Treitz. The distal end is oversewn and passed in a retrocolic position to the hepatic hilum. (From Tagge DU, Tagge EP, Drongowski RA, et al: A long-term experience with biliary atresia. *Ann Surg* 214:591, 1991.)

**Figure 44-9.** CT scan of a 20-year-old woman in whom severe portal hypertension developed. Note marked atrophy of the left lobe of the liver, severe splenomegaly, and varices around the stomach.

### INTRAHEPATIC CYSTS

Biliary cysts or “lakes” may develop within the livers of long-term survivors and cause recurring attacks of cholangitis (Fig. 44-10).<sup>92</sup> Prolonged antibiotic treatment and ursodeoxycholic acid may be helpful in preventing cholangitis, but unremitting infection is an indication for liver transplantation.

### HEPATOPULMONARY SYNDROME

Diffuse intrapulmonary shunting may occur as a complication of chronic liver disease in children with biliary atresia, probably as a result of vasoactive compounds from the mesenteric circulation bypassing sinusoidal inactivation. The syndrome is characterized by cyanosis, dyspnea on exertion, hypoxia, and finger clubbing. It is more prevalent in children with syndromic biliary atresia. The diagnosis is confirmed by using a combination of arterial blood gas estimations with and without inspired oxygen, radionuclide lung scans with

**Figure 44-10.** CT scan of a 17-year-old with biliary atresia. Multiple biliary cysts or “lakes” have developed within the liver of this long-term survivor and caused recurrent attacks of cholangitis.

macroaggregated albumin to quantify the degree of shunting, and contrast bubble echocardiography. This complication is progressive and can usually be reversed by liver transplantation. Pulmonary hypertension is a rarer complication but also may develop in long-term survivors after portoenterostomy.

### HEPATIC MALIGNANCY

Rarely, malignant change (hepatocellular carcinoma or cholangiocarcinoma) may complicate long-standing biliary cirrhosis after portoenterostomy. A case of hepatocellular carcinoma has been reported in a 19-year-old young man after Kasai instrumentation for biliary atresia,<sup>93</sup> indicating the need for a high index of suspicion for the development of carcinoma, even in young patients.

### OTHER COMPLICATIONS

Because of the presence of residual hepatic disease, metabolic problems associated with malabsorption of fat, protein, vitamins, and trace minerals can occur postoperatively because of impairment of bile flow to the gut.<sup>94,95</sup> Weight gain after surgical correction may be retarded if hepatic dysfunction persists. Essential fatty acid deficiencies and rickets are common problems related to metabolic derangements.<sup>96</sup> Long-term monitoring of clinical symptoms and adequate nutritional supplementation are required. Ectopic intestinal variceal bleeding and pulmonary arteriovenous fistulas are sometimes seen in long-term survivors with incomplete relief of impaired liver function.<sup>37,46</sup>

As more postoperative biliary atresia patients are reaching adulthood, the issue of pregnancy in females is becoming more common. In untransplanted postoperative biliary atresia patients, preterm cesarean delivery at around the 34th week appears to be reasonable because the pregnancy is high risk in a patient with poor hepatic reserve. Conversely, abdominal delivery at full term may be possible for selected patients with favorable liver function.<sup>97</sup>

### Results and Prognosis

Without question, the Kasai hepatic portoenterostomy has greatly improved the prognosis of infants with biliary atresia and the results of surgical treatment have improved steadily over the past 30 years. However, a wide discrepancy exists in reported long-term postoperative results. One study from Japan found postoperative outcome to be excellent, with a 10-year survival rate of more than 70% if corrective surgery was performed before 60 days of age.<sup>98</sup> However, a nationwide survey of the Surgical Section of the American Academy of Pediatrics found that long-term survival was only 25%.<sup>26</sup> Other reported survival rates include 40% to 50% from the United Kingdom and 68% for a French national study on 10-year overall survival.<sup>1,99</sup> Results are considerably worse if the infant is older than 100 days at the time of portoenterostomy because obliterative cholangiopathy and hepatic fibrosis are more advanced.<sup>99,100</sup> The major determinants of satisfactory outcome after portoenterostomy are (1) age at initial

operation, (2) successful achievement of postoperative bile flow, (3) presence of microscopic ductal structures at the hilum, (4) the degree of parenchymal disease at diagnosis, and (5) technical factors of the anastomosis. The age at which the surgical drainage is performed is the single most widely quoted prognostic variable. A favorable outcome is expected if the procedure is performed before 60 days of age because cirrhosis can develop by 3 to 4 months of age.<sup>85</sup> Infants who show a significant decrease in serum bilirubin and have fecal signs of good bile excretion also have improved results. The serum bilirubin value at 3 months after surgical correction can be used to predict long-term survival.<sup>101</sup>

The presence of microscopic ducts at the hilum is somewhat controversial. Some authors have suggested that duct size is important. However, not all agree.<sup>102,103</sup> Types I and II biliary atresia generally have good prognosis if treated early. In the more typical type III biliary atresia, the presence of larger bile ductules at the porta hepatis (>150  $\mu$ m in diameter) is associated with a better prognosis. The subgroup of infants with syndromic biliary atresia have worse outcomes in terms of both clearance of jaundice and overall mortality.<sup>1,28</sup> The latter is related to associated malformations, particularly congenital heart disease, a predisposition to developing hepatopulmonary syndrome, and possibly immune compromise from functional hyposplenism. Anecdotal evidence suggests that infants with concomitant CMV infection fare less well after a portoenterostomy.

The importance of surgical technical experience was demonstrated by a British survey in which patients who underwent treatment at centers treating one case per year had significantly worse outcome than patients who underwent surgical treatment at centers performing more than five cases per year.<sup>104</sup> Thus, the level of surgical skill and the experience with postoperative management are critical factors for optimizing outcome.

Certain substances may act as prognostic factors in biliary atresia. Serum levels of interleukin (IL)-6, IL-1ra, insulin-like growth factor-1 (IGF-1), vascular cell adhesion molecule-1 (VCAM-1), and ICAM-1 correlate with liver dysfunction in postoperative biliary atresia patients.<sup>42,105,106</sup> Immunohistochemically, a reduction in the expression of CD68 and ICAM-1 at the time of portoenterostomy is associated with a better postoperative prognosis.<sup>107</sup> The presence of ductal plate malformation in the liver predicts poor bile flow after hepatoportoenterostomy in infants with biliary atresia.<sup>108</sup> Growth failure and poor mean weight z-scores 3 months after hepatoportoenterostomy were associated with a poor clinical outcome.<sup>109</sup>

### Liver Transplantation

Biliary atresia is the most common indication for liver transplantation in children, and the majority of affected children will eventually come to transplant. Infants whose jaundice is not cleared after portoenterostomy, or those with complications associated with

end-stage chronic liver disease that develops despite initially successful portoenterostomy, require liver transplantation. Most of these cases require transplantation within the first few years of life. The indications for liver transplantation in postoperative biliary atresia patients are (1) no bile drainage at all, because major clinical deterioration will be inevitable; (2) the presence of signs of developmental retardation or their sequelae if they become uncontrollable; and (3) complications/side effects being socially unacceptable.

A high hepatic artery resistance index measured on Doppler ultrasonography is an indication for relatively urgent transplantation. Deterioration in hepatic status may be precipitated by adolescence or pregnancy.<sup>110</sup> However, as many as 20% of patients undergoing portoenterostomy will remain well and reach maturity with good native liver function.

The dramatic improvement in survival with the use of cyclosporin and tacrolimus immunosuppression after liver transplantation raises the question of transplantation becoming a more conventional form of surgical treatment for biliary atresia. The donor supply is always a problem, alleviated to some extent by reduced-size liver transplantation. Favorable experience with living-related liver transplantation at Kyoto University in Japan has been widely reported.<sup>111</sup>

Five-year survival after liver transplantation for biliary atresia is currently 80% to 90%, and techniques such as split-liver grafting and living-related liver transplantation have decreased waiting times. The combination of Kasai portoenterostomy and liver transplantation has transformed a disease that was almost invariably fatal in the 1960s into one with an overall 5-year survival of about 90%. Furthermore, long-term studies of postoperative biliary atresia patients have shown that survivors have an acceptable to good quality of life.<sup>112,113</sup> A more recent study summarized the largest series (n = 464) of post-Kasai portoenterostomy biliary atresia patients who had undergone living-related liver transplantation. The outcome of living-related liver transplantation in adult biliary atresia patients was significantly worse than in the pediatric patients. The overall 5- and 10-year survival rates were 70% and 56% in adults versus 87% and 81% in pediatric patients, respectively.<sup>114</sup> On the other hand, there is another report concluding that living-related liver transplantation for post-Kasai portoenterostomy can be performed safely in adults with a long-term survival rate equivalent to that for pediatric patients.<sup>115</sup> Longer immunosuppression might ultimately lead to increased co-morbidity, including higher rates of cancer, infection, and metabolic diseases later in life. In addition, in living-related liver transplantation, the risk to the donor is also a matter of concern.<sup>116</sup> The optimal timing of transplantation for successful long-term outcome in post-Kasai portoenterostomy biliary atresia patients has yet to be established.

Despite the debate over whether hepatic portoenterostomy or primary liver transplantation should be performed as the initial surgical procedure for biliary atresia, the consensus among pediatric surgeons all

over the world is that hepatic portoenterostomy is still the most reasonable first choice. However, liver transplantation plays an important role in the long-term management of biliary atresia.

## CHOLEDOCHAL CYST

Choledochal cyst was first reported by Douglas in 1852.<sup>117</sup> This condition is relatively rare, with an estimated incidence in Western populations of 1 in 13,000 to 15,000 live births.<sup>118</sup> However, it is far more common in the East, with rates as high as 1 per 1000 live births having been described in Japan. Although the etiology remains unknown, choledochal cyst is likely to be congenital. Pathologic features frequently include an anomalous junction of the pancreatic duct and CBD (pancreaticobiliary malunion [PBMU]), intrahepatic bile duct dilatation with or without downstream stenosis, and varying degrees of hepatic fibrosis.

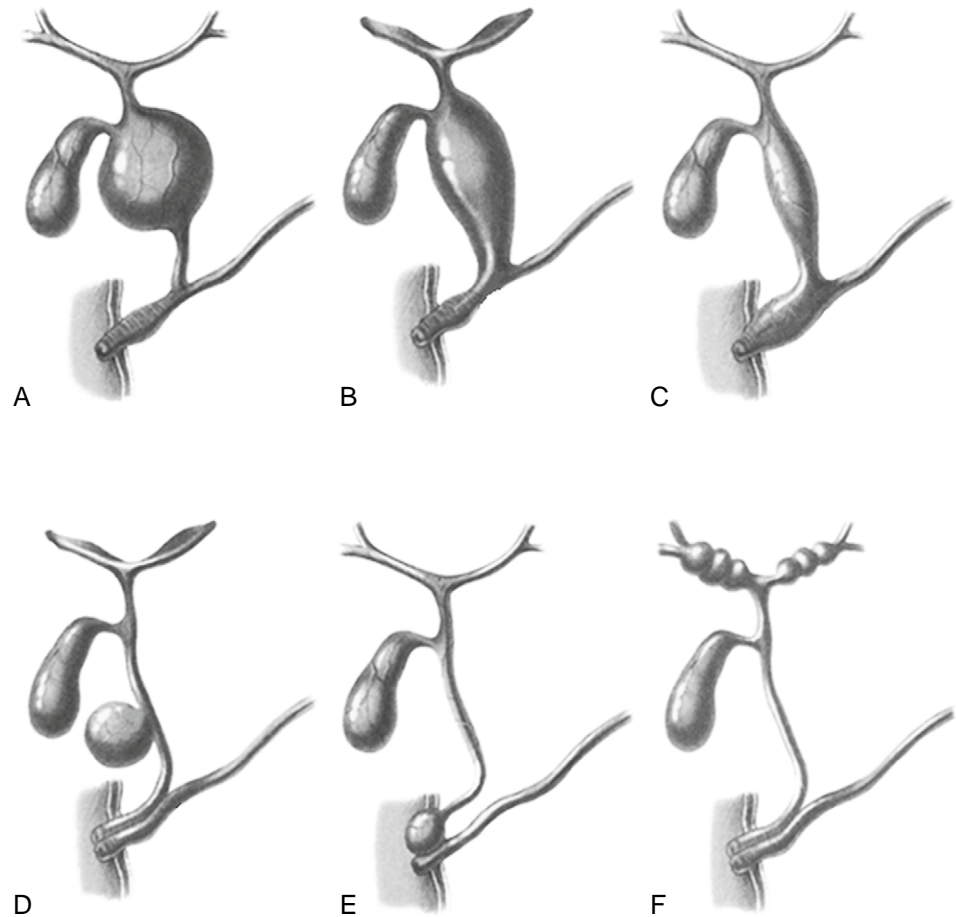

Choledochal cyst is usually classified into three groups, based on anatomy.<sup>119</sup> However, other forms and subgroups have been described, based on cholangiographic findings of intrahepatic ducts or the presence of a long common duct shared by the liver and the pancreas (PBMU).<sup>120,121</sup> Based on our experience, we prefer to classify choledochal cyst into groups according to the presence or absence of PBMU (Fig. 44-11). The vast majority of cases of choledochal cyst are associated with PBMU. Thus, the following comments are related primarily to cystic (saccular), fusiform, and forme fruste choledochal cysts (FFCC).

## Pathogenesis

A number of theories have been proposed for the etiology of choledochal cyst. Congenital weakness of the bile duct wall, a primary abnormality of proliferation during embryologic ductal development, and congenital obstruction have been postulated.<sup>122-124</sup> An early obstructive factor has gained popularity after an experimental study in which cystic dilatation of the CBD was produced by ligation of the distal end of the CBD in neonatal lambs, but not at later stages of development.<sup>125</sup>

In 1969, the "long common channel theory" was proposed.<sup>126</sup> It was postulated that PBMU allows reflux of pancreatic enzymes into the CBD, which leads to disruption of the duct walls. This theory is supported by the high amylase content of fluid that is usually aspirated from choledochal cyst. In theory, the CBD could become obstructed distally because of edema or fibrosis caused by refluxed pancreatic fluid.

We support the "long common channel theory" anatomically because almost all cases of choledochal cyst have PBMU, but we cannot agree with the hypothesis that weakness of the choledochal wall is due to reflux of pancreatic fluid. Our experimental data in puppies showed that the chemical reaction initiated by refluxed pancreatic fluid in the CBD is extremely mild.<sup>127</sup> In addition, there are a number of patients with PBMU and high gallbladder amylase levels with

**Figure 44-11.** Classification of choledochal cysts with pancreaticobiliary malunion (PBMU). **A**, Cystic dilatation of the extrahepatic bile duct. **B**, Fusiform dilatation of the extrahepatic bile duct. **C**, Forme fruste choledochal cyst without PBMU. **D**, Cystic diverticulum of the common bile duct. **E**, Choledochoceles (diverticulum of the distal common bile duct). **F**, Intrahepatic bile duct dilatation alone (Caroli's disease).

no dilation of the CBD. Also, choledochal cyst can be diagnosed as early as the fifth month of gestation. At this time in gestation, the fetal pancreas does not produce functional enzymes. Thus, the exact role of the pancreatic fluid is unclear.

From research on human fetuses, the pancreaticobiliary ductal junction has been demonstrated to be outside the duodenal wall before the eighth week of gestation and then migrates normally toward the duodenal lumen. Thus, PBMU may persist as a result of arrest in this migration.<sup>128</sup>

Based on these studies, we believe that PBMU and congenital stenosis are the basic causative factors of choledochal cyst rather than destruction caused by reflux of pancreatic fluid.

### Clinical Presentation

Choledochal cyst can present at any age, but more than half of patients are initially seen within the first decade of life. Clinical manifestations differ according to the age at onset. Young infants may have obstructive jaundice, acholic stools, and hepatomegaly, resembling biliary atresia, and may even have advanced liver fibrosis. At cholangiography, there is a patent communication with the duodenum and a well-developed intrahepatic bile duct (IHBD) tree.

Young infants may also present with a large upper abdominal mass without jaundice. In young children, presenting symptoms can be divided roughly into two groups: a right upper quadrant mass with intermittent jaundice due to biliary obstruction, seen in patients with saccular choledochal cyst, and abdominal pain due to pancreatitis, which is characteristic of fusiform choledochal cyst or FFCC. In adolescence and adulthood, choledochal cyst has often been misdiagnosed for many years as cholelithiasis, cirrhosis, portal hypertension, hepatic abscess, and biliary carcinoma. Surgical treatment in this group is much more difficult than in children. The incidence of postoperative complications is quite high, even after primary cyst excision.<sup>129</sup>

### Pathology

In choledochal cyst, bile duct mucosa shows erosion, epithelial desquamation, and papillary hyperplasia with regenerative atypia.<sup>130</sup> Bile duct mucosal dysplasia without carcinoma can also be found frequently.<sup>131</sup> Additionally, metaplastic changes, such as mucous cells, goblet cells, and Paneth cells can be seen. Hyperplasia and metaplasia increase with age and can progress to carcinoma in adults. These changes are seen in all types of choledochal cyst.<sup>132</sup>

The gallbladder mucosa in patients with PBMU shows cholecystitis, cholesterosis, adenomyosis or adenomyomatosis, polyp including adenoma, and epithelial hyperplasia. The gallbladder mucosa in FFCC is characterized by diffuse epithelial hyperplasia, with or without metaplasia of the pyloric glands, goblet cells, and Paneth cells.

## Diagnosis

For the diagnosis of choledochal cyst, it is important to detect not only dilatation of the extrahepatic bile duct but also PBMU.

Currently, abdominal ultrasonography is probably the best screening method in patients who are suspected of having choledochal cyst. In recent years, the number of patients who are diagnosed by antenatal ultrasonography is increasing. Ultrasonography also clearly demonstrates IHBD dilatation and the state of the liver parenchyma.

Preoperatively, endoscopic retrograde cholangiopancreatography (ERCP) can accurately visualize the configuration of the pancreaticobiliary ductal system in fine detail. However, it is invasive and therefore unsuitable for repeated use and is contraindicated during acute pancreatitis.

Magnetic resonance cholangiopancreatography (MRCP) can provide excellent visualization of the pancreaticobiliary ducts, allowing detection of narrowing, dilatation, and filling defects with medium to high degrees of accuracy (Fig. 44-12).<sup>133,134</sup> MRCP is

**Figure 44-12.** Magnetic resonance cholangiopancreatography in a patient with a choledochal cyst, showing fusiform dilatation of the extrahepatic bile duct, long common channel (between arrows), protein plugs (arrowheads), and pancreatic duct. (From Miyano T, Yamataka A: Choledochal cysts. *Curr Opin Pediatr* 9:285, 1997.)

noninvasive and can be useful for delineating the pancreatic and biliary ducts proximal to an obstruction. However, in children younger than 3 years, MRCP may not visualize the pancreaticobiliary ductal system because of the small caliber. Percutaneous transhepatic cholangiography is also available, especially for patients with IHBD dilatation and severe jaundice. Also, intraductal ultrasonography has been applied successfully to delineate the distal parts of the CBD and pancreatic duct, which is useful for diagnosing choledochal cyst.<sup>135</sup>

Intraoperative cholangiography is unnecessary if the entire biliary system has been delineated before cyst excision, but it should be used if the pancreaticobiliary ductal system has not been completely visualized.

## Treatment

Cyst excision is the definitive treatment of choice for choledochal cyst because of the high morbidity and high risk for carcinoma after internal drainage, a commonly used treatment in the past. Recently, more attention has been paid to the treatment of intrahepatic and intrapancreatic ductal diseases such as IHBD dilatation, focal stenosis, debris in the IHBD, and protein plugs or stones in the common channel.<sup>136,137</sup> The transection level of the common hepatic duct and excisional level of the intrapancreatic bile duct also are highly controversial.<sup>136,138</sup>

### The Common Bile Duct

Usually more adhesions are found between a saccular choledochal cyst, the portal vein, and hepatic artery than with a fusiform choledochal cyst, especially in older children. In adolescents and adults, adhesions are often very dense and great care is required during cyst excision.

Before excision, we always open the anterior wall transversely (Fig. 44-13). After opening the anterior wall, the posterior wall is visible from the inside, facilitating the dissection of the portal triad. If the cyst is extremely inflamed and the adhesions are very dense, mucosectomy of the cyst (Figs. 44-14 and 44-15) should be performed rather than attempting full-thickness dissection to minimize the risk for injuring the portal vein and hepatic artery.

### The Distal Common Bile Duct

To prevent postoperative pancreatitis or stone formation, or both, in a remnant cyst, the caudal CBD should be resected as close as possible to the pancreaticobiliary ductal junction. In saccular choledochal cyst, the caudal CBD is sometimes so narrow that it cannot be identified and it is quite unlikely that a residual cyst will develop within the pancreas. In contrast, in fusiform choledochal cyst, delineation of the diseased duct is more difficult, because the caudal CBD is still wide at the pancreaticobiliary ductal junction and the likelihood of leaving some remnant of the CBD is high. If the caudal CBD is resected along line 1 shown in

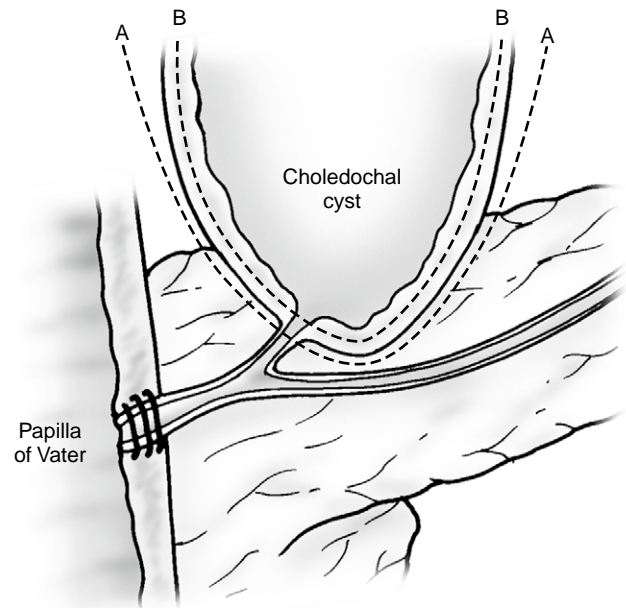

**Figure 44-13.** Schema showing transection of a choledochal cyst. (From Miyano T: Congenital biliary dilatation. In Puri P [ed]: *Newborn Surgery*. Oxford, UK, Butterworth-Heinemann, 1996, p 436.)

Figure 44-16, over time a cyst will re-form around the distal CBD left within the pancreas, leading to recurrent pancreatitis, stone formation, or malignancy in the residual cyst (Fig. 44-17). In contrast, if the distal duct is resected along line 2 in Figure 44-16, just above the pancreaticobiliary ductal junction, cyst re-formation due to residual duct within the pancreas is unlikely.<sup>120</sup>

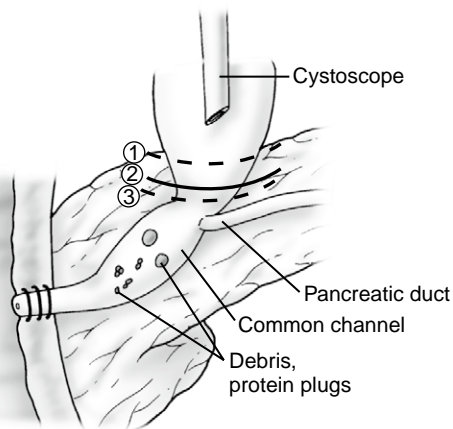

**Figure 44-14.** If there is significant inflammation surrounding the choledochal cyst that precludes mobilization of the cyst from the hepatic artery and portal vein posteriorly, mucosectomy of the distal portion of the cyst is an alternate operative technique.

**Figure 44-15.** Operative technique for excision of the distal portion of choledochal cyst. A, full-thickness layer; B, mucosectomy layer. (From Miyano T: Congenital biliary dilatation. In Puri P [ed]: *Newborn Surgery*. Oxford, UK, Butterworth-Heinemann, 1996, p 437.)

Before the introduction of intraoperative endoscopy, it was difficult to excise the pancreatic portion of a fusiform choledochal cyst completely and safely because of the risk for injury to the pancreatic duct. Endoscopy now allows safe excision of most of the wall of a fusiform choledochal cyst in the pancreas without damaging the pancreatic duct. We believe this reduces the risk for postoperative complications.

**Figure 44-16.** Diagram of intraoperative endoscopy of the bile duct distal to a cyst with debris and protein plug. After identification of the orifice of the pancreatic duct, the cyst is excised. Level 1, High likelihood of leaving some residual cyst. Level 2, Adequate excision level of the cyst. Level 3, High likelihood of injuring the pancreatic duct. (From Miyano T, Yamataka A, Long Li: Congenital biliary dilatation. *J Pediatr Surg* 9:190, 2000.)

### The Proximal Common Bile Duct

The common hepatic duct is transected at the level of distinct caliber change. Because any remaining proximal cyst mucosa is prone to malignant changes, care must be taken to excise it completely, especially when a large anastomosis is performed (Fig. 44-18).

Dilatation of the peripheral IHBD in patients with choledochal cyst may be associated with late complications such as recurrent cholangitis, stone formation, and anastomotic stricture. Severe dilatation of the IHBD can be managed by segmentectomy of the liver, intrahepatic cystoenterostomy, or balloon dilatation of a stenotic lesion at the time of cyst excision.<sup>139-142</sup> However, the incidence of late complications appears to be low, especially in younger children, so such excessive surgical intervention may be unnecessary, except in specific cases. If IHBD dilatation persists after definitive surgery, careful follow-up is mandatory.

Intraoperative endoscopy is also useful for examining for the presence of debris in the dilated IHBD (Fig. 44-19). Recently, we found a high incidence of IHBD debris that was not detected by preoperative radiologic investigations, and some debris that had been shown in preoperative studies that had been overlooked.<sup>143</sup> These facts indicate that intraoperative endoscopy is extremely useful at the time of cyst excision. Another striking finding was that this debris could be present even in the absence of IHBD dilatation, although this was uncommon. We believe endoscopic inspection of the IHBD to be so valuable that it should be a routine part of the operative treatment of choledochal cyst.

### The Anastomosis

An end-to-end anastomosis of the jejunum to the cephalad remnant of the CBD is recommended if the ratio between the diameters of the CBD and the proximal Roux-en-Y jejunum is less than or equal to 1 (common hepatic duct) to 2.5 (jejunum) (Fig. 44-20). If the

**Figure 44-17.** Endoscopic retrograde cholangiopancreatography showing stones (arrows) in the residual intrapancreatic terminal choledochus after excision of fusiform-type choledochal cyst. (From Yamataka A, Ohshiro K, Okada Y, et al: Complications after cyst excision with hepaticoenterostomy for choledochal cyst and their surgical management in children versus adults. *J Pediatr Surg* 32:1099, 1997.)

**Figure 44-18.** Diagrams of intraoperative endoscopy of the bile duct proximal to a cyst. **A**, Ideal level of resection of the common hepatic duct is safely determined without injuring the orifices of the intrahepatic duct and without leaving any redundant common hepatic duct. **B**, Stenosis of the common hepatic duct near the hepatic hilum is safely excised, and a wide anastomosis is made. Level 1, Adequate level of resection of the common hepatic duct. Level 2, Inadequate level of resection. (From Miyano T, Yamataka A, Long Li: Dilatation of the intrahepatic duct. *Semin Pediatr Surg* 9:187-195, 2000.)

**Figure 44-19.** Massive debris in the intrahepatic bile duct observed through the pediatric cystoscope. (From Shima H, Yamataka A, Yanai T, et al: Intracorporeal electrohydraulic lithotripsy for intrahepatic bile duct stone formation after choledochal cyst excision. *Pediatr Surg Int* 20:70-72, 2004.)

biliary duct is too small, then an end-to-side anastomosis is preferred. The anastomosis should be as close as possible to the closed end of the jejunal limb (see Fig. 44-20, inset). An end-to-side anastomosis that is performed away from the closed end of the proximal jejunum will allow a blind pouch to form as the child grows (Fig. 44-21). Bile stasis in the blind pouch can lead to intrahepatic stone formation, especially if the intrahepatic ducts are dilated. We believe that using an end-to-end hepaticojejunostomy and our end-to-side jejunojejunostomy technique will help prevent both stone formation and ascending cholangitis.

Some surgeons predetermine the length of the Roux-en-Y jejunal limb without considering the size of the child. This causes the Roux-en-Y jejunal limb to be unnecessarily long, especially in infants and younger children. Redundancy of the Roux limb is likely as the patient grows. This leads to bile stasis in the limb itself which, in turn, leads to cholangitis or stone formation. Construction of the Roux-en-Y as shown (see Fig. 44-20) should prevent redundancy of the Roux limb. We recommend securing the jejunal limb from the ligament of Treitz to the Roux limb in a side-to-side fashion for about 8 cm proximal to the end-to-side anastomosis to ensure smooth flow of bile and bowel contents distally. Without using this technique, the jejunojejunostomy will tend to be T shaped, promoting reflux of jejunal contents into the Roux limb, a situation we recently encountered in a patient who had surgery elsewhere (see Fig. 44-21).<sup>144</sup>

### Laparoscopic Surgery

In 1995, the first laparoscopic choledochal cyst excision in a child was reported.<sup>145</sup> Since then, the number of reports has increased. Intraoperative bile duct endoscopy

can also be performed laparoscopically.<sup>146</sup> Recently, robot-assisted laparoscopic resections of choledochal cyst have been reported by several centers.<sup>147,148</sup>

### Results

Satisfactory surgical outcome with low morbidity in the short to mid-term is expected in patients after cyst excision. However, in the long term, many complications have been reported and careful long-term follow-up is mandatory.

In an American survey in 1981, 14 of 198 patients with choledochal cyst were reported to have died of biliary atresia, cholangitis with sepsis, hepatic failure, or carcinoma.<sup>149</sup> Other late and serious complications were cholangitis, obstructive jaundice, pancreatitis, stone formation, and portal hypertension. Thirty-six patients had been lost to follow-up, and only 115 patients were alive without liver disease.

In 1997, we reported 200 children who were 15 years old or younger at the time of cyst excision.<sup>129</sup> The onset of symptoms was 5 years or earlier in 175 children and between 6 and 15 years in the remaining 25 children. The mean age when initial symptoms began was 3 years. The mean age at cyst excision was 4.2 years. Primary cyst excision was performed in 176 children, 5 had cyst excision converted from internal drainage,

**Figure 44-20.** Adequate Roux-en-Y hepaticojejunostomy at the time of cyst excision. *Arrowheads*, Approximated native jejunum and distal Roux-en-Y limb. *Arrows*, Smooth flow without reflux of small bowel contents. (From Yamataka A, Kobayashi H, Shimotakahara A, et al: Recommendations for preventing complications related to Roux-en-Y hepaticojejunostomy performed during excision of choledochal cyst in children. *J Pediatr Surg* 38:1830-1832, 2003.)

**Figure 44-21.** Inadequate Roux-en-Y hepaticojejunostomy at the time of cyst excision. Note hepaticojejunostomy far from the closed end of the blind pouch (arrowhead). Double arrows in the inset, Elongation of the blind pouch. Shaded arrow, Reflux of jejunal contents into the Roux-en-Y limb through a T-shaped Roux-en-Y jejunojejunostomy. (From Yamataka A, Kobayashi H, Shimotakahara A, et al: Recommendations for preventing complications related to Roux-en-Y hepaticojejunostomy performed during excision of choledochal cyst in children. *J Pediatr Surg* 38:1830-1832, 2003.)

and 19 had cyst excision converted from other biliary surgery such as percutaneous transhepatic cholangio-drainage, T-tube drainage, and cholecystectomy. Intra-operative endoscopy was performed in 70 children. The mean follow-up period was 10.9 years. Roux-en-Y hepaticojejunostomy was performed in 188 patients, 11 had standard hepaticoduodenostomy, and 1 had a jejunal interposition hepaticoduodenostomy. There was no operative mortality. Eighteen (9%) children had 25 complications after cyst excision, including ascending cholangitis, intrapancreatic terminal CBD calculi, pancreatitis, and bowel obstruction (Table 44-2). Fifteen of the 18 children required further surgical intervention such as revision of the hepaticoenterostomy, percutaneous transhepatic cholangioscopic lithotomy, excision of the residual intrapancreatic terminal CBD, endoscopic sphincterotomy, pancreaticojejunostomy, or laparotomy for bowel obstruction. Neither stone formation, anastomotic stricture, nor cholangitis was seen in the 70 children who had intraoperative endoscopy. No malignancy was found.

In patients who underwent cyst excision when aged 5 years or younger, no major complications such as intrahepatic stones, intrapancreatic terminal CBD calculi, or stricture of the hepaticoenterostomy were seen. Thus, early diagnosis followed by cyst excision and intraoperative endoscopy is extremely important to prevent postoperative complications.

Even after primary cyst excision, malignancy can arise from the intrapancreatic terminal CBD,<sup>150</sup> the hepaticojejunostomy anastomosis site,<sup>151</sup> and the IHBD.<sup>152</sup> Of the 40 adult patients in our series who had cyst excision at age 16 years or older, 2 died of cholangiocarcinoma. One of these patients had had primary cyst excision at 25 years of age.

**Table 44-2** Complications after Cyst Excision in Children versus Adults

Incidence in 200 Children	Complication	Incidence in 40 Adults
3	Ascending cholangitis	9
3	Intrahepatic bile duct stones	5
3*	Intrapancreatic terminal choledochus calculi	1
1	Pancreatic duct calculus	1
1*	Stones in the blind pouch of the end-to-side Roux-en-Y hepaticojejunostomy	0
9†	Bowel obstruction	3‡
0	Cholangiocarcinoma	2
0	Liver dysfunction	1
5	Pancreatitis	5
25 (18)	TOTAL	27 (17)

Note: The numbers in parentheses indicate the patients who had complications after cyst excision (18 children and 17 adults had 25 and 27 complications after cyst excision, respectively).

\*One patient with intrapancreatic terminal choledochus calculi also had a stone in the blind pouch of the end-to-side hepaticojejunostomy.

†Adhesions in 6 patients and intussusception in 3 patients.

From Yamataka A, Ohshiro K, Okada Y, et al: Complications after cyst excision with hepaticoenterostomy for choledochal cysts and their surgical management in children versus adults. *J Pediatr Surg* 32:1098, 1997, with permission.

In the past 18 years, we have performed a total of 92 Roux-en-Y hepaticojejunostomies (70 end-to-end and 22 end-to-side) by using our cyst excision technique with intraoperative endoscopy and the Roux-en-Y hepaticojejunostomy technique mentioned previously. We reviewed these patients after a mean follow-up period of 8.0 years (range: 9 months to 16 years), and there were no major complications.<sup>144</sup>

## OTHER BILIARY TRACT DISORDERS

### Biliary Hypoplasia

Biliary hypoplasia is a lesion characterized by an exceptionally small but grossly visible and radiographically patent extrahepatic biliary duct system. The diagnosis is made at the time of surgical exploration for the investigation of jaundice in infancy. Biliary hypoplasia is not a specific disease entity but a manifestation of a variety of hepatobiliary disorders: neonatal hepatitis,  $\alpha_1$ -antitrypsin deficiency, intrahepatic biliary atresia, Alagille syndrome, and nonsyndromic paucity of IHBDs. Biliary hypoplasia cannot be improved by surgical maneuvers. The prognosis is highly variable and depends on the primary disease. Some patients die in infancy and others live to adolescence, often with jaundice, pruritus, and stunted growth. Still, others recover fully.

Alagille syndrome is a genetic defect that results in a typical constellation of features: peculiar facies with a high, prominent forehead and deep-set eyes, chronic cholestasis, posterior embryotoxon, butterfly-like vertebral arch defects, and heart disease (usually peripheral pulmonary stenosis) (Fig. 44-22). These patients

often respond to supportive measures such as treatment with ursodeoxycholic acid and phenobarbital.<sup>153</sup> They often have hypercholesterolemia and may eventually require liver transplantation because of ongoing hepatic scarring and the development of hepatocellular carcinoma.

Nonsyndromic paucity of bile ducts may be associated with liver changes similar to those seen in Alagille syndrome but without the associated findings. Treatment is similar for both conditions.

### Idiopathic Perforation of Bile Ducts: Bile Ascites

Bile ascites typically is first seen with gradually worsening abdominal distention and jaundice in a neonate. The disease may be associated with an episode of sepsis or ABO blood group incompatibility. More typically, it is an isolated finding, probably related to duct malformation. Although the almost universal site of perforation is at the junction of the cystic duct with the CBD, spontaneous rupture of the intrahepatic duct has been also reported, especially at the left IHBD.<sup>154</sup> The diagnosis is made by hepatobiliary scan, demonstrating radioactivity in the free peritoneal cavity. There is a report that radiologic demonstration of the degree of leakage by ERCP is useful and that internal stenting can be performed laparoscopically.<sup>155</sup>

At operation, sterile bile ascites and bile staining are found. An operative cholangiogram should be performed throughout the gallbladder. The lesion is usually self-limiting, and the perforation seals with drainage. Aggressive surgical intervention is not indicated because the small, delicate, presumably

**Figure 44-22.** This photograph shows an infant with Alagille syndrome. Note the high prominent forehead and deep-set eyes.

congenitally weakened bile duct may be further damaged during attempts at anastomosis.<sup>156</sup>

## Gallbladder Disease

Gallbladder disease in children is being diagnosed with increasing frequency. This is related both to increased detection associated with more widespread use of routine ultrasonography and to an increased incidence secondary to dietary changes that have developed. Biliary dyskinesia is being diagnosed more frequently in the pediatric population, and these patients do well with laparoscopic cholecystectomy.<sup>157,158</sup> Gallbladder disease also may develop in infants supported with total parenteral nutrition.

### *Hydrops of the Gallbladder*

Acute distention with edema in the wall of the gallbladder has been reported in association with a number of septic or shock-like states, including Kawasaki disease, severe diarrhea with dehydration, hepatitis, scarlet fever, familial Mediterranean fever, leptospirosis, and mesenteric adenitis. Hydrops is suspected if a palpable mass of the gallbladder is confirmed by ultrasonography. In most cases, hydrops resolves spontaneously. If symptoms intensify, cholecystectomy may be necessary.<sup>159</sup>

### *Acalculous Cholecystitis*

Hydrops and acalculous cholecystitis are probably manifestations of the same disease entity and usually arise after a patient has been resuscitated from a state of primary sepsis or shock. Presumably, asymptomatic hydrops of the gallbladder then develops and becomes secondarily infected. Patients are often intubated in an intensive care unit setting, so early manifestations of the disease are not evident. The most common presentation is one of deterioration and signs of sepsis in a previously stable patient. If suspected, the diagnosis can be confirmed by ultrasonography, which demonstrates gallbladder distention and intraluminal echogenic debris. Hepatobiliary scans show nonfunction of the gallbladder. Treatment in mild cases can be conservative with antibiotics. However, if the patient's condition deteriorates, cholecystectomy is indicated. In patients who are very ill, percutaneous or open cholecystostomy may be a useful temporary measure.

### *Hemolytic Cholelithiasis*

Historically, the usual cause of gallstones in children has been hemolytic disease. Hereditary spherocytosis, sickle cell anemia, and thalassemia are the most common hemolytic disorders resulting in the development of gallstones. Jaundice also may occur intermittently because of hemolysis and therefore does not necessarily mean that common duct calculi are present. In patients with spherocytosis, ultrasonography is recommended before splenectomy. Demonstration of stones dictates that simultaneous cholecystectomy should be performed. In sickle cell disease, the incidence of

stones progresses from 10% to 55% as the child grows older. Unless symptomatic, cholecystectomy is currently not recommended for children with sickle cell disease, unless symptomatic. Also, cholecystectomy should be performed electively rather than as an emergency procedure during a hemolytic crisis.<sup>160</sup> In the past, partial exchange transfusion was performed before operation to reduce the hemoglobin S level to less than 40%. Alternatively, preoperative transfusion to a hemoglobin of 10 mg/dL is currently being utilized in many centers. In patients with thalassemia major, the incidence of gallstones has now dropped to 2% to 3% because of hypertransfusion regimens.

### *Cholesterol Cholelithiasis*

Cholesterol gallstones appear to occur in children and adolescents because of the same pathophysiologic disturbances that cause such stones in adults. In most North American institutions, the incidence is increasing and has come to surpass hemolytic disease as the leading cause of cholelithiasis in pediatric patients. The typical patient is a markedly obese young girl. The clinical symptoms are usually vague abdominal pain and minimal physical findings. The classic history of fatty food intolerance is often not present. The diagnosis is usually made at ultrasonography, and the treatment is typically laparoscopic cholecystectomy. Cholesterol stones can occur in infants on prolonged total parenteral nutrition or after ileal resection. Cholecystectomy is still the treatment of choice, although these patients typically have had multiple previous operations and laparoscopy may be more difficult.

### *Congenital Deformities*

A variety of abnormal configurations and locations of the gallbladder such as gallbladder agenesis, duplication, bi-lobation, floating gallbladder, diverticula, and ectopia have been reported. They are usually of no real clinical relevance unless they impair gallbladder emptying. In such cases, calculi are frequent and treatment is almost always cholecystectomy.

## PORTAL HYPERTENSION

Portal hypertension in children produces some of the most uniquely challenging problems encountered in clinical pediatric practice. Although the predictable consequences of increased pressure in the portal system (bleeding esophageal varices, hypersplenism, and ascites) are the same in adults and children, their etiology, outcome, and appropriate management are very different. For example, the onset of bleeding esophageal varices in an adult is often a preterminal event or, at best, a grave prognostic indicator of impending clinical deterioration. In children, at least half of all esophageal variceal bleeding occurs as an isolated, albeit life-threatening, problem in a setting of normal liver metabolism in which portal hypertension has resulted from portal vein thrombosis. Even when portal hypertension has

resulted from cirrhosis, the overall outcome in children is much better than in adults. For these reasons, palliation per se is almost never the treatment goal in children. Rather, the aim is for growth, development, and improvement in quality and length of life. Modern therapeutic management of isolated manifestations of portal hypertension should not limit any chance a child has for liver transplantation. As a result, treatment has moved increasingly away from shunting toward non-shunt management, such as esophageal variceal endosclerosis, splenic embolization, vigorous nutritional support, and diuretics.

## Pathophysiology

Portal hypertension results from an increase in resistance to venous flow through the liver. The site of obstruction is categorized anatomically as being prehepatic, intrahepatic, or suprahepatic. Prehepatic causes of portal hypertension are relatively unique to the pediatric age group, and hepatic parenchymal function is well maintained. Moreover, coagulopathy plays no role in the bleeding episodes. Intrahepatic and suprahepatic causes typically have associated liver dysfunction, which increases the risk for bleeding resulting from coagulopathy, increases the formation of ascites, and affects all aspects of a patient's care.

The hemodynamic effects of portal venous obstruction are complex. In experimental animals, it has been shown that, in addition to portal venous obstruction, an increase in mesenteric arterial flow is required to cause an increase in portal venous pressure.<sup>161</sup> The interplay of these hemodynamic changes, coupled with the development of collateral vessels in the growing child, makes any prediction of long-term outcome after therapy difficult and emphasizes the importance of long-term follow-up.

### Prehepatic Obstruction

In the past, portal vein thrombosis was the most common cause of portal hypertension in children.<sup>162</sup> Now, with extended survival achieved through operative bile drainage in children with choledochal cyst, intrahepatic obstruction (hepatic fibrosis) nearly equals portal vein thrombosis as a cause for portal hypertension in children.<sup>163</sup> Portal vein thrombosis may result from perinatal omphalitis, cannulation of the umbilical vein in the newborn period, intra-abdominal sepsis, or dehydration. However, in more than half the cases, no causal event is known. In contrast to those with cirrhosis, patients with portal vein thrombosis usually have normal liver synthetic function (bilirubin, prothrombin time, albumin), but manifestations of portal hypertension (variceal hemorrhage and hypersplenism) are pronounced.

### Intrahepatic Obstruction

Biliary atresia is the single most common cause of intrahepatic obstruction leading to portal hypertension in children. Even when bile drainage is achieved,

histopathologic studies show that the liver is affected by hepatic fibrosis of varying degrees, even in the newborn period. Approximately one third of patients with choledochal cyst with successful bile drainage do well, have normal liver function, and continue normal growth and development. The remaining two thirds have clinical evidence of liver disease, with half requiring liver transplantation to survive, and the other half growing, but with clinical or laboratory manifestations of liver dysfunction. In the last group, postsinusoidal obstruction is the result of hepatic venous compression by regenerating nodules.

Congenital hepatic fibrosis may occur as an isolated disease of the liver characterized by hepatosplenomegaly that becomes manifest at age 1 to 2 years or in association with multiple forms of kidney disease, the most common of which is infantile polycystic disease. The disease is defined histopathologically by the presence of linear fibrous bands within the liver that result in pre-sinusoidal obstruction. Although hepatomegaly is present, no stigmata of chronic liver disease are seen. In the liver, the parenchyma is spared (pre-sinusoidal obstruction), hepatocellular function is preserved, and serum bilirubin, transaminase, and alkaline phosphatase levels, and prothrombin time are usually normal. Portal hypertension is the most frequent complication of congenital hepatic fibrosis.<sup>164</sup> Often, children are first seen with hepatosplenomegaly and frequently have bleeding esophageal varices.

Other causes of intrahepatic portal hypertension in children include focal biliary cirrhosis,  $\alpha_1$ -antitrypsin deficiency, chronic active hepatitis, and complications secondary to irradiation or chemotherapy. The incidence of focal biliary cirrhosis with portal hypertension occurring in patients with cystic fibrosis ranges from 0.5% to 8% in children and from 5% to 20% in adolescents and young adults.<sup>165</sup>

### Suprahepatic Obstruction

Obstruction of the hepatic veins (Budd-Chiari syndrome) is a rare cause of portal hypertension in children. This syndrome may be seen in association with coagulation disorders, use of oral contraceptives, malignant disease, autoimmune disorders, and hepatic vein webs. The course is typically insidious, with a long interval between the onset of hepatomegaly, abdominal pain, and ascites and the recognition of the syndrome. If symptoms develop urgently, they can be associated with sudden severe liver enlargement and liver damage with central lobular congestion and necrosis.

## Clinical Presentations

Variceal hemorrhage occurs most commonly from the distal esophagus. Increased portal pressure leads to dilation of the portosystemic collateral veins, the most important of which link the coronary vein to the short gastric vein and the submucosal plexus of the lower esophagus. As blood flow through the system increases, esophageal varices develop and can be

frighteningly large. The typical presentation is one of vomiting bright red blood, but melena also may occur. Retroperitoneal, periumbilical, and hemorrhoidal collaterals also develop. Although these can be large, they do not tend to cause significant bleeding.

After control of an acute hemorrhage, the cause for the bleeding (i.e., portal hypertension) is sought. In a patient without stigmata of liver disease, portal vein thrombosis is by far the most likely diagnosis. Physical examination typically shows an enlarged spleen and a normal-sized liver. Doppler ultrasound imaging is nearly 100% diagnostic. In contrast, patients with concurrent liver disease usually have signs of liver failure, and the liver is almost always firm and enlarged, with associated malnutrition, splenomegaly, ascites, and jaundice.

Occasionally, splenomegaly and hypersplenism are the first signs of portal hypertension in children. Splenic size does not correlate with the degree of venous pressure elevation, but the hematologic effects of hypersplenism do correlate with the size of the spleen. All formed blood elements may be affected. Long-standing portal hypertension can cause splenic fibrosis, which then reduces the hematologic consequences. This also makes the effects of subsequent shunting less efficacious.

## Diagnosis and Treatment

The initial management of upper gastrointestinal hemorrhage is the same regardless of etiology and involves fluid-volume resuscitation, nasogastric tube placement for gastric lavage, and stabilization. Accurate monitoring of cardiovascular parameters and urine output and frequent laboratory determination of blood counts necessitate an intensive care setting. Balloon tamponade with a Sengstaken-Blakemore tube may be necessary initially to control the hemorrhage, and children often require tracheal intubation, sedation, and ventilation. Once the patient's condition has stabilized, endoscopic and Doppler ultrasonography are used to delineate the status of the portal vein. Ultrasonography can accurately document portal venous

thrombosis as well as cirrhosis with hepatofugal flow and can quantify arterial inflow. Liver function tests document hepatic functional status. Esophagoscopy can be performed electively to document clinical status and for therapeutic purposes.

Endoscopic varix sclerosis in children requires deep sedation and tracheal intubation. Short-term results are typically excellent in experienced hands.<sup>166</sup> Patients with acute hemorrhage are re-injected every 2 to 3 days until bleeding ceases. Patients who are not actively bleeding should have repeated endoscopy at 6-week intervals until all varices are obliterated. Nearly complete control of bleeding can be achieved using this regimen. Minor complications include superficial esophageal ulceration, pleural effusion, and atelectasis. Occasionally, very serious complications of varix injection can occur. These include esophageal stricture, perforation, spinal cord paralysis, systemic venous thrombosis, and respiratory distress syndrome related to the use of excessive volumes of sclerosant.<sup>167,168</sup>

An alternative to sclerosants is band ligation of esophageal varices. It is just as effective for controlling bleeding and has fewer systemic complications (Fig. 44-23).<sup>169</sup> Therapeutic endoscopic variceal clipping is now widely used to control hemorrhage secondary to portal hypertension in elective or emergency conditions, even in the case of rupture.<sup>170</sup>

Other therapy after acute esophageal bleeding is dependent on the underlying pathophysiology. Portal hypertension resulting from intraparenchymal liver disease most likely will require liver transplantation. Evaluation for transplantation has usually already started, and variceal bleeding usually expedites assessment of these patients. Conversely, if patients are found to have good liver function with either suprahepatic or portal venous obstruction, other surgical interventions may be more appropriate. For patients who have a prehepatic cause for portal hypertension, shunt therapy should be considered after the first hemorrhage and is specifically indicated if repeated bleeding occurs despite sclerotherapy.<sup>171,172</sup> Because these patients typically have good liver function, the incidence of post-shunt encephalopathy is low.<sup>173,174</sup> Selective

**Figure 44-23.** Endoscopic variceal ligation. A, Preoperative photograph. B, Ligation with rubber band. C, Postoperative photograph.

splenorenal shunting also is a satisfactory option.<sup>175</sup> However, the increased complexity of this procedure, coupled with the observations that most children at the time of shunt surgery already have hepatofugal flow in the portal vein, and the fact there is loss of selectivity of the distal splenorenal shunt over time usually work against its use in pediatric patients.<sup>176</sup>

Of special consideration are those patients who bleed from varices in the stomach, small bowel, or colon. These vessels are not amenable to sclerotherapy. Thus, these patients may require earlier intervention with shunt therapy. In 1998, a new operative technique using direct bypass of an extrahepatic portal venous obstruction (a cavernoma) was described.<sup>177</sup> In this procedure, the obstructive lesion was bypassed by interposing a venous jugular autograft between the superior mesenteric vein and the distal portion of the left portal vein (Rex shunt). Although this procedure is restricted to those patients in whom the intrahepatic left portal branch can be confirmed to be patent by Doppler ultrasonography, it is certainly an option and may be utilized more frequently in the future.

Long-standing splenomegaly is occasionally accompanied by clinically significant hypersplenism. Because of the recognized hazard of postsplenectomy sepsis in children, embolization methods aimed at eliminating hypersplenism while conserving splenic immune function have been developed. Maddison was the first to perform embolization for hypersplenism in 1973.<sup>178</sup> Since then, improvements in materials and methods have made splenic embolization the treatment of choice for hypersplenism in children. The

technique usually involves injection of surgical gel particles until 60% to 80% splenic infarction has been achieved. The immediate postembolization morbidity rate is high, with fever and pain being present in all children. Ileus, pleural effusion, and atelectasis also are common. However, major complications such as splenic rupture and splenic abscess are rare, and post-splenectomy sepsis has not developed with long-term follow-up.<sup>179</sup>

---

## ASCITES

Children can have severe ascites, typically associated with end-stage liver disease, and portal hypertension. Ascites may contribute to respiratory embarrassment because of elevation of the diaphragm and to malnutrition because of protein loss. Occasionally, chylous ascites may develop as a result of portal hypertension and liver disease. Long-term total parenteral nutrition and the use of somatostatin analogs reduce the volume of fluid produced.<sup>180</sup> Conservative management consists of dietary sodium and water restriction, spironolactone, furosemide, and periodic paracentesis. In the absence of infection in the ascitic fluid, coagulopathy, and primary cardiac failure, peritoneovenous shunt procedures can return the ascitic fluid to the circulating blood volume, but this is rarely performed in the pediatric age group. Most patients with refractory ascites require liver transplantation, and therapy should be directed at preparing the patient for that procedure.

# SOLID ORGAN AND INTESTINAL TRANSPLANTATION

Frederick C. Ryckman, MD • Maria H. Alonso, MD • Jaimie D. Nathan, MD • Greg Tiao, MD

The ability to undertake successful solid organ transplantation in children has led to a remarkable improvement in survival and quality of life. Although the vast majority of solid organ transplant recipients are adults, the innovative techniques that have been developed to meet the challenges of pediatric transplantation and the unique demands of immunosuppression in infancy continue to be a forum for the advancement of transplant care. In this chapter we examine each of the solid organ transplant procedures with their indications, operative procedures, and postoperative complications that are relevant to the practicing pediatric surgeon.

## LIVER TRANSPLANTATION

Few subspecialties have undergone the dramatic improvements in survival that have occurred in pediatric liver transplantation. In the early 1980s, survival rates of 30% limited the enthusiasm for this costly and work-intensive operation. The introduction of more effective immunosuppression along with refinements in the operative and postoperative management of infants and children improved survival rates to greater than 90%. When compared with the universally fatal outcome these patients would experience without transplantation, it is not surprising that liver transplantation has been embraced as the preferred therapy for several conditions.

Along with this improved survival rate has come an increasing need for donor organs suitable for pediatric recipients of all ages and sizes. This wide spectrum of needs, coupled with the national shortage of transplant donor organs, has stimulated the pioneering development of surgical procedures such as reduced-size liver transplantation, "split-liver" transplantation, and living donor (LD) liver transplantation. However, the excellent survival and organ availability offered by the complementary use of these transplant options cannot

overshadow the need for comprehensive evaluation and selective application of liver transplantation.

## Indications

The primary aim of the evaluation process is to define which patients require or would benefit from orthotopic liver transplantation (OLT) and when such therapy should be undertaken. Evaluation is directed toward the identification of (1) progressive deterioration of hepatocellular function, (2) portal hypertension and gastrointestinal bleeding, and (3) nutritional and growth failure. Referral for transplantation should occur when progressive deterioration is noted and before the development of life-threatening complications.

The most common clinical presentations prompting transplant evaluation in children can be classified as follows: (1) primary liver disease with the expected outcome of hepatic failure, (2) stable liver disease with significant morbidity or known mortality, (3) hepatic-based metabolic disease, (4) fulminant hepatic failure, and (5) hepatic malignancy, particularly hepatoblastoma, when the lesion is not resectable by conventional means. In addition, children with diffuse and extensive arteriovenous anomalies or benign vascular tumors leading to irreversible heart failure should also be considered for hepatectomy and transplantation.

Table 45-1 reviews the primary diagnoses leading to pediatric liver transplantation. These disease entities define a bimodal age distribution of pediatric transplant recipients. Infants and children with biliary atresia and, occasionally, rapidly progressive hepatic failure secondary to metabolic abnormalities, such as neonatal tyrosinemia and hemochromatosis, or neonatal hepatic vascular tumors are the patients who may require transplantation early in life. Patients with metabolic disturbances, fulminant hepatic failure, and cirrhosis present as older children and adolescents requiring OLT.

**Table 45-1** Indications for Liver Transplantation at Cincinnati Children's Hospital Medical Center, 1986-2007

Primary Diagnosis	No. Patients	% Total
Biliary atresia	173	42.5
Fulminant liver failure	62	15.2
$\alpha_1$ -Antitrypsin deficiency	38	9.3
Hepatoblastoma/tumor	16	3.9
Cryptogenic cirrhosis	16	3.9
Alagille syndrome	11	2.7
Tyrosinemia	11	2.7
Autoimmune hepatitis	11	2.7
Urea cycle defects	10	2.5
Primary sclerosing cholangitis	10	2.5
Glycogen storage disease	5	1.2
Neonatal hepatitis	5	1.2
TPN cholestasis/short gut	5	1.2
Primary hyperoxaluria	4	1.0
Cystic fibrosis	3	0.7
Wilson's disease	3	0.7
Gastroschisis	2	0.5

### Biliary Atresia

Children with extrahepatic biliary atresia constitute about 50% of the pediatric liver transplant population. Successful biliary drainage achieving an anicteric state after the Kasai portoenterostomy is the most important factor affecting preservation of liver function and long-term survival. Primary transplantation without portoenterostomy is not recommended in patients with biliary atresia unless the initial presentation is at more than 120 days of age and the liver biopsy shows advanced cirrhosis.<sup>1,2</sup> We believe that the Kasai portoenterostomy should be the primary surgical intervention for all other infants with extrahepatic biliary atresia. Patients with progressive disease after a Kasai procedure should be offered early OLT. The sequential use of these two procedures optimizes overall survival and organ use.<sup>2</sup>

Patients with extrahepatic biliary atresia who are seen for transplantation form several cohorts. Infants with a failed Kasai procedure have recurrent bacterial cholangitis, ascites, rapidly progressive portal hypertension, malnutrition, and progressive hepatic synthetic failure. Most require OLT within the first 2 years of life. Children with the successful establishment of biliary drainage have an improved prognosis, but

this alone does not preclude the development of progressive cirrhosis, with eventual portal hypertension, hypersplenism, variceal hemorrhage, and ascites formation. These patients are seen in later childhood for OLT. Individual patients with mild hepatocellular enzyme and bilirubin elevation and mild portal hypertension can be safely observed with ongoing medical therapy. Approximately 20% of all patients with biliary atresia do not require OLT.<sup>3,4</sup>

### Alagille Syndrome

Alagille syndrome (angiohepatic dysplasia) is an autosomal dominant genetic disorder manifest as bile duct paucity leading to progressive cholestasis and pruritus, xanthomas, malnutrition, and growth failure. Liver failure occurs late, if at all. Occasionally, severe growth retardation, hypercholesterolemia, and pruritus can compromise the patient's overall well-being to the point that transplantation is valuable. Specific criteria for OLT are difficult to quantitate. Evaluation must include assessment for congenital cardiac disease and renal insufficiency, both of which are associated with this syndrome. Hepatocellular carcinoma has also been seen in occasional patients.<sup>5,6</sup>

Experience using external biliary diversion or internal ileal bypass accompanied by ursodeoxycholic acid therapy has demonstrated a significant decrease in both pruritus and complications of hypercholesterolemia.<sup>7</sup> Both of these procedures may ameliorate or decrease the rate of ongoing parenchymal destruction and cirrhosis, obviating the need for liver transplantation. The vast improvement in growth and nutrition and the resolution of pruritus, hypercholesterolemia, and xanthoma allow these quality of life issues to be criteria for consideration for OLT.<sup>8-10</sup>

### Metabolic Disease

The leading indication for hepatic transplantation in older children is hepatic-based metabolic disease. In these patients, OLT not only is lifesaving but also accomplishes phenotypic and functional cure. A review of these diseases and their mode of presentation can be seen in Tables 45-2 and 45-3.

Hepatic replacement to correct the metabolic defect should be considered before other organ systems are affected and before complications develop that would preclude transplantation, such as in patients with tyrosinemia, in whom there is a high risk of hepatocellular carcinoma.<sup>11</sup> Although results of transplantation are excellent in the metabolic disease subgroup, replacement of the entire liver to correct single enzyme deficiencies is an inefficient but presently necessary procedure. Current research efforts may demonstrate that orthotopic partial hepatic replacement, hepatocyte transplantation, and gene therapy may better serve this patient population in the future.<sup>12-16</sup> Patients with primarily extrahepatic manifestations of their disease, such as cystic fibrosis, are occasionally helped by liver transplantation, although their prognosis is most often determined by their primary illness.<sup>17</sup>

### Fulminant Hepatic Failure

Patients with fulminant hepatic failure without recognized antecedent liver disease present diagnostic and prognostic difficulties. Rapid clinical deterioration frequently makes establishment of a definitive diagnosis impossible before there is an urgent need for transplantation. Acute viral hepatitis of undefined type makes up the largest group, followed by drug toxicity and toxin exposure. Previously unrecognized metabolic disease must also be considered. Recently, an immune-based defect has been recognized as a cause of fulminant liver failure. This population needs to be identified because these children may require a combination of bone marrow and liver transplantation to achieve long-term survival. When acceptable clinical and metabolic stability make liver biopsy safe, diagnostic information allowing directed treatment of the primary liver disease is helpful. The presence of ongoing coagulopathy often dictates the need for an open approach to biopsy.

The prognosis of patients with fulminant liver failure is difficult to predict, and neurologic outcome is potentially suboptimal.<sup>15,18,19</sup> Use of intracranial pressure monitoring in patients with progressive encephalopathy has allowed early recognition and directed treatment of increased intracranial pressure. Monitoring should be instituted for patients with advancing grade III encephalopathy and in all patients with grade IV encephalopathy. Intracranial monitoring is continued intraoperatively and for 24 to 48 hours after OLT because significant increases in intracranial pressure have been identified throughout the entire clinical course. Failure to maintain a cerebral perfusion pressure of more than 50 mm Hg and an intracranial pressure less than 20 mm Hg has been associated with very poor neurologic outcome.<sup>19</sup> Survival after transplantation is significantly decreased in patients who reach grade IV encephalopathy. Efforts to identify and perform transplantation in children before this deterioration are obviously important. When candidates are identified before they develop irreversible neurologic abnormalities, the results of transplantation can be dramatic. Hepatocyte transplantation can provide neurologic protection during organ acquisition or while awaiting spontaneous recovery.<sup>16,18,20</sup>

### Liver Tumors

Transplantation for hepatoblastoma is recommended for individuals who, after the administration of several cycles of chemotherapy, have a neoplasm confined to the liver that is unresectable by conventional means. Children who had prior isolated metastasis that disappeared while undergoing preoperative chemotherapy can be considered in selected instances. Factors associated with a favorable prognosis include (1) absence of prior surgical resection attempts, (2) unifocal rather than multifocal involvement, (3) absence of vascular invasion, and (4) fetal histology compared with anaplastic or embryonal histology. In addition to these staging factors, a favorable response to pretransplant chemotherapy suggests a more favorable long-term

prognosis. Historically, recurrent disease has accounted for 50% of postoperative mortality.<sup>21</sup> However, in our experience, transplantation for unresectable hepatoblastoma followed by postoperative chemotherapy has led to an overall survival of 88%.<sup>22</sup> The role of transplantation has evolved such that in an upcoming Children’s Oncology Group treatment study in the management of children who have hepatoblastoma, early referral for transplant evaluation is recommended for those children who present with large lesions that appear unresectable by conventional surgery.

Transplantation for hepatocellular carcinoma is complicated by less successful chemotherapy options and frequent extrahepatic involvement. The reported 2-year survival rates of 20% to 30% compare unfavorably to the recent experience with hepatoblastoma. Most deaths are due to recurrent carcinoma within the allograft or to extrahepatic tumor involvement. When primary hepatocellular carcinoma is discovered incidentally within the cirrhotic native liver at the time of hepatectomy, the overall prognosis is unaffected by the tumor.<sup>23</sup>

Vascular tumors represent a group of patients with diffuse pathology who can benefit from transplantation. Children with progressive, intractable congestive heart failure, even when caused by non-neoplastic arteriovenous malformations or hemangioendothelioma, offer a unique opportunity for complete removal of the vascular malformation and correction of congestive heart failure. In our experience, transplantation in these patients offers significantly better long-term survival compared with embolization or hepatic artery occlusion that can precipitate sudden and widespread hepatic necrosis. Pretransplant biopsy is essential in large or complex lesions to exclude angiosarcoma.

### Contraindications

Contraindications to transplantation include (1) extrahepatic unresectable malignancy, (2) malignancy metastatic to the liver, (3) progressive terminal nonhepatic disease, (4) uncontrolled systemic sepsis, and (5) irreversible neurologic injury.

Relative contraindications to transplantation that need to be individually evaluated include (1) advanced or partially treated systemic infection, (2) advanced hepatic encephalopathy (grade IV), (3) severe psychosocial difficulties, (4) portal venous thrombosis extending throughout the mesenteric venous system, and (5) serology positive for human immunodeficiency virus.

### Donor Considerations

#### Donor Options

The single factor limiting the availability of OLT is the supply of donor organs. The number of patients awaiting liver transplantation has increased by 11-fold since 1991. Available donor resources have not kept pace. Because of this donor shortage, the time to transplant (waiting time) for all pediatric age groups has increased significantly. Infants and young children have been

**Figure 45-1.** Number of patients on the United Network of Organ Sharing (UNOS) waiting list for liver transplantation compared with the number of cadaver donors and cadaver liver recipients, 1988 to 2006. (From Organ Procurement Transplant Network—2007 Annual Report.)

most affected (Figs. 45-1 and 45-2). This severely limited supply of available donor organs has driven the advancement of many innovative liver transplant surgical procedures. The development of reduced-size liver transplantation allowed significant expansion of the donor pool for infants and small children. This has not only improved the availability of donor organs but has also allowed access to donors with improved stability and organ function. Evolution of these operative techniques has allowed the development of both split liver transplantation and LD transplantation.

In the hands of experienced transplant teams, these procedures all have equivalent success to whole-organ transplantation. Furthermore, access to these many donor options has reduced the waiting list mortality rate to less than 5%. Infants and children requiring transplantation benefit greatly from having access to

**Figure 45-2.** Time to transplant (waiting time) for pediatric liver transplant recipients subdivided by age at the time of registration. Comparison of 1994 and 2001 waiting times.

all of these transplant options to minimize waiting time and optimize organ use.

### Organ Allocation

In 1998, the “Final Rule” established by the Health Resources and Service Administration (HRSA) mandated the formation of a system for candidate stratification based on a continuous severity score reflecting 90-day waiting list mortality (i.e., outcome).<sup>24</sup> The system that was developed for pediatrics, the Pediatric End-Stage Liver Disease (PELD) score, was created using analysis of the prospective registry of children listed for transplantation by the Studies of Pediatric Liver Transplantation (SPLIT). The parameters selected included total bilirubin, international normalized ratio (INR), albumin, age younger than 1 year, and evidence of failure to thrive (Table 45-4). The assumption was that this score would allow equitable stratification of children by severity of disease and mortality risk and allow integration with the adult Model for End-Stage Liver Disease (MELD) system. The primary function of PELD is the stratification of candidates for transplantation by risk of 90-day waiting list mortality, allowing optimal use of donor organs. When death rates for all children listed were analyzed, PELD was an accurate predictor of mortality risk and demonstrated progressive risk until high scores were reached (>35) (Fig. 45-3).<sup>25</sup>

### Donor Selection

Assessment of donor organ suitability is undertaken by evaluating clinical information, static biochemical tests, and dynamic tests of hepatocellular function. The clinical factors reviewed identify donors who are at the limits of age, have had prolonged intensive-care hospitalization with potential sepsis, and have vasomotor instability requiring excessive vasoconstricting inotropic agents. Static biochemical tests identify preexisting functional abnormalities or organ trauma but do not serve as good benchmarks to differentiate among acceptable and poor donor allografts. Donor liver biopsy is helpful in questionable cases to identify preexisting liver disease or donor liver steatosis. The shortage of donor organs has led to expanded efforts to use individuals of advanced age and marginal stability, termed *extended-criteria donors*.

Anatomic replacement of the native liver in the orthotopic position requires selection or surgical

**Table 45-4** Pediatric End-Stage Liver Disease (PELD) Score

$$\text{PELD score} = 0.436 \times (\text{age}) - 0.687 \log_e (\text{albumin [g/dL]}) \\ + 0.480 \log_e (\text{total bilirubin [mg/dL]}) + 1.857 \log_e (\text{INR}) + 0.667 \\ (\text{growth failure})$$

INR, International normalized ratio.

preparation of the donor liver to fill but not to exceed available space in the recipient. When using full-sized allografts, a donor weight range 15% to 20% above or below that of the recipient is usually appropriate, taking into consideration body habitus and factors that would increase recipient abdominal size such as ascites and hepatosplenomegaly.

Surgical preparation of reduced-size liver allografts is based on the anatomy of the hepatic vasculature and bile ducts. Prolonged cold ischemic preservation allows for the safe application of the extensive hypothermic bench surgery necessary for reduction techniques. The need for this preparation also limits the acceptability of extended-criteria donors for these procedures. The three primary reduced-size allografts used are the right lobe, the left lobe, and the left lateral segment, all prepared by *ex vivo* hepatic resection.

The right lobe graft, using segments V to VIII, can be accommodated when the weight difference is no greater than 2:1 between donor and recipient. The thickness of the right lobe makes this allograft of limited usefulness in small recipients. Similar anatomic grafts from LDs have become widely used in adults. The left lobe, using segments I to IV, is applicable with a donor-to-recipient (D:R) disparity from 4:1 to 5:1. A left lateral segment graft (segments II and III) can be used up to a 10:1 D:R weight difference. For a left or right lobe graft, the parenchymal resection follows the anatomic lobar plane through the gallbladder fossa to the inferior vena cava (IVC).<sup>26,27</sup> A crush and tie technique is preferred to achieve good closure of vascular and biliary structures. The middle hepatic vein is retained with the graft in all left lobe and many right lobe preparations. The bile duct, portal vein, and hepatic artery are divided and ligated at the right or left confluence. The vena cava is left incorporated with the allograft in both right and left lobe preparation. Vena caval reduction by posterior caval wall resection

and closure is only occasionally necessary. Resection of the inferior protruding portion of the caudate lobe is necessary during left lobe preparation to reduce the likelihood of arterial angulation, which can result in arterial thrombosis. This also facilitates shortening of the IVC to fit in a small recipient.<sup>28</sup>

When using left lateral segment (LLS) allografts, the parenchymal dissection follows the right margin of the falciform ligament with preservation of the left hilar structures. Direct implantation of the left hepatic vein into the combined orifice of the right and middle/left hepatic veins in the recipient IVC is preferred. The donor vena cava is not retained with this segmental allograft. Further reduction of the LLS graft to a monosegmental graft may be necessary in very small recipients. Resection of the distal LLS is technically easier than an anatomic segment II/III division.

Biliary reconstruction in all allograft types is achieved through an end-to-side choledochojejunostomy. Primary bile duct reconstruction is not used with reduced-size allografts owing to the risk of ischemia in the common bile duct. The bile ducts are perfused by a dense arterial plexus, which travels within the common connective tissue “vasobiliary sheath.”<sup>29</sup> Dissection should be limited to that necessary to identify the bile duct for anastomosis.

The use of LDs has increased as the safety and success of this procedure has been demonstrated (Fig. 45-4).<sup>30-32</sup> One of the critical elements of LD transplantation is the proper selection of a donor, usually a parent or relative. This procedure is performed on the assumption that donor safety can be assured and that the donor’s liver function is normal. Donors should be 21 to 55 years of age, have an ABO compatible blood type, and have no acute or chronic medical condition. Careful attention must be paid to proper living donor consent. Parental concerns to help their ill child make true informed consent a challenge. A dedicated “donor advocate” not directly associated with the transplant team should assist with this process. Independent medical assessment of the donor is essential. The United

**Figure 45-4.** Number of living donor transplants per year subdivided by the age of the transplant recipient, 1991-2008 (From Organ Procurement Transplant Network data).

Graft estimate to weigh  $\geq 1\%$  body weight of recipient.

Best to weigh 2%-3% of recipient body weight.

BW, body weight; ELV, estimated liver volume; BSA, body surface area.

Network for Organ Sharing (UNOS) has recently established clear criteria for this process. After a satisfactory medical and psychological examination by a physician not directly involved with the transplant program, computed tomography (CT) is used to measure the volume of the potential donor segment to ensure that it will meet the metabolic needs but not exceed the space available in the recipient (Table 45-5). If acceptable, CT angiography or arteriography is undertaken to assess the hepatic arterial anatomy, thereby excluding potential donors with multiple arteries to segments II and III and facilitating minimal hilar vascular dissection at the time of OLT. When donors were deemed unacceptable, experience has shown that 90% of patients were excluded on the basis of history, examination, laboratory screening, and ABO type. Donor safety has been excellent in all pediatric LD series.<sup>33-35</sup>

In most pediatric patients, the LLS donated from an adult is used as the graft. At the time of harvest, the left hepatic vein is divided from the IVC and the left branch of the portal vein and proper hepatic artery are removed with the allograft.<sup>33</sup> Vascular continuity of the hepatic arterial branches to segment IV is maintained if possible. Recently, increased experience has been gained using the right lobe as an LD allograft for larger recipients such as adolescents and adults.<sup>30,36,37</sup> This more extensive operation has proven to be a challenge to the donor and recipient alike, with a complication and mortality rate significantly exceeding that of left lateral segmentectomy. Although the number of right lobe LD recipients now greatly exceeds the number of children receiving LD grafts, several publicized donor deaths and increased interest in “split-liver” cadaveric procurement have slowed the enthusiasm for right lobe donation.

Split-liver grafting involves the preparation of two allografts from a single donor. Two techniques have been used to accomplish hepatic division in the donor with similar overall success. The ex situ split procedure divides the right lobe allograft (segments V to VIII) from the LLS allograft (segments II and III) after the whole donor organ has been procured. Because this division is undertaken under vascular hypothermic conditions without hepatic perfusion, the vascular integrity of segment IV is difficult to assess and it is frequently discarded. Conventional techniques for implanting the respective allografts are then used.<sup>29</sup> The successful experience with in situ division of the LD left lateral

segment is the basis for the in situ split procedure. Here the LLS is prepared identically to that of a living related donor. The viability of segment IV can be examined at the time of the division, and it is usually incorporated with the right lobe graft to increase the cellular mass of the allograft. Because this procedure adds considerably to the donor procurement time, and the necessary skill of the donor team, it is more demanding and occasionally difficult to successfully orchestrate. However, despite these considerations, this is the preferred method for split-liver donor preparation.<sup>30,32,38,39</sup>

The benefits of split-liver transplantation are best achieved when ideal donors are selected. Strict restrictions on age, vasopressor administration, predonation hepatic function, and limited donor hospitalization have been used to select optimal candidates for this donor procedure. When these donors are selected, the results from both in situ and ex situ techniques are similar, with both techniques now having patient survival for both allografts of 90% to 93% and graft survival rates of 86% to 89%.<sup>40</sup>

The selection of a donor segment with an appropriate parenchymal mass for adequate function is critical to

success. However, the minimal mass necessary for recovery is not yet established. Any calculation must take into account loss of function after preservation damage, acute rejection, and technical problems. When the D:R weight range falls within the normal 8:1 to 10:1 ratio, risk is minimal. Estimates of donor graft to recipient body weight ratio (GRWR) may prove to be a more accurate predictor of adequate graft volume. When the GRWR is less than 0.7%, overall allograft and patient survival suffered. In extreme cases in which small-for-size grafts are used, excessive portal flow can lead to hemorrhagic necrosis of the graft. Large-for-size allografts (GRWR > 5.0%) have a less deleterious effect.<sup>41</sup> A review of these donor anatomic options is shown in Figure 45-5.

Creative use of the techniques refined for reduced-size liver transplantation has allowed additional donor options in individual cases. Resection of the left lobe of the native liver followed by auxiliary partial orthotopic transplantation of a reduced-size LLS allograft has been successfully undertaken for patients with metabolic disease (ornithine transcarbamylase deficiency, Crigler-Najjar syndrome) and fulminant hepatic failure.<sup>42,43</sup>

**Figure 45-5.** Anatomic donor options available through surgical reduction. The numbers correlate to the segmental hepatic anatomy as defined by Couinaud. IVC, inferior vena cava; BD, bile duct; PV, portal vein; HA, hepatic artery; LHV, left hepatic vein.

This provides for normal hepatic synthesis and function while leaving the right lobe of the donor liver in situ. The auxiliary partial OLT technique has also been undertaken using an LD for similar indications.<sup>44</sup> Auxiliary placement of a reduced-size allograft has also been successfully performed for fulminant hepatic failure in patients deemed too unstable for OLT. In these cases, recovery of the recipient native liver function can ultimately allow discontinuation of immunosuppression and atrophy of the donor allograft if it is no longer required to supplement organ function.<sup>45,46</sup>

## Preoperative Preparation

Efforts to correct abnormalities noted during candidate evaluation decrease both the operative risk and postoperative complications. Complications of portal hypertension and malnutrition are vigorously treated. Assessment of prior viral exposure and meticulous attention to the delivery of all normal childhood immunizations, particularly the live-virus vaccines, are imperative, if time allows, before OLT. Additionally, patients receive a one-time inoculation with pneumococcal vaccine and appropriate administration of hepatitis B vaccine. Preoperative assessment of specific cardiopulmonary reserve and hepatic vascular anatomy is also necessary.

## The Transplant Procedure

The transplant procedure is carried out through a bilateral subcostal incision with midline extension. Meticulous ligation of portosystemic collaterals and vascularized adhesions is necessary to avoid slow but relentless hemorrhage. Dissection of the hepatic hilum, with division of the hepatic artery and portal vein above their bifurcation, allows maximal recipient vessel length to be achieved. The bile duct, when present, is divided high in the hilum to preserve the length and vasculature of the distal duct in case it is needed for primary reconstruction in older recipients. Preservation of the Roux-en-Y limb in biliary atresia patients who have undergone Kasai portoenterostomy simplifies later biliary reconstruction. Complete mobilization of the liver, with dissection of the suprahepatic vena cava to the diaphragm and the infrahepatic vena cava to the renal veins, completes the hepatectomy.

In children with serious vascular instability who cannot tolerate caval occlusion, and in LD transplantation, "piggy-back" implantation is necessary. In this procedure, the recipient vena cava is left intact and partial caval occlusion allows end-to-side implantation of a combined donor hepatic vein patch. Access to the infrarenal aorta to implant the celiac axis of the donor liver or iliac artery vascular conduits, provided by mobilizing the right colon and duodenum, is our preference for arterial reconstruction in complex allograft recipients.

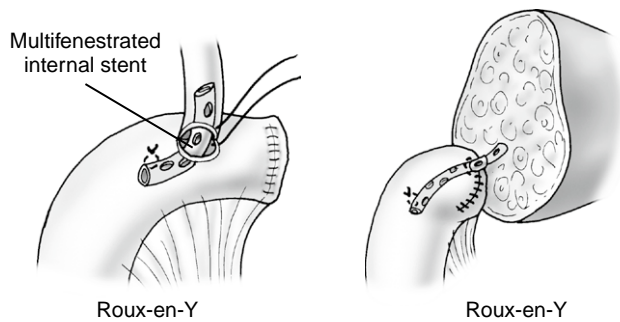

Control of hemorrhage is essential during the recipient hepatectomy and requires meticulous surgical technique. Coagulation factor assays (V, VII, VIII, fibrinogen, platelets, prothrombin time, partial thromboplastin time) allow specific blood product

supplementation to improve clotting function. The use of venovenous bypass is reserved for recipients weighing more than 40 kg who demonstrate hemodynamic instability at the time of venous interruption. Early institution of venovenous bypass combined with high-dose vasopressin (0.2 to 0.6 units/min) is occasionally used in patients with marked friable retroperitoneal variceal hypertension before completing hepatic mobilization.

Removal of the diseased liver is completed after vascular isolation is achieved. Retroperitoneal hemostasis is achieved before implanting the donor liver. In standard OLT, the suprahepatic vena cava is prepared by suture ligating any large phrenic orifices and creating one caval lumen from the confluence of the IVC and hepatic vein orifices. The donor liver is implanted using conventional vascular techniques and monofilament suture for the vascular anastomosis. In small recipients, interrupted suture techniques, monofilament dissolving suture material, and a "growth factor" knot have all been used to allow for vessel growth. When LLS reduced-size grafts are used, the left hepatic vein orifice is anastomosed directly to the anterolateral surface of the infradiaphragmatic IVC using the combined right-middle hepatic vein orifices. The LLS allograft is later fixed, when necessary, to the undersurface of the diaphragm to prevent torsion and venous obstruction of this anastomosis. Similar fixation is not necessary with right or left lobe allografts or with whole-organ transplants.

Before completing the vena caval anastomosis, the hyperkalemic preservation solution is flushed from the graft using 500 to 1000 mL of hypothermic normokalemic intravenous solutions. When using full-sized grafts in older patients, we prefer to complete all venous anastomoses before reconstructing the hepatic artery. In reduced-size allografts and in small recipients in whom we prefer to use direct aortic vascular inflow reconstruction, the hepatic arterial anastomosis is completed before reconstructing the portal vein to improve visibility of the infrarenal aorta without placing traction on the portal vein anastomosis. We prefer to complete all anastomoses during vascular isolation before organ reperfusion, although some transplant teams reperfuse after venous reconstruction is complete.

Before re-establishing circulation to the allograft, anesthetic adjustments must be made to address the large volume of blood needed to refill the liver and the presence of hypothermic solutions released at reperfusion. Inotropic support using dopamine (5 to 10  $\mu\text{g}/\text{kg}/\text{min}$ ) is begun. Calcium and sodium bicarbonate are administered to combat the effects of hyperkalemia from any remaining preservation solution and systemic acidosis after aortic and vena caval occlusion. Sufficient blood volume expansion, administered as packed red blood cells to raise the central venous pressure to 15 to 20 cm H<sub>2</sub>O and the hematocrit to 40%, minimizes the development of hypotension with unclamping and prevents dilutional anemia. Cooperative communication between the surgical and

**Figure 45-6.** Bile duct reconstruction is shown using the common hepatic duct in whole organ transplants (left) and segmental hepatic ducts into a Roux-en-Y intestinal limb for reduced-sized liver transplants (right). An internal multi-fenestrated stent is used in both situations. (From Ryckman F: Liver transplantation. In Ziegler MM, Azizkhan RG, Weber T [eds]: Operative Pediatric Surgery. New York, McGraw-Hill, 2003, p 1275.)

anesthesia teams facilitates a smooth sequential re-establishment of vena caval, portal venous, and then arterial recirculation to the allograft.

Biliary reconstruction in patients with biliary atresia or in those weighing less than 25 kg is achieved through an end-to-side choledochojejunostomy using interrupted dissolving monofilament sutures. A multi-fenestrated Silastic internal biliary stent is placed before completing the anastomosis (Fig. 45-6). In most cases, the previous Roux-en-Y jejunal limb can be used, with a 30- to 35-cm length being preferred. Primary bile duct reconstruction without stenting is used in older patients with whole-organ allografts.

When closing the abdomen, increased intra-abdominal pressure should be avoided. In many cases, avoidance of fascial closure and the use of mobilized skin flaps and running monofilament skin closure are advisable. Musculofascial abdominal closure can be completed before patient discharge.

## Immunosuppressive Management

Most centers use an immunosuppressive protocol based on the administration of multiple complementary medications. All use corticosteroids and cyclosporine or tacrolimus. Additional antimetabolites (azathioprine, mycophenolate) are used when more treatment is needed. Prior protocols using polyclonal or monoclonal induction therapy have been abandoned in most cases owing to the extent of the immunosuppressive potency. The recent introduction of humanized monoclonal antibodies to interleukin-2 (basiliximab, daclizumab) has stimulated interest in induction immunosuppression protocols because these agents appear to have a low risk of associated opportunistic infections. The role that they will play in the future is not clear at present. A sample protocol is given in Table 45-6.

## Postoperative Complications

Most postoperative complications present as cholestasis, increasing hepatocellular enzyme levels, and, on occasion, fever, lethargy, and anorexia. This nonspecific symptom complex requires specific diagnostic evaluation before instituting treatment.

Therapy directed at the specific causes of allograft dysfunction is essential. Empirical therapy for presumed complications is fraught with misdiagnoses, morbidity, and mortality. A flow diagram outlining this evaluation is shown in Figure 45-7.

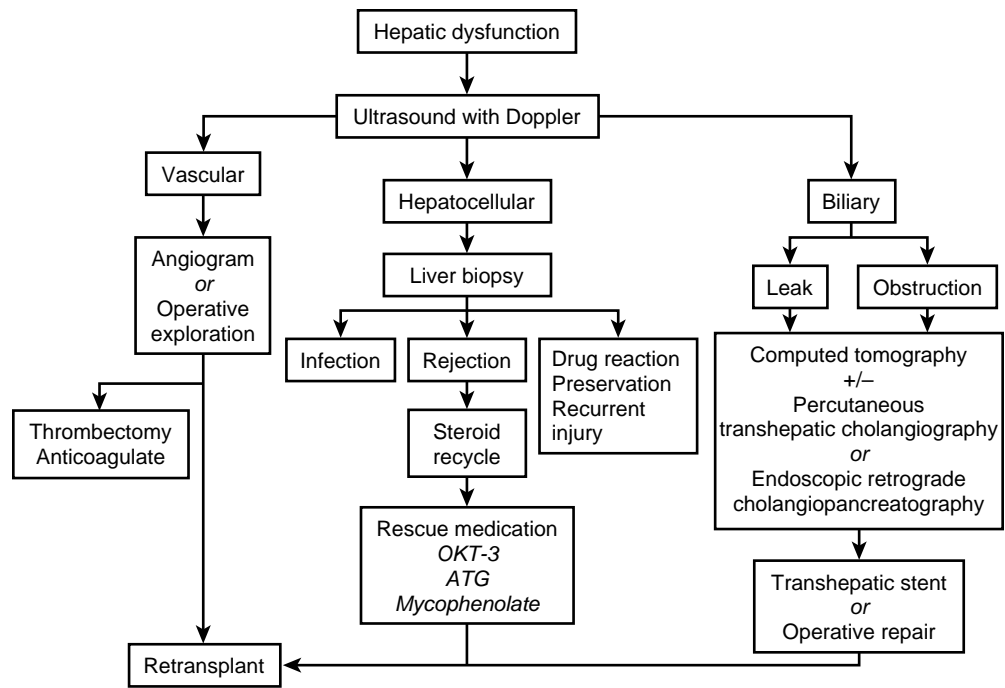

## Primary Nonfunction

Primary nonfunction of the hepatic allograft implies the absence of metabolic and synthetic activity after transplantation. Complete nonfunction requires immediate retransplantation before irreversible coagulopathy and cerebral edema occur. Lesser degrees of allograft dysfunction occur more frequently and can be associated with several donor, recipient, and operative factors (Table 45-7).

The status of the donor liver contributes significantly to the potential for primary nonfunction. Ischemic injury secondary to anemia, hypotension, hypoxia, or direct tissue injury is often difficult to ascertain in the history of multiple trauma victims. Donor liver steatosis has also been recognized as a factor contributing to severe dysfunction or nonfunction in the donor liver. Macrovesicular steatosis on donor liver biopsy is somewhat more common in adult than pediatric donors and, when severe, is recognized grossly by the enlarged yellow, greasy consistency of the donor liver. The risk of primary nonfunction increases as the degree of fatty infiltration increases. Microscopic findings are classified as mild if less than 30% of the hepatocytes have fatty infiltration, moderate if 30% to 60% are involved, and severe if more than 60% of the hepatocytes have fatty infiltration. Livers with severe fatty

infiltration should be discarded. Donors with moderate involvement are used with some concern, with the degree of steatosis and the condition of the recipient determining use of the allograft. Microvesicular steatosis is not related to primary nonfunction.<sup>47-53</sup>

Immediate post-transplant immunologic events, such as humoral antibody-mediated hyperacute rejection, can occur but are uncommon after OLT. Initial reports suggested that a positive cytotoxic antibody crossmatch between the donor and recipient did not affect the viability or function of the allograft.<sup>54</sup> However, more recent experience with crossmatch positive donors has demonstrated significantly decreased allograft and patient survival.<sup>55,56</sup>

**Table 45-7** Factors Related to Primary Nonfunction

**Donor Factors**

Preexisting disease or injury to donor, anemia, hypoxia, hypotension before organ harvest  
Donor organ steatosis (>60% macrovesicular fat)

**Transplant Factors**

Prolonged cold ischemic storage (>8-12 hr)  
Prolonged warm ischemic time at implantation  
Complex vascular anastomosis requiring surgical revision  
Significant size discrepancy between donor and recipient

**Recipient Factors**

Post-reperfusion hypotension  
Vascular thrombosis  
Immunologic factors  
ABO incompatible, positive crossmatch

The use of ABO-incompatible donors has been controversial. Allograft and patient survival rates in adult recipients have not been comparable to those achieved using ABO-identical or ABO-compatible donors.<sup>57,58</sup> However, pediatric recipients of ABO-incompatible allografts have achieved survival rates equivalent to those using ABO-compatible and ABO-identical donors, using either cadaver donors (CDs) or LDs.<sup>59-61</sup>

Documentation of functional hepatic recovery is best undertaken by evaluating the ongoing hepatic output of clotting factors (V, VII) with improvement in coagulation parameters (prothrombin time, partial thromboplastin time) and the synthesis of bile. Hepatic biopsies assist in the documentation of histologic and immunologic events, but they cannot accurately predict the likelihood of recovery.

### Vascular Thrombosis

Hepatic artery thrombosis occurs in children three to four times more frequently than in adult transplant series, occurring most often within the first 30 days after transplantation. Factors influencing the development of hepatic artery thrombosis are listed in Table 45-8.

Hepatic artery thrombosis presents as a variable clinical picture that may include (1) fulminant allograft failure, (2) biliary disruption or obstruction, or (3) systemic sepsis. Doppler ultrasound imaging has been accurate in identifying arterial thrombosis. It is used as the primary screening modality to assess blood flow after transplantation or whenever complications arise. Acute hepatic artery thrombosis with allograft failure most often requires immediate retransplantation. Successful thrombectomy and allograft salvage is possible if undertaken before allograft necrosis.<sup>62</sup> Biliary

complications are particularly common after hepatic artery thrombosis. Ischemic biliary disruption with intraparenchymal biloma formation or anastomotic disruption presents as cholestasis associated with systemic sepsis. The development of systemic septicemia or multifocal abscesses in sites of ischemic necrosis secondary to gram-negative enteric bacteria, *Enterococcus*, anaerobic bacteria, or fungi can also be seen. Antibiotic therapy directed toward these organisms, along with surgical drainage, is indicated when specific abscess sites are identified. Percutaneous drainage and biliary stenting may control bile leakage and infection until retransplantation is possible.

Late postoperative thrombosis can be asymptomatic or present as slowly progressive bile duct stenosis. Rarely, allograft necrosis occurs. Arterial collaterals from the Roux-en-Y limb can provide a source of revascularization of the thrombosed allograft through hilar collaterals. These collateral channels develop during the first postoperative months, often making late thrombosis a clinically silent event. Conversely, disruption of this collateral supply during operative reconstruction of the central bile ducts in patients with hepatic artery thrombosis can precipitate hepatic ischemia and parenchymal necrosis. When hepatic artery thrombosis is asymptomatic, careful follow-up alone is indicated.

Prevention of hepatic artery thrombosis requires meticulous microsurgical arterial reconstruction at the time of transplantation. Anatomic reconstruction is preferred in whole-organ allografts. Direct implantation of the celiac axis into the infrarenal aorta is recommended for all reduced-size liver allografts. All complex vascular reconstructions of the donor hepatic artery should be undertaken *ex vivo* whenever possible using microsurgical techniques before transplantation. When vascular grafts are required, they should also be directly implanted into the infrarenal aorta.<sup>63</sup> We do not routinely use systemic anticoagulation, but aspirin (20 to 40 mg/day) is administered to all children for 100 days. Complex protocols administering

both procoagulants and anticoagulants have also been very successful.<sup>49</sup>

Portal vein thrombosis is uncommon in whole-organ allografts unless prior portosystemic shunting has altered the flow within the splanchnic vascular bed or unless severe portal vein stenosis in the recipient has impaired flow to the allograft. Preexisting portal vein thrombosis in the recipient can be overcome by thrombectomy, portal vein replacement, or extra-anatomic venous bypass. In biliary atresia recipients, preexisting portal vein hypoplasia is best corrected by anastomosis to the confluence of the splenic and superior mesenteric veins in the recipient. When inadequate portal vein length is present on the donor organ, iliac vein interposition grafts are used. Early thrombosis after transplantation requires immediate anastomotic revision and thrombectomy. Discrepancies in venous size imposed by reduced-size allografts can be modified to allow anastomotic construction.<sup>64,65</sup> Deficiencies of anticoagulant proteins, such as protein C and S, and antithrombin III deficiency in the recipient must also be excluded as a contributing cause for vascular thrombosis.<sup>66</sup> Failure to recognize portal vein thrombosis can lead to either allograft demise or, on a more chronic basis, to significant portal hypertension with hemorrhagic sequelae or intractable ascites.

### Biliary Complications

Complications related to biliary reconstruction occur in approximately 10% of pediatric liver transplant recipients. Their spectrum and treatment is determined by the status of the hepatic artery and the type of allograft used. Although whole and reduced-size allografts have an equivalent risk of biliary complications, the spectrum of complications differs.<sup>67,68</sup>

Primary bile duct reconstruction is the preferred biliary reconstruction in adults, but it is less commonly used in children. It has the advantages of preserving the sphincter of Oddi, decreasing the incidence of enteric reflux and subsequent cholangitis, and not requiring an intestinal anastomosis. Early experience using primary choledochocholedochostomy without a T-tube has been favorable.<sup>69</sup> Late complications after any type of primary ductal reconstruction include anastomotic stricture, biliary sludge formation, and recurrent cholangitis. Endoscopic dilation and internal stenting of anastomotic strictures has been successful in early postoperative cases. Roux-en-Y choledochojejunostomy is the preferred treatment for recurrent stenosis or postoperative leak.

Roux-en-Y choledochojejunostomy is the reconstruction of choice in small children and is required in all patients with biliary atresia. Recurrent cholangitis, a theoretical risk, suggests anastomotic or intrahepatic biliary stricture formation or small bowel obstruction within the Roux limb or distal to the Roux-en-Y anastomosis. In the absence of these complications, cholangitis is uncommon.

Reconstruction of the bile ducts in patients with reduced-size allografts is more complex. Division of

the bile duct in close proximity to the cut-surface margin of the allograft, with careful preservation of the biliary duct collateral circulation, decreases but does not eliminate ductal stricture formation secondary to ductal ischemia. In our early experience, in 14% of patients with left lobe reduced-size allografts, a short segmental stricture developed requiring biliary anastomotic revision (Fig. 45-8). Operative revision of the biliary anastomosis and reimplantation of the bile ducts into the Roux-en-Y limb are necessary. Percutaneous transhepatic cholangiography is essential to define the intrahepatic ductal anatomy before operative revision, and temporary catheter decompression of the obstructed bile ducts allows treatment of cholangitis and elective reconstruction. Operative reconstruction is accompanied by transhepatic passage of exteriorized multifenestrated biliary ductal stents, which remain until reconstructive success is documented. Late stenosis is unlikely. Dissection away from the vasobiliary sheath in the donor has significantly decreased the incidence of this complication.

Biliary complications have been seen with an increased frequency after living donation in pediatric recipients. The left lateral segment II and III bile ducts are frequently separate at the plane of parenchymal division. The need for individual drainage of these small biliary ducts makes the development of late anastomotic stenosis more frequent. Individual segmental strictures may not lead to jaundice in the recipient but rather are identified by elevated  $\gamma$ -glutamyltransferase enzymes or through ultrasound surveillance. Reoperation after ductal dilatation allows for easier reconstruction owing to the increased caliber of the segmental bile duct.

### Acute Cellular Rejection

Allograft rejection is characterized by the histologic triad of endothelialitis, portal triad lymphocyte infiltration with bile duct injury, and hepatic parenchymal cell damage.<sup>70</sup> Allograft biopsy is essential to establish the diagnosis before treatment. The rapidity of the rejection process and its response to therapy dictates the intensity and duration of antirejection treatment.

Acute rejection occurs in approximately two thirds of patients after OLT.<sup>71</sup> The primary treatment of rejection is a short course of high-dose corticosteroids. Administration of bolus doses over several days with a rapid taper to baseline therapy is successful in 75% to 80% of cases.<sup>72</sup> When refractory or recurrent rejection occurs, antilymphocyte therapy using the monoclonal antibody OKT-3 (Ortho Biotech Products, Bridgewater, NJ) or Thymoglobulin (Genzyme Transplant, Cambridge, MA) is successful in 90% of cases.<sup>28</sup>

### Chronic Rejection

Uniform diagnosis and management of chronic rejection are complicated by the lack of a consistent definition or clinical course. Chronic rejection occurs in 5% to 10% of transplanted patients. Its incidence appears to be decreasing in all transplant groups, perhaps

**Figure 45-8.** Segmental bile duct stricture at the junction of the left lateral and left medial segmental bile ducts in a left lobe reduced-size allograft. *Solid arrow*, bile duct stricture; *open arrow*, Roux-en-Y loop and bile duct anastomosis. (From Ryckman FC: Liver transplantation in children. In Suchy FJ [ed]: Liver Disease in Children. St. Louis, CV Mosby, 1994, p 941.)

related to better overall immunosuppressive strategies. There is some suggestion that the use of primary tacrolimus-based immunosuppression is a key element in this apparent decrease.<sup>73,74</sup> Risk factors for its development are many, and no factor predicts the outcome of treatment. The chronic rejection rate was significantly lower in recipients of living-related grafts than in recipients of cadaver grafts. African-American recipients had a significantly higher rate of chronic rejection than did white recipients. In addition, the number of acute rejection episodes, transplantation for autoimmune disease, occurrence of post-transplant lymphoproliferative disease (PTLD), and cytomegalovirus (CMV) infection were also significant risk factors for chronic rejection.<sup>75</sup> The primary clinical manifestation is a progressive increase in biliary ductal enzymes (alkaline phosphatase,  $\gamma$ -glutamyltransferase) and progressive cholestasis. This course can be initially asymptomatic or often will follow an unsuccessful treatment course for acute rejection. The syndrome can occur within weeks of transplantation or later in the clinical course.

Chronic rejection can follow one of two clinical forms.<sup>76</sup> In the first, the injury is primarily to the biliary epithelium and the clinical course is typically slowly progressive with preservation of synthetic function. Histologic evidence shows interlobular bile duct destruction in the absence of ischemic injury or the presence of hepatocellular necrosis. In full expression, this lesion is characterized as acute vanishing bile duct syndrome, defined by severe ductopenia in at least 20 portal tracts.<sup>77,78</sup> The eventual spontaneous resolution in up to one-half of affected patients with tacrolimus therapy has led to the development of enhanced immunosuppression protocols for this patient subgroup.<sup>76</sup> Retransplantation is occasionally necessary but rarely emergent.

The second subtype is characterized by the early development of progressive ischemic injury to both

bile ducts and hepatocytes, leading to ductopenia and ischemic necrosis with fibrosis. The clinical picture of cholestasis is accompanied by significant synthetic dysfunction with superimposed vascular thrombosis or biliary stricture formation. The vascular endothelial injury responsible for the progressive ischemic changes is characterized by the development of subintimal foam cells or fibrointimal hypertrophy. The clinical course is relentlessly progressive and nearly always requires retransplantation. Unfortunately, recurrence of chronic rejection in the retransplanted allograft is common.<sup>77</sup>

The immunologic nature of this process is emphasized by the primary target role played by the biliary and vascular endothelium. These are the only tissues in the liver that express class II antigen. Other interdependent cofactors such as CMV infection, HLA mismatching, positive B-cell crossmatching, and differing racial demographics of the donor to recipient combination have all failed to show consistent correlation with the development of chronic rejection.<sup>76,77</sup>

### Renal Insufficiency

The long-term success of liver transplantation has been related to effective immunosuppression with calcineurin inhibitors (CNI), such as cyclosporine and tacrolimus. However, nephrotoxicity associated with their long-term use has become a major problem and affects up to 70% of all nonrenal recipients. Renal insufficiency can present in many ways after CNI administration and liver transplantation. When this occurs during the initial post-transplant weeks, it is most often related to transient excessive blood levels and is reversible with appropriate dose correction. Impaired glomerular filtration rate (GFR) seen in pediatric recipients with stable graft function represents a more serious problem. Up to 20% may have a drop in their GFR to below 50 mL/min/1.73 m<sup>2</sup>, and 5% may progress to end-stage renal disease (ESRD). Adult studies have shown a progressive increase in chronic renal failure from 0.9% at year 1 to 8.6% at year 13 after OLT.<sup>79</sup> Similarly, ESRD rose from 1.6% at year 1 to 9.5% at year 13 post OLT, yielding a total incidence of renal dysfunction of 18%. The presence of an elevated serum creatinine value before OLT and at 1-year post transplant and the presence of hepatorenal syndrome before transplant were all identified risk factors.<sup>79,80</sup> Cyclosporine and tacrolimus both appear to have a similar risk.

In a recent review from our program, in children who were more than 3 years post liver transplant, we found that 32% had a GFR less than 70 mL/min/1.73 m<sup>2</sup>.<sup>22</sup> The primary factors related to lower GFR were the presence of an elevated creatinine at 1-year post transplant and the length of time after transplantation. Our data supported the concept of a continued decline in renal function after liver transplantation. Considering the long survival for children undergoing liver transplantation, the possibility of progressive asymptomatic renal insufficiency leading to severe kidney disease poses a critical challenge.

Efforts to reverse ongoing renal insufficiency using protocols that include instituting non-nephrotoxic agents, such as mycophenolate mofetil, while decreasing the CNI dose, have shown some limited success in improving GFR while protecting against acute rejection at the time of immunosuppressive drug conversion.<sup>81</sup> Efforts have also been undertaken to use the new class of monoclonal anti-CD25 antibodies for induction therapy coupled with mycophenolate mofetil and corticosteroids in an effort to avoid administration of CNI during the first post-transplant week. These agents appear to afford sufficient protection against rejection to successfully allow the late administration of CNI. Whether these efforts will prevent the later development of renal insufficiency is unknown.<sup>82</sup>

Efforts to completely eliminate CNI administration have been complicated by acute or ductopenic rejection. Present efforts suggest that earlier staged reduction of calcineurin inhibitors before the development of severe GFR reduction will decrease but not eliminate this complication. Once established, chronic renal failure does not appear to resolve with calcineurin inhibitor dose adjustment. Although calcineurin inhibitor toxicity is now appreciated, the association of both hepatic and renal disease in many metabolic diseases of childhood may also contribute to the identified GFR abnormalities seen in post-transplant patients.

### Infection

Infectious complications have become the most common source of morbidity and mortality after transplantation. Multiple organism infection is common as are concurrent infections by different infectious agents.

Bacterial infections occur in the immediate post-transplant period and are most often caused by gram-negative enteric organisms, *Enterococcus*, or *Staphylococcus* species. Intra-abdominal abscesses or infected collections of serum along the cut surface of the reduced-size allograft are best addressed with extraperitoneal or laparotomy drainage. Percutaneous drainage is less successful in our experience. Intrahepatic abscesses suggest hepatic artery stenosis or thrombosis, and treatment is directed by the vascular status of the allograft and associated bile duct abnormalities. Sepsis originating at sites of invasive monitoring lines can be minimized by replacing or removing all intraoperative lines soon after transplantation. Antibacterial prophylactic antibiotics are discontinued as soon as possible to prevent the development of resistant organisms.

Fungal sepsis represents a significant potential problem in the early post-transplant period. Aggressive protocols for pretransplant prophylaxis are based on the concept that fungal infections originate from organisms colonizing the gastrointestinal tract of the recipient. Selective bowel decontamination was successful in eliminating pathogenic gram-negative bacteria from the gastrointestinal tract in 87% of adult patients.<sup>83,84</sup> Moreover, *Candida* was eliminated in all patients. However, these protocols have not been practical in pediatric patients because there is a long waiting time for pediatric organs and the taste of the

oral antibiotics is poorly accepted. These regimens are, however, commonly used in the preoperative preparation for combined liver/small intestinal transplantation. Fungal infection most often occurs in patients requiring multiple operative procedures and those who have had multiple courses of antibiotics. Development of fungemia or urosepsis requires renal and cardiac investigation and a search for renal fungal involvement. Antifungal therapy should be promptly undertaken because severe fungal infection has a mortality greater than 80%. All patients undergoing OLT should receive antifungal prophylaxis with fluconazole.

The majority of early and severe viral infections are caused by viruses of the Herpesvirus family, including Epstein-Barr virus (EBV), CMV, and herpes simplex virus (HSV). CMV transmission dynamics are well studied and serve as a prototype for herpesvirus transmission in the transplant population. The likelihood that CMV infection will develop is influenced by the preoperative CMV status of the transplant donor and recipient.<sup>85,86</sup> Seronegative recipients receiving seropositive donor organs are at greatest risk, with seropositive donor to recipient combinations at the next greatest risk. Use of various immune-based prophylactic protocols including intravenous IgG or hyperimmune anti-CMV IgG, coupled with acyclovir or ganciclovir/valganciclovir, have all achieved success in decreasing the incidence of symptomatic CMV infection. However, seroconversion in recipients of seropositive donor organs inevitably occurs.

The clinical diagnosis of CMV infection is suggested by the development of fever, leukopenia, maculopapular rash, hepatocellular abnormalities, respiratory insufficiency, or gastrointestinal hemorrhage. Hepatic biopsy or endoscopic biopsy of colonic or gastroduodenal sites allows early diagnosis with immunohistochemical recognition. Rapid blood and urine assays for CMV can also expedite diagnosis. In suspected cases, treatment should be instituted while awaiting culture or biopsy results, owing to the potential rapidity and severity of this infection in a previously uninfected child. The treatment of CMV has been greatly improved by the development of ganciclovir. Early treatment with intravenous IgG and ganciclovir is successful in most cases.

HSV syndromes, similar to those seen in nontransplant patients, require treatment with acyclovir when diagnosed. Other viral infections leading to significant post-transplant infectious complications include adenovirus infection, hepatitis, varicella, and enterovirus-induced gastroenteritis. Recurrent viral hepatitis is an uncommon problem in pediatric transplantation, but it is commonly seen in adult patients. *Pneumocystis* infection has been nearly eliminated by the prophylactic administration of sulfamethoxazole-trimethoprim or aerosolized pentamidine.

EBV infection occurring in the perioperative period represents a significant risk to the pediatric transplant recipient.<sup>87</sup> It has a varying presentation, including a mononucleosis-like syndrome, hepatitis-simulating rejection, extranodal lymphoproliferative infiltration with bowel perforation, peritonsillar or lymph node

enlargement, or encephalopathy. In small children, its primary portal of entry is often the tonsils, making asymptomatic tonsillar hypertrophy a common initial presentation.<sup>88</sup> EBV infection can occur as a primary infection or after reactivation of a past primary infection. When serologic evidence of active infection exists, an acute reduction in immunosuppression is indicated. It has become clear that continuous surveillance is necessary because the presentation is often nonspecific and the prognosis is related to early diagnosis. Screening by determination of EBV blood viral load by quantitative PCR appears to be the best current predictor of risk. However, viral loads have been identified in asymptomatic patients and patients recovering from PTLD, limiting the specificity of this test. The balance between viral load, measured by quantitative polymerase chain reaction (PCR) and specific cellular immune response, perhaps mediated by CD8 T-cells specific to EBV, may explain this lack of specificity to viral load alone.<sup>89-91</sup>

Many pediatric transplant centers now use serially measured quantitative EBV-DNA PCR as an indication for primary immunosuppression modulation. We recommend monthly EBV-DNA PCR counts to monitor increased genomic expression. Increasing viral load levels warrant more frequent monitoring on an every 2-week or 1-week basis. In the EBV seronegative pretransplant patients, more than 40 genomes/10<sup>5</sup> peripheral blood leukocytes and more than 200 genomes/10<sup>5</sup> peripheral blood leukocytes identify patients for reduction in primary immunosuppression by 25% to 100%. Institution of antiviral therapy with ganciclovir and CMV-IgG is also used in most cases, although only nonrandomized observational studies support their use. Both agents are active in vitro against linear replicating forms of the EBV but have no activity against the circular episome in immortalized B cells. Treatment should be continued until symptoms of lymphadenopathy have resolved and viral EBV-DNA PCR has returned to baseline.<sup>87,92</sup> However, it should be cautioned that PTLD can develop and progress without increases in EBV-PCR viral load.<sup>93</sup>

PTLD, a potentially fatal abnormal proliferation of B lymphocytes, can occur in any situation in which immunosuppression is undertaken. The importance of PTLD in pediatric liver transplantation is a result of the intensity of the immunosuppression required, its lifetime duration, and the absence of prior exposure to EBV infection in 60% to 80% of pediatric recipients. PTLD is the most common tumor in children after transplantation and represents 52% of all tumors, compared with 15% in adults. About 80% of cases occur within the first 2 years after transplantation.<sup>90</sup>

Multiple studies analyzing immunosuppressive therapy and the development of PTLD have shown a progressive increase in the incidence of PTLD with (1) the increase in total immunosuppressive load, (2) EBV-negative recipients, and (3) intensity of active viral load.<sup>94</sup> No single immunosuppressive agent has been directly related to PTLD, although high-dose cyclosporine, tacrolimus, polyclonal antilymphocyte sera (MALG, ALG), and monoclonal antibodies (OKT-3)

have all been implicated. Immunosuppressive strategies using these agents as sequential therapy in low doses have not produced an increase in PTLD when successful induction prevents recurrent high-dose or long-duration immunotherapy for rejection. However, prolonged treatment with anti-T-cell agents and the increased duration, intensity, and total immunosuppressive load are the origin of the defective immunity that creates the background for neoplasia.

The second pathogenic feature influencing PTLD appears to be EBV infection. Primary or reactivation infections usually precede the recognition of PTLD. Active EBV infection, whether primary or reactivation, involves B-cell proliferation. A simultaneous increase in cytotoxic T-cell activity is the normal primary host mechanism preventing EBV dissemination. Loss of this natural protection, as a result of the administration of T-cell inhibitory immunotherapy, allows polyclonal B-cell proliferation to progress. Polyclonal proliferation of B lymphocytes occurs after EBV viral replication and release. These EBV proliferating cells express specific viral antigens that represent possible targets for the immune system, thereby explaining the well-described regression of PTLD after immunosuppressive tapering. With time, transformation of a small population of cells results in a malignant monoclonal aggressive B-cell lymphoma.<sup>89,95-97</sup>

Most tumors seen in children are large cell lymphomas, 86% being of B-cell origin. Extranodal involvement, uncommon in primary lymphomas, is seen in 70% of PTLD cases. Extranodal sites include central nervous system (27%), liver (23%), lung (22%), kidney (21%), intestine (20%), and spleen (13%). Allograft involvement is common and can mimic rejection. T-cell and B-cell immunohistochemical markers of the infiltrating lymphocyte population define the B-cell infiltrate and assist in establishing an early diagnosis.

Treatment of PTLD is stratified according to the immunologic cell typing and clinical presentation.<sup>98</sup> Documented PTLD requires an immediate decrease or discontinuation of immunosuppression and institution of anti-EBV therapy. We prefer to use intravenous ganciclovir for initial antiviral therapy, owing to the high incidence of concurrent CMV infection. Acyclovir is used for long-term treatment. The development of newer antiviral alternatives such as valganciclovir may offer better long-term treatment options in the future.<sup>99</sup> Patients with polyclonal B-cell proliferation frequently show regression with this treatment.<sup>87,92</sup> If tumor cells express B-cell marker CD20 at histology, the anti-CD20 monoclonal antibody rituximab can be administered as weekly infusions of 375 mg/m<sup>2</sup>. Although associated in many cases with significant reduction in tumor mass, patients have frequently experienced reversible neutropenia requiring granulocyte colony-stimulating factor and hypogammaglobulinemia requiring supplementation.<sup>100</sup> Acute liver rejection has frequently been reported during rituximab treatment. Patients with aggressive monoclonal malignancies have poor survival even with immunosuppressive reduction, acyclovir, and conventional

chemotherapy or radiation therapy. These additional treatment modalities often precipitate the development of fatal systemic infection. Efforts to reconstitute the EBV-specific cellular immunity using partially HLA-matched EBV-specific cytotoxic T-cells may offer improved treatment outcomes for advanced cases, and future development of an anti-EBV vaccine may decrease the current significant risks of this unique complication of pediatric transplantation.<sup>101,102</sup> When treatment is successful, careful follow-up to identify recurrent disease or delayed central nervous system involvement is essential.

## Retransplantation

The vast majority of retransplantation procedures in pediatric patients are done as a result of acute allograft demise caused by hepatic artery thrombosis or primary nonfunction. Acute rejection, chronic rejection, and biliary complications are more uncommon causes. Many of these complications are associated with concurrent sepsis, which further complicates reoperation and compromises success. Survival after transplantation is directly related to prompt identification of appropriate patients and acquisition of a suitable organ. When retransplantation is promptly undertaken for early graft failure, in our experience the patient survival rate is 73%. However, when retransplantation is undertaken for chronic allograft failure, often complicated by multiple organ system failure (MOSF), the survival rate is only 45%.<sup>22</sup>

Similar findings were reported by UNOS Region I in their combined experience. Patients undergoing retransplantation for acute organ failure had twice the overall survival rate as those undergoing retransplantation for chronic disease.<sup>103</sup> In addition, acute retransplantation survival was significantly influenced by the time to acquire a retransplant organ, with a more than 3-day wait decreasing the survival rate from 52% to 20%. The overall incidence of retransplantation is 15% in our series and compares with others' experience of 8% to 29%. This incidence is similar when primary whole-organ allografts are compared with primary reduced-size allografts. Reduced-size allografts are frequently used when retransplantation is required in view of their greater availability and their decreased incidence of allograft-threatening complications.<sup>28,104,105</sup> These findings emphasize the need for early identification of children requiring retransplantation and expeditious reoperation before the development of MOSF or sepsis.

## Outcome

Although the potential complications after liver transplantation are frequent and severe, the overall results are rewarding. Improvements in organ preservation, operative management, immunosuppression, and treatment of postoperative complications have all contributed to the excellent survival rate that currently exists. Factors influencing the survival of children undergoing transplantation are detailed in

**Table 45-9** Factors Affecting Transplant Survival

Medical status at orthotopic liver transplantation
Primary diagnosis
Age and size
Comorbid conditions
Encephalopathy
Infection
Multiple organ dysfunction

**Table 45-9.** Most successful transplant programs have reached overall 1-year survival rates of 90%, with greatly decreased risk thereafter.<sup>106,107</sup> Similar, if not better results, have resulted from living donor transplantation, especially for small recipients.<sup>108-110</sup> Infants younger than 1 year of age or weighing less than 10 kg have historically had reported survival rates of 65% to 88% overall, an improvement over initial reported rates of 50% to 60% during the early era of OLT development.<sup>104,111,112</sup> Survival rates in infants now equal those seen in older children.<sup>113</sup> Improved survival in these small recipients is consistent throughout all levels of diseases and results from a decrease in life-threatening and graft-threatening complications, such as hepatic artery thrombosis and primary nonfunction, in the reduced-size donor organ.

Patients with fulminant hepatic failure have an overall survival rate that is significantly lower than other diagnostic groups, with patients having metabolic disease having the highest survival rate. Prior surgical procedures, especially in patients who have undergone multiple reoperations, and the presence of multiple episodes of subacute bacterial peritonitis prior to OLT influence the incidence of complications, especially bowel perforation, but do not adversely affect overall survival in most cases. However, the most important factor determining survival is the severity of the patient's illness at the time of transplantation.<sup>28,114</sup> When stratified for illness by PELD scores, Pediatric Risk of Mortality (PRISM) score, and the previous UNOS score, the PRISM score was the most accurate in predicting both survival and morbidity during the perioperative period.<sup>115</sup> Present efforts to use surgically altered allografts, such as reduced-size orthotopic liver transplant (RSOLT), LD-OLT, and split-liver OLT, have shown similar survival rates as those for whole-organ recipients (Fig. 45-9).<sup>104,116</sup>

The increased donor availability for small recipients achieved with the use of surgically reduced, split-liver, or LD organs has also brought about a significant decrease in waiting list mortality. In our center, the mortality rate for patients awaiting transplantation has decreased from 29% to 2%, and similar results have been reported by other pediatric centers.<sup>104,105,117</sup> Efforts to enhance donor availability are essential before major improvements in postoperative survival rates will occur.

The significant success now achieved after liver transplantation cannot overshadow the need for improved management of post-transplant consequences of

immunosuppression and pre-OLT chronic disease. In our program, the most significant factors contributing to long-term failure of the allograft or patient death are consequences of immunosuppressive medications, such as late infection, PTLD, and chronic rejection of the allograft.<sup>107,118-120</sup> Our ability to successfully address these challenges will determine the lifelong success of transplantation for our youngest recipients.

## Follow-up

The overriding objective of liver transplantation in children is complete rehabilitation with an improved quality of life. Factors contributing to the attainment of this goal include improved nutritional status with appropriate growth and development as well as enhanced motor and cognitive skills, allowing social reintegration.

## Nutrition and Growth

Optimal postoperative nutrition significantly facilitates recovery and rehabilitation. This initially requires 100 to 130 calories/kg/day in recipients weighing less than 10 kg. Hepatic synthetic function, gut absorption, and appetite all improve after successful pediatric liver transplantation.

Despite these improvements, growth disturbances do not immediately resolve.<sup>121-123</sup> In the first year after transplantation, very little catch-up growth occurs. During the second and third year after transplantation patients usually show significant catch-up growth, with the potential for catch-up growth being directly correlated with the degree of preoperative growth retardation. Decreased corticosteroid administration accelerates this recovery. This growth is further improved by the use of alternate-day corticosteroids or complete corticosteroid withdrawal in patients with stable allograft function 2 years after OLT.<sup>124</sup> The "steroid-sparing" effects of new immunosuppressive agents, such as tacrolimus, could diminish this unwanted consequence of immune modulation.

**Figure 45-9.** 10-Year patient and allograft survival subdivided by whole and surgically reduced grafts (SRG). (Data from Cincinnati Children's Hospital Medical Center, Liver Care Center.)

## Neuropsychological Outcome

Although most pediatric transplant recipients are returning to normal age-appropriate activities (e.g., accomplishing normal developmental milestones, restarting school), recent studies indicate that they may be experiencing subtle functional difficulties.<sup>125-127</sup> Neuropsychological function studies of children after transplantation demonstrate multiple deficits involving learning and memory, abstraction, concept formation, visuospatial function, and motor function. The well-documented neurologic and cerebral abnormalities associated with chronic cirrhosis precede transplantation but certainly influence these results.<sup>126,128-130</sup>

The long-term impact that transplantation has on the psychosocial and financial health of the entire family unit is also the subject of much concern. Long-term pediatric liver transplant survivors need in-depth, multicenter longitudinal studies to clarify these issues.

Health Related Quality of Life (HRQOL) surveys of post-transplant families and patients demonstrate improved health and physical perception compared with their pretransplant status. However, as can be imagined, the overall impact on the family is significant. In one study, HRQOL in pediatric liver transplant recipients was lower than that reported for healthy children but similar to that for children with other chronic illness.<sup>131</sup> Age at transplantation, the time elapsed since transplantation, hospitalizations within the previous year, maternal education, and race were significant predictors of physical health. Age at transplantation and maternal education also predicted psychosocial function.

Both younger children and adolescents continue to have self-confidence and body image concerns, and their participation in out-of-family activities and sports is often limited. Caregivers and mothers, in particular, are heavily impacted by the need for care of their chronically ill children before and after transplant. Many have experienced job losses, career changes, and significant family stress.

## MULTIVISCERAL/ISOLATED INTESTINAL TRANSPLANTATION

Intestinal failure is a significant problem in the pediatric population. Total parenteral nutrition (TPN) remains the first line of therapy of children who have a loss of gastrointestinal function and is a proven, effective means of treatment. However, complications of long-term parenteral alimentation such as TPN-induced cholestatic liver disease, a paucity of access due to venous thrombosis, and recurrent catheter sepsis may preclude its continued use. When complications of long-term TPN become life threatening, the only alternative is intestinal transplantation. Although the exact incidence of intestinal failure in children is unclear, more than two thirds of the patients who are currently on the national intestinal transplantation waiting list are in the pediatric age group.<sup>132</sup>

Recent developments in the use of immunosuppression and the technical aspects of surgery have improved the outcome of patients who have undergone intestinal transplantation.<sup>133,134</sup> With the improved outcome, the role of intestinal transplantation has evolved from a heroic last effort to salvage patients with no remaining treatment options to a standard part of the armamentarium in the management of patients with intestinal failure. As a result, in October 2000, the Centers for Medicare and Medicaid Services issued a memorandum approving federal reimbursement for intestinal transplantation for selected indications.<sup>135</sup> In this section, we review the role of intestinal transplantation in pediatric patients with intestinal failure.

## Indications

Intestinal failure is the inability of the native gastrointestinal tract to provide nutritional autonomy. Patients who suffer from intestinal failure require TPN to maintain a normal state of nutrition, fluid and electrolyte balance, as well as growth and development. The cause of intestinal failure can be divided into three categories: short bowel syndrome, intestinal dysmotility syndromes, and congenital epithelial mucosal disorders. Short bowel syndrome, usually caused by the loss of intestinal length due to surgical resection for an intra-abdominal catastrophe, is the most common cause of intestinal failure. Disease processes necessitating surgical intervention that may result in short bowel syndrome range from necrotizing enterocolitis and gastroschisis in the newborn to Crohn's disease and traumatic injury to the main intestinal blood supply in the older population. Midgut volvulus, another frequent cause of short bowel syndrome, may occur at any age, although the majority of cases occur in infants.

The intestinal dysmotility syndromes include total intestinal aganglionosis (Hirschsprung's disease) and the constellation of disorders known as chronic idiopathic intestinal pseudo-obstruction. Congenital epithelial mucosal diseases, which through impaired enterocyte absorption lead to intractable diarrhea, include microvillus inclusion disease, epithelial dysplasia, and autoimmune enteritis. Although these disorders are rare, affected children face life-long difficulty with gastrointestinal function and require TPN for survival.

TPN is the standard treatment for patients who experience acute intestinal failure. Bowel rehabilitation should be tried because intestinal adaptation may result in eventual enteral autonomy. Bowel rehabilitation programs utilizing a combination of TPN, gradual re-introduction of enteral feeds, and intestinal antimotility agents are successful in achieving enteral autonomy in some patients.<sup>136,137</sup> Bowel lengthening procedures may be beneficial in selected patients.<sup>138</sup> Survival and complete return of gastrointestinal function may be predicted when the postresection length of intestine exceeds 5% of normal for gestational age, when the ileocecal valve remains or is greater than 10% of normal if the ileocecal valve has been lost.<sup>139</sup>

Unfortunately, a subset of patients will fail bowel rehabilitation and require life-long TPN for survival.

Although TPN is lifesaving, complications of long-term TPN may eventually preclude its use. The current Medicare-approved indications for intestinal transplantation are shown in Table 45-10.<sup>135</sup>

Impending liver failure from TPN-induced cholestasis is associated with a significant mortality. Unless the TPN can be stopped, it is a strong indication for combined liver/intestinal transplantation. Studies have shown that the presence of hyperbilirubinemia of more than 3 mg/dL or bridging fibrosis and cirrhosis found on liver biopsy in an infant dependent on TPN is associated with a 1-year survival of less than 30%.<sup>140</sup> All of the remaining indications reflect patients with chronic problems from continued TPN use and are relative indicators for intestinal transplantation.

Currently, with improved outcomes after intestinal transplantation, some centers advocate early intestinal transplantation before the onset of TPN-induced complications.<sup>133,134</sup> These groups believe that graft and patient survival after intestinal transplantation may improve if recipients undergo transplantation before the onset of secondary organ damage, especially liver disease. Furthermore, the quality of life in patients who have undergone successful intestinal transplantation may be better than that of patients who require long-term TPN. This issue is controversial and requires further study because TPN is a well-established and effective means of treatment for intestinal failure. A better understanding of the natural history of long-term TPN use and the progression at which TPN induces complications is necessary.

## Contraindications

The contraindications to intestinal transplantation are similar to those for any other solid organ transplantation. The presence of an active nonresectable malignancy, severe neurologic disabilities, or life-threatening extraintestinal illness precludes intestinal transplantation.

## Operative Considerations

Currently, there are three types of intestinal grafts: multivisceral, liver/small bowel composite, and small bowel alone. The type of intestinal transplant utilized is dictated by the needs of the individual patient. The biggest limitation to intestinal transplantation is the need for size-matched grafts. Patients with intestinal failure generally have limited abdominal domain (due in part to a lack of intestine volume), which necessitates near-identical-size donors. Recent developments using reduced-size liver grafts have increased the flexibility of recipient to donor size match.<sup>141</sup> However, between 40% and 50% of patients on the intestinal transplant waiting list die before undergoing transplantation owing to the lack of appropriate donors.<sup>132,142</sup> In the past, it was believed that recipients who were CMV negative should not receive intestinal grafts from CMV-positive donors because they experienced severe,

**Table 45-10 Medicare-Approved Indications for Intestinal Transplantation**

1. Impending or overt liver failure due to TPN-induced liver injury. Liver failure defined as increased serum bilirubin or liver enzyme levels or both, splenomegaly, thrombocytopenia, gastroesophageal varices, coagulopathy, stomal bleeding, hepatic fibrosis, or cirrhosis
2. Thrombosis of two or more central veins (subclavian, jugular, or femoral)
3. The development of two or more episodes of systemic sepsis secondary to line infection that requires hospitalization or a single episode of line-related fungemia, or septic shock or acute respiratory distress syndrome or both
4. Frequent episodes of severe dehydration despite intravenous fluid supplementation in addition to TPN

TPN, total parenteral nutrition.

potentially life-threatening CMV infection after transplantation.<sup>143</sup> However, with current antiviral therapy, it appears this barrier has been overcome.

An ileostomy is created in all recipients so that surveillance endoscopy and biopsy of the small bowel mucosa can be performed to monitor the allograft for rejection. If absent, a Stamm gastrostomy, placed for gastric decompression, can be used for access to the gastrointestinal tract.

## Multivisceral Graft

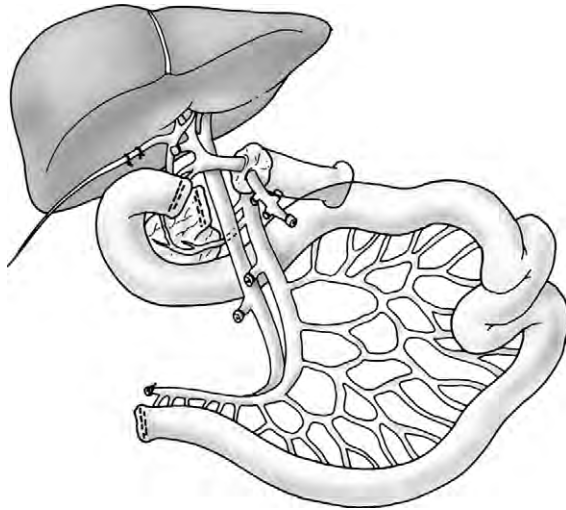

Multivisceral transplantation entails transplantation of the stomach, duodenum, pancreas, small intestine, and if necessary, the liver. In the pediatric population, the primary indications for multivisceral transplantation are the intestinal dysmotility syndromes. On occasion, a giant desmoid tumor of the mesentery that extensively infiltrates the mesentery may require this form of transplantation. Exenteration of the native intra-abdominal viscera is followed by transplantation of the multivisceral graft using arterial inflow through the donor celiac and superior mesenteric artery. Venous outflow occurs via the transplanted liver placed in the standard orthotopic position.

## Liver/Small Bowel Composite Graft

A liver/small bowel composite graft is a modification of the multivisceral graft in which the stomach is removed during procurement. This form of transplantation is indicated in patients with intestinal failure and impending or overt TPN-induced liver failure and is the most common type of intestinal transplant currently utilized (Fig. 45-10). The recipient's liver and residual small intestine are removed while the native stomach, duodenum, pancreas, and spleen are left intact. A portacaval shunt from the native portal vein to the inferior vena cava is necessary to provide venous outflow from the recipient's foregut organs (Fig. 45-11). The donor celiac and superior mesenteric artery remain the source of arterial inflow to the

transplanted organs. The donor portal vein and biliary tree are intact, having not undergone dissection during procurement. As a result, no portal vein or bile duct reconstruction is necessary. The pancreas is left intact to protect the peribiliary ductal vessels and to prevent the possibility of pancreatic leak from a divided surface. Venous outflow from the transplanted organs is once again provided by the donor liver placed in a standard

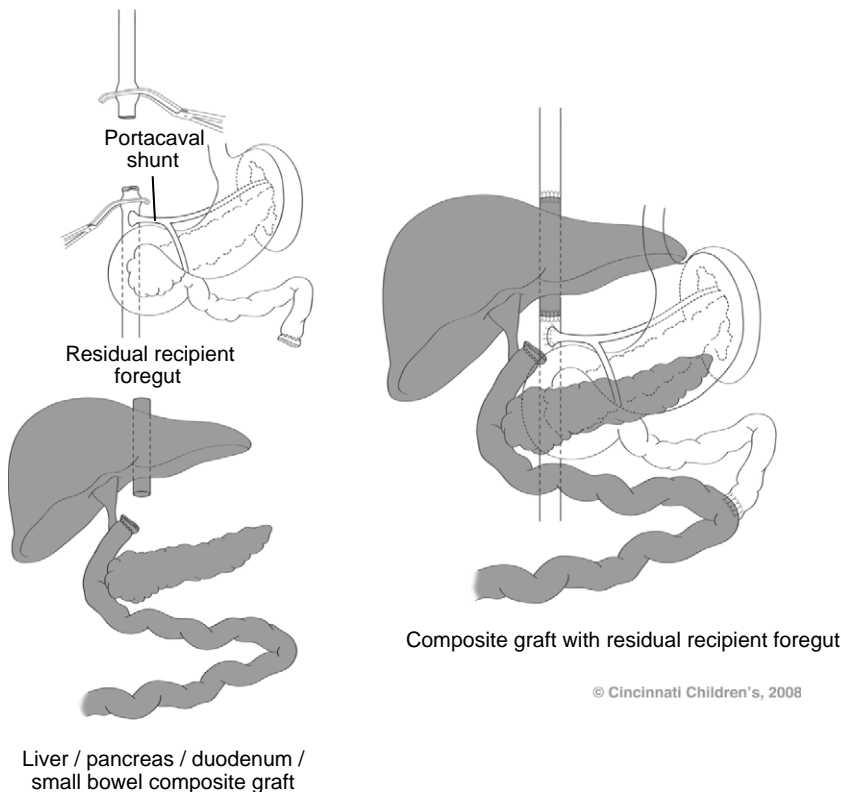

orthotopic position. If the liver is too large, an *ex vivo* hepatic lobectomy can be performed usually removing the right lobe of the liver (Fig. 45-12). Luminal continuity from the patient's stomach and duodenum to the newly transplanted bowel is achieved by anastomosis of the recipient's duodenum to the donor jejunum. If the recipient has any colon, a donor ileum to recipient colonic anastomosis is created distal to the ileostomy.

**Figure 45-10.** Schematic diagram of liver/intestine composite allograft. (From Abu-Elmagd K, Reyes J, Todo S, et al: Clinical intestinal transplantation: New perspectives and immunologic considerations. *J Am Coll Surg* 186:512-527, 1998.)

### Small Intestine Graft

Transplantation of the small intestine alone entails procurement of only the jejunum and ileum. During procurement, the superior mesenteric artery and vein are divided just below the third portion of the duodenum at the root of the mesentery, generating a graft of jejunum and ileum (Fig. 45-13). This type of transplant is indicated in patients with intestinal failure without other organ dysfunction. Depending on space requirements, the recipient's residual small bowel is removed. Arterial inflow is provided by anastomosis of the superior mesenteric artery to the recipient's aorta. Venous drainage of the transplanted intestines is either directly into the inferior vena cava or the native superior mesenteric vein. Initially it was believed that venous drainage into the native portal circulation was beneficial to the liver, but recent studies suggest minimal benefit.<sup>144</sup> Therefore, currently the most common form of venous reconstruction is an end-to-side anastomosis of the donor superior mesenteric vein to the native vena cava. Luminal continuity is restored by

**Figure 45-11.** Schematic diagram of liver/intestine composite allograft with native portacaval shunt. (© Cincinnati Children's, 2008.)

**Figure 45-12.** Schematic diagram of reduced-size liver/intestine composite allograft. (From Reyes J, Mazariegos GV, Bond GMD, et al: Pediatric intestinal transplantation: Historical notes, principles and controversies. *Pediatr Transplant* 2002;6:193-207.)

anastomosis of the recipient's proximal bowel to the transplanted jejunum. Once again, if residual colon is present, a donor ileum to colonic anastomosis is created downstream from the ileostomy.

### Postoperative Complications

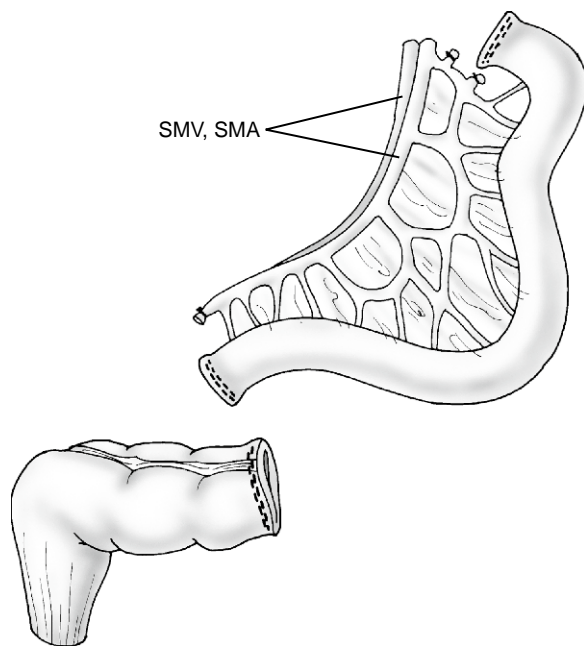

Although the success rate after intestinal transplantation continues to improve, postoperative complications are common. A breakdown of intestinal integrity either at sites of anastomosis or in areas of mucosal injury from ischemia and reperfusion will necessitate re-exploration. Bowel perforation may also occur during surveillance endoscopy. Patients with a significant amount of peritoneal contamination after bowel perforation may require serial operative exploration to

clear foci of intra-abdominal infection. Postoperative bleeding is frequent, especially in patients who undergo liver/small intestine composite grafts, because preexisting portal hypertension results in varices throughout the abdomen. Chylous leaks are also frequent because lymphatic drainage may be disrupted during both the procurement and the recipient operative procedure. Most chylous leaks can be managed conservatively. Almost all patients who undergo intestinal transplantation will require re-exploration at some point in the postoperative period.

### Immunosuppression/Rejection

The most significant advances in the management of an intestinal transplant recipient have occurred in the use of immunosuppression. Rejection remains the most common complication after intestinal transplantation with virtually every patient experiencing an episode of rejection in the first 6 months after transplantation. Overwhelming rejection was one of the most frequent causes of graft loss during the initial experience with intestinal transplantation due, in part, to the limited number of immunosuppressive agents available. Before tacrolimus was developed, high-dose immunosuppression was necessary to prevent rejection. Infections and PTLD, side effects of high-dose immunosuppression, became frequent causes of a poor outcome. The goal of current immunosuppressive regimens is to use just enough immunosuppression to prevent rejection but not so much that infections and PTLD become common. The management of immunosuppression in patients who undergo intestinal transplantation remains the most challenging aspect of patient care.

Surveillance endoscopy and biopsy is initiated 5 days after transplantation to evaluate for rejection and is performed at least two to three times per week for the first month. Significant progress in the definition of the histologic characteristics of small bowel rejection has been achieved. If rejection is diagnosed, a short course of high-dose corticosteroids is administered. If rejection persists, anti-lymphocyte antibody immunosuppression using agents such as OKT-3 or thymoglobulin is required. In an effort to achieve

**Figure 45-13.** Schematic diagram of isolated small intestinal transplant. SMV, superior mesenteric vein; SMA, superior mesenteric artery. (Adapted from Abu-Elmagd K, Fung J, Bueno J, et al: Logistics and technique for procurement of intestinal, pancreatic, and hepatic grafts from the same donor. *Ann Surg* 232:680-687, 2000.)

tolerance, some centers are using a combination of thymoglobulin, graft irradiation, and bone marrow transplantation.<sup>145</sup>

### Infections

Owing in large part to the high level of immunosuppression needed after intestinal transplantation, bacterial and fungal infections are common in the postoperative period. Patients with intestinal failure are frequently colonized with antibiotic-resistant bacteria due to recurrent infections while on TPN. As mentioned previously, because intestinal perforation is common, peritonitis is a frequent complication often requiring repeat intra-abdominal explorations to completely clear the peritoneum.

CMV, EBV, and adenovirus are the most frequent viral pathogens found in the postoperative period. PTLD, an EBV-driven process, remains a significant problem because most infants are EBV negative at the time of transplantation. Surveillance for CMV and EBV using PCR, followed by aggressive treatment when detected, has diminished the impact of these dangerous pathogens on patient outcome. All patients are maintained on prophylactic antiviral agents in the perioperative period.

### Outcome

The initial experience of patients who underwent intestinal transplantation was dismal with few long-term survivors.<sup>146</sup> Thus, because TPN was so successful at treating patients with intestinal failure, the interest in intestinal transplantation was limited. As long-term use of TPN increased, the complications of TPN became increasingly apparent. As a result, renewed interest in intestinal transplantation occurred. With the development of tacrolimus, intestinal transplantation became a viable alternative. Currently, over 70% of patients survive 1 year and 50% survive 5 years after transplantation.<sup>146-148</sup> Recent data from the University of Pittsburgh have shown that in children using a combination of thymoglobulin induction followed by tacrolimus monotherapy, graft and patient survival of 100% at 1 year can be achieved.<sup>149</sup> Such results support the conclusion that the role of intestinal transplantation in the management of children with intestinal failure has moved from experimental to an integral part of the treatment for intestinal failure.<sup>150</sup>

## RENAL TRANSPLANTATION

### Indications

Acute renal failure in infants is most often the consequence of hemodynamic instability, with poor perfusion or hypoxia resulting in acute tubular necrosis (ATN). Most of these patients either recover sufficient renal function for normal long-term survival or die of multisystem failure.

Chronic renal failure is uncommon in infants, with the estimate of infants with ESRD placed at 0.2 per million total population for infants younger than 1 year of age.<sup>151,152</sup> Congenital lesions, such as renal dysplasia, obstructive malformations, or complex urogenital malformation, and congenital nephrosis are the most common causes of ESRD in children younger than 5 years of age. These diseases account for about half the cases. Glomerulonephritis, including focal segmental glomerulosclerosis, membranoproliferative glomerulonephritis, and lupus nephritis, as well as recurrent pyelonephritis, are common causes of ESRD in older children (Table 45-11).<sup>153</sup> Hereditary causes of renal failure should be identified to plan an appropriate overall treatment strategy, including evaluating other family members and providing

**Table 45-11** Primary Diagnoses in Children Requiring Renal Transplantation (NAPRTCS, 2008)

Primary Diagnosis	No. Patients	Percentage

genetic counseling when needed. Recently, because the number of patients who have undergone renal transplantation in childhood has increased, chronic rejection after renal transplantation has become a frequent cause of ESRD.

Knowledge of the etiology of the ESRD is important to allow assessment of the potential for recurrence within a transplant allograft and consideration of LD transplantation. Patients with a “structural/congenital” etiology without an immunologic component also enjoy better graft survival rates than those patients with glomerulonephritis.<sup>154</sup>

## Pretransplant Management

Pretransplant management is critical in infants and children with ESRD. Children with ESRD beginning in infancy or early childhood experience significant complications from growth retardation, renal osteodystrophy, and neuropsychiatric developmental delay. Recent advances in dialysis regimens, nutritional supplementation, and recombinant human erythropoietin and growth hormone have significantly improved the pretransplant management of these patients.

### Dialysis

Dialysis is indicated when complications of ESRD occur despite optimal medical management, specifically hyperkalemia, volume overload, acidosis, intractable hypertension, and uremic symptoms such as vomiting. In older children, lethargy and poor school performance can signal the need for more aggressive treatment. In addition, dialysis may be necessary to facilitate the administration of adequate protein as part of an extensive nutritional resuscitation plan.

When dialysis is needed, the use of peritoneal dialysis is preferred for the following reasons: (1) it avoids the multiple blood transfusions associated with hemodialysis; (2) it allows a gradual correction of electrolyte abnormalities, preventing cerebral disequilibrium syndrome in small infants; (3) it allows for easier control of osteodystrophy; (4) it optimizes nutrition; and (5) it is easy to administer.

Hemodialysis is used when there is an unsuitable peritoneal cavity secondary to prior surgery or multiple peritoneal infections. However, the construction and maintenance of adequate long-term vascular access sites in small infants and children is difficult. Use of central venous catheters, rather than arteriovenous fistulas, is our preferred mode for temporary hemodialysis access in infants and small children, although infection and vascular thromboses complicate this therapy. Access via the internal jugular veins is preferred over subclavian routes to avoid venous occlusion from the upper extremity, which compromises future arteriovenous fistula sites. Although dialysis and its complications, such as infection, have a great influence on the complexity of care, they do not affect the ultimate results of renal transplantation.<sup>155</sup>

## Nutritional Support

The need for vigorous nutritional support of the infant with uremia has been well documented by the growth retardation seen in infants and children with ESRD. The etiology of this growth disturbance is multifactorial, including anorexia that leads to protein and calorie insufficiency, renal osteodystrophy, aluminum toxicity, uremic acidosis, impaired somatomedin activity, and growth hormone and insulin resistance.<sup>156</sup> Because the most intense period of growth occurs during the first 2 years of life, careful nutritional support during that time is essential.

With extensive nutritional efforts, the mean weight at the time of transplantation for all patients has improved from 2.2 standard deviation (SD) to 1.6 SD below the appropriate age-adjusted and gender-adjusted mean for normal children in the recent North American Pediatric Renal Transplant Cooperative Study (NAPRTCS).<sup>157</sup> Similar height deficits occurred. This growth deficit was greater (2.8 SD) in children younger than 5 years of age. Transplantation afforded a +0.8 SD increase in growth over the first post-transplant year. However, this accelerated growth then reaches a stable plateau. After 2 to 3 years, the mean weight values were comparable to those in normal children.<sup>153</sup> Children 6 years of age and older show no improvement in their height deficit 5 years after transplantation.<sup>158,159</sup> These limitations to “catch-up” growth emphasize the need for early transplantation in young ESRD patients. If epiphyseal closure has occurred (bone age >12 years), additional bone growth is often not achieved.<sup>152,160,161</sup> Normalization of growth rarely occurs with the introduction of either hemodialysis or peritoneal dialysis.

The importance of normalizing nutritional parameters is emphasized by the adverse impact of uremia on the developing nervous system in the infant. The significance of this problem was emphasized in a study in which progressive encephalopathy, developmental delay, microcephaly, hypotonia, seizures, and dyskinesia developed in 20 of 23 children with ESRD before 1 year of age.<sup>162</sup> All of these patients had significant growth impairment. Monitoring of the head circumference has been suggested to identify the infant at risk, with the intent to initiate dialysis, nutritional support, or transplantation if this parameter deviates from the normal curve.<sup>152</sup>

## Transplant Management

### Preoperative Evaluation

In preparation for transplantation, an extensive evaluation of the patient’s urinary tract and immunologic status is necessary. The increased frequency of urinary tract abnormalities as the primary cause of ESRD in infants and children necessitates the investigation of the urinary tract for sites of obstruction, presence of ureteral reflux, and functional state and capacity of the urinary bladder.<sup>163</sup> This investigation is best accomplished by ultrasonography or intravenous pyelography of the upper urinary tract and a voiding

cystourethrogram to assess bladder and reflux parameters. Any questions related to bladder function or structure require urodynamics and cystoscopy.

In patients with long-standing oliguric ESRD, the bladder capacity may appear very small. In the absence of abnormal obstructive or neuromuscular bladder pathology, adequate enlargement of the bladder in the presence of normal urinary production is to be expected. Any surgical correction of urethral obstruction or bladder augmentation should be undertaken far in advance of the kidney transplant. Preoperative sterilization of the urinary tract and development of unobstructed urinary outflow should be the ultimate goals of evaluation and reconstruction. Although complex anomalies of the urogenital tract often require many extensive operative procedures to augment, reconstruct, or create an acceptable lower urinary tract, virtually all such children can undergo successful reconstruction with continent urinary reservoirs without the use of intestinal conduits.<sup>164</sup>

Immunologic assessment includes tissue typing and panel reactive antibody analysis. Patients should be monitored periodically for the development of a positive crossmatch to their potential LD or a positive cytotoxic antibody to a panel of random donors to assess immunologic reactivity. In addition, reactivity to CMV, EBV, HSV, and hepatitis should be investigated. Childhood immunizations should be current, and immunization against hepatitis B virus should be instituted. Any immunizations with live virus vaccines should be given well in advance of transplantation because their use is contraindicated in the early post-transplant period.

Selection of the appropriate donor for transplantation is a decision for the transplant team and family to consider together. A related immediate family member (LD) has the advantage of a low incidence of postoperative acute tubular necrosis, an improved histologic matching (leading to fewer rejection episodes and the need for less immunosuppression), and the possibility of extended organ function. In addition, any operative procedures required for recipient preparation, as well as the transplant procedure, can be scheduled around the needs of the patient, simplifying preoperative care and potentially avoiding the complications

of dialysis. Parents form the majority of donors. Siblings younger than 18 years of age are rarely considered unless they are identical twins. At present, 60% of children receive a related LD kidney.<sup>158</sup> Complete evaluation of the potential donor to exclude intrinsic renal anomalies, vascular anomalies, and systemic illness is necessary.

Cadaver donor (CD) kidneys are used for 40% of renal transplants. The unpredictability of donor organ availability and the need to establish a negative antibody crossmatch for CD transplantation make surgical planning impossible. The size of a potential allograft, whether CD or LD, is also important. Kidneys from small adult donors can be transplanted into infants as small as 5 kg with good technical success.<sup>165</sup> CD organs from pediatric donors 5 years of age or older also yield an excellent survival rate. However, a progressive decrease in 1-year graft survival has been noted when kidneys from donors younger than 3 to 4 years of age have been used.<sup>166,167</sup> This decrease in graft and patient survival rate is related to the donor organ source. Children 2 to 5 years of age have a similar survival rate as the overall pediatric population when living related donors are used. Recognition of this potential risk has led to reluctance by most centers to use donors younger than 5 years of age. An effect of donor age on graft survival has been attributed to an increased rate of both graft thrombosis and acute rejection.<sup>153</sup>

The decision to use a CD is often strengthened by the possibility of disease recurrence within the transplanted kidney. The incidence of disease recurrence after transplantation and the risk of graft loss are listed in Table 45-12.<sup>168</sup> The decision to proceed with LD transplantation in small children is influenced by the recent improvements in outcomes that show similar 1-year graft survival for all age groups.

## Preemptive Transplantation

The desire to begin preemptive transplantation before undertaking dialysis is often fueled by the patient's or parents' desire to avoid the surgical procedures, potential infections or cardiovascular complications, and psychological impairment inherent with dialysis.

**Table 45-12** Recurrence Rates and Graft Loss from Recurrent Disease in Children

Disease	Recurrence Rate (%)	Clinical Severity	% of Those with Recurrence Whose Graft Failed
FSGS	25-30	High	40-50
MPGN type I	70	Mild	12-30
MPGN type II	100	Low	10-20
SLE	5-40	Low	5
HSP	55-85	Low/mild	5-20
HUS			
Classic	12-20	Moderate	0-10
Atypical	±25	High	40-50

FSGS, focal segmental glomerulosclerosis; HSP, Henoch-Schönlein purpura; HUS, hemolytic uremic syndrome; MPGN, membranoproliferative glomerulonephritis; SLE, systemic lupus erythematosus.

From Fine RN, Ettenger R. In Morris PJ (ed): *Kidney Transplantation: Principles and Practice*, 4th ed. Philadelphia, WB Saunders, 1994, p 418.

A recent NAPRTCS review found 26% of primary transplantations were performed without prior dialysis.<sup>168</sup> Most cases used LDs rather than CDs. There was no difference in patient or graft survival in this group when compared with patients who undergo dialysis before transplantation. Preemptive transplantation is not possible when uncontrolled hypertension, massive proteinuria, or recurrent infection require prior native kidney removal or when oliguric renal failure requires immediate dialysis.

### Operative Procedure

Preparation for transplantation should include placing adequate large-bore intravenous lines and using the largest urinary catheter possible. Central venous lines are used in all infants and children to ensure vascular access, hemodynamic monitoring, and a route for postoperative immunosuppressive delivery. Perioperative prophylactic antibiotics are administered. Arterial pressure monitoring lines are only necessary in small infants and patients with hemodynamic compromise, allowing preservation of future hemodialysis access sites.

Transplantation in infants and small children can be undertaken through a generous retroperitoneal approach or transabdominal placement of the allograft within the peritoneal cavity posterior to the right or left colon. An extraperitoneal approach to the retroperitoneum allows the maintenance of postoperative peritoneal dialysis and should be strongly considered when size permits. The arterial anastomosis is constructed end-to-side into the distal aorta or common iliac artery, and venous outflow of the allograft should be into the IVC or common iliac vein (Fig. 45-14) Ureteral implantation using the Lich extravescical ureteroneocystostomy avoids the presence of a cystotomy and minimizes postoperative blood clots within the bladder, which may obstruct the urinary catheter. When larger donor kidneys are used in small recipients, the vessels must be shortened to avoid

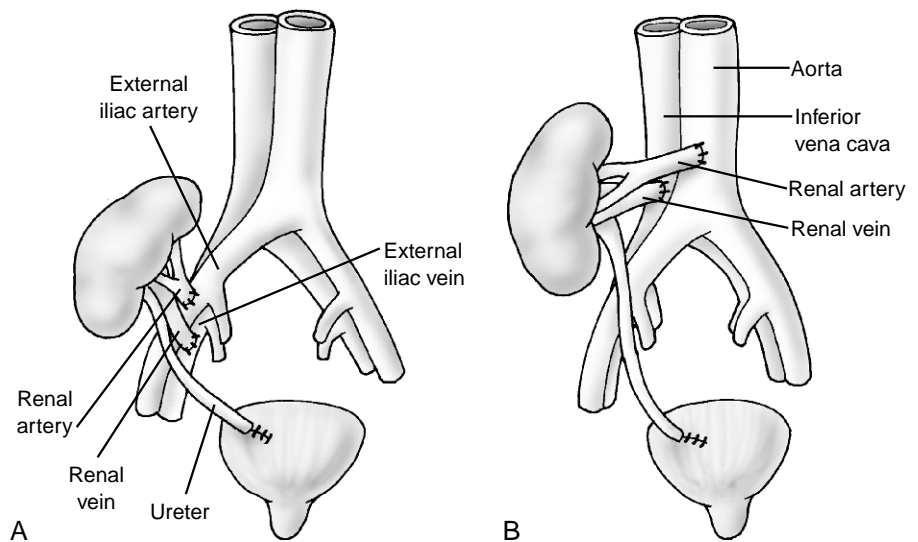

redundancy when the kidney is positioned in the retroperitoneum. The internal iliac artery is not used in pediatric transplants so that pelvic blood flow is preserved. Ureteral “double-J” stents are used when small ureter size may lead to obstruction.

Anesthetic management of the infant and small child during kidney transplantation is complicated by preexisting electrolyte abnormalities and the large fluid fluxes that occur in the operating room. Intravascular blood volume must be augmented during allograft implantation to allow maintenance of normal systemic blood flow when allograft blood flow is re-established. Perfusion of the allograft with hypothermic lactated Ringer’s solution before implantation to remove any remaining hyperkalemic graft preservation solution is necessary in infants and small children to avoid massive potassium infusion with establishment of allograft perfusion. Blood volume loading to a central venous pressure of 13 to 15 cm H<sub>2</sub>O and administration of bicarbonate, calcium, and low-dose vasopressors (dopamine, 5 µg/kg/min) should be started before graft reperfusion.

### Postoperative Management

Post-transplant management requires careful screening for technical complications, rejection, recurrence of the primary renal disease, and prevention of immunosuppression-related complications.

Frequent fluid and electrolyte monitoring is necessary immediately after transplantation because larger kidneys can excrete the equivalent of the infant’s blood volume within a single hour. Careful attention to serum concentrations of calcium, phosphorus, magnesium, and electrolytes is necessary. Urine output is initially replaced isovolumetrically and is then tapered as the high-output state subsides. Glucose-free urine replacement fluids minimize hyperglycemia and attendant osmotic diuresis in the recipient. Selection of appropriate electrolyte concentrations is guided by urinary electrolyte excretion, which is regularly monitored. Central venous filling pressures

**Figure 45-14.** Schematic diagram showing the transplant arterial and venous anastomosis to the iliac vessels (A) or the aorta and vena cava (B). Ureteral implantation using the Lich extravescical ureteroneocystostomy is preferred.

should be maintained at 7 to 10 cm H<sub>2</sub>O to ensure adequate intravascular volume. In patients with high-output renal failure, urine losses from both the native and transplant kidneys need to be replaced to avoid hypoperfusion and thrombosis. Maintenance of catheter patency is essential. Any episode of decreased urinary output should be rapidly investigated to exclude urinary catheter occlusion and bladder distention. An algorithm for the evaluation of early postoperative oliguria is shown in Figure 45-15.

## Technical Complications

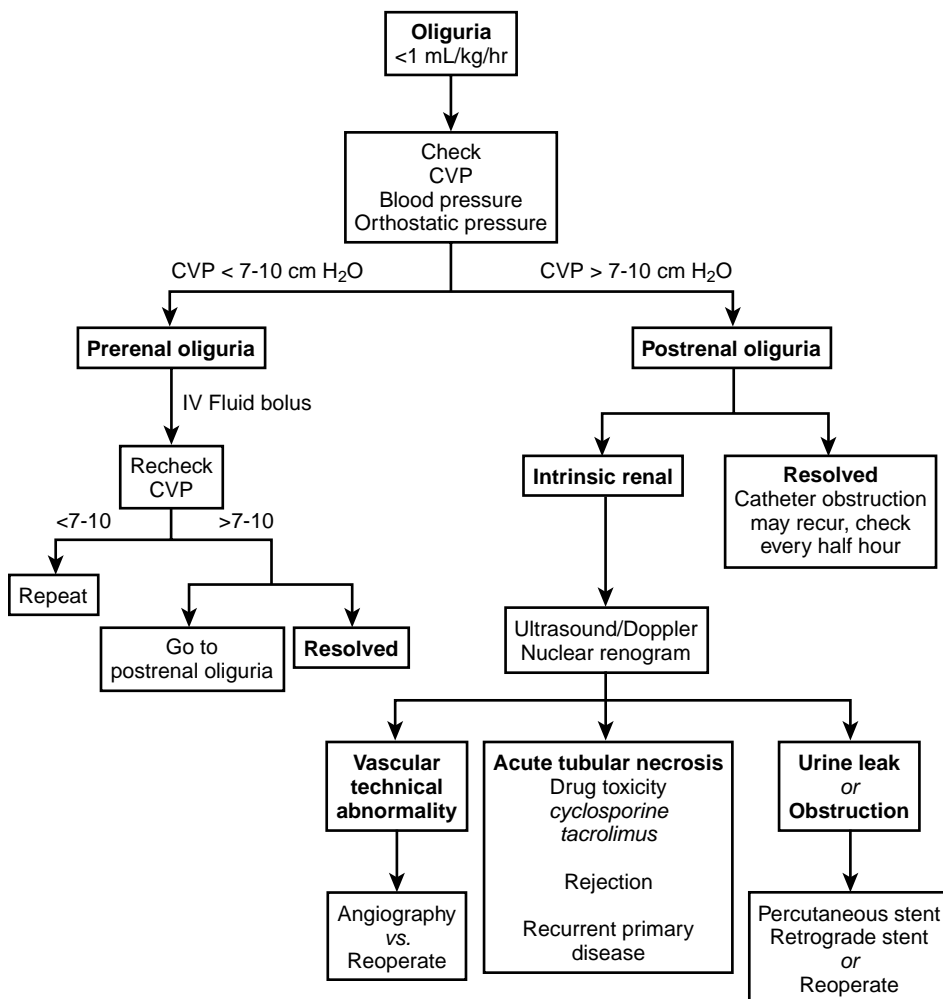

Vascular thrombosis still accounts for graft loss in up to 13% of initial transplants and 19% of repeat transplants in children. Graft thrombosis is significantly more frequent in children younger than 2 years of age and is directly related to the age of both the donor and the recipient. In addition, prolonged cold ischemic preservation time (>24 hours) and the related presence of ATN with delayed graft function also increase this risk. Prior transplantation and more than five pretransplant blood transfusions have also been shown to be independent risk factors. Immediate post-transplant Doppler ultrasound vascular imaging is helpful in confirming suitable allograft blood flow after

abdominal closure, especially when large allografts are implanted into small recipients. Adequate hydration is important to maintain suitable perfusion. Anticoagulation has not been used in most series.

Urinary leak, most often at the neocystostomy site, presents as oliguria and persisting uremia. Ultrasound or nuclear imaging can be used to identify an extravascular fluid collection. Direct operative repair is necessary to prevent urinoma formation and its potential infectious complications. Urinary collections must be differentiated from lymphoceles at the transplant site. Unresolving lymphoceles are best opened into the peritoneal cavity using laparoscopy.

## Hypertension

Hypertension after renal transplantation is common. One month after transplantation, 72% of patients require treatment, although this percentage decreases to 53% at 30 months. Careful attention to the pretransplant control of hypertension and dietary management improves post-transplant control. Hypertension presents a significant risk to possible renal function when using small allografts. Hypertension in the early postoperative period is most often due to fluid overload or acute rejection, but it can also originate from the native kidneys.

**Figure 45-15.** Algorithm for the evaluation of early postoperative oliguria after pediatric renal transplant. CVP, central venous pressure.

Preexisting hypertension is augmented by the immunosuppressive drugs cyclosporine, tacrolimus, and prednisone. The development of hypertension more than 3 months after transplantation suggests possible renal artery stenosis and warrants Doppler ultrasound flow studies for initial evaluation. Arteriography is needed in questionable cases. Transluminal angioplasty has been successful in managing the majority of these cases when recognized. Surgical correction is reserved for angioplasty failures and vessels with a complex arterial anastomosis.

### Infection

Most long-term complications are related to infection and occur within the first 6 post-transplant months. During this time, immunosuppression is intense and susceptibility to life-threatening infection is increased. The frequent use of organs from donors who have had prior exposure to CMV and EBV in infants and children who are seronegative enhances the risk of these specific infections. Expanded use of antiviral prophylaxis using ganciclovir and acyclovir has decreased the intensity of these infections and their associated morbidity or mortality. Trimethoprim-sulfamethoxazole is used for *Pneumocystis jiroveci* pneumonia prophylaxis as well.

### Immunosuppression

Many immunosuppressive regimens are available, and all share similar strategy. Most regimens include corticosteroids, cyclosporine or tacrolimus, and azathioprine or mycophenolate. Polyclonal or monoclonal antilymphocyte antibodies are used when ATN is anticipated or for retransplantation in highly presensitized patients. Significant efforts to decrease or discontinue corticosteroids have been attempted to enhance growth and development. At 4 years after transplantation, 31% of LD and 23% of CD recipients were receiving alternate-day prednisone.<sup>153</sup>

Overall, there has been a decrease in the frequency of acute rejection, with 12-month probabilities in LD recipients of 32% and CD recipients of 36%. The risk of rejection is similar for LD and CD recipients in the first few post-transplant weeks. Factors that increase the likelihood of rejection or long-term graft loss include receiving a graft from a CD rather than a related LD, receiving a graft from a donor younger than 5 years of age, having the graft in cold storage for more than 24 hours, being an African-American recipient, and delayed graft function from ATN.<sup>153</sup> The ability to treat rejection has also improved with complete reversal of acute rejection in 65% of episodes. The rate of success in treating rejection declines with each successive rejection episode, increased recipient age, and late rejection episodes.<sup>153</sup> Most rejection episodes can be treated with corticosteroid administration alone (78%). Monoclonal anti-T-cell agents such as OKT-3 are needed in 32%. In patients who remain rejection free for the first post-transplant year, the risk of rejection in the following year is 20%.<sup>155</sup>

## Results

The overall results of renal transplantation in children are steadily improving. Overall 1-year transplant graft survival rates of 88% to 100% have been reported for LD allografts, with results for CD allografts being 50% to 72%.<sup>152,165-168</sup> In the 2008 NAPRTCS report, 1-, 3-, and 5-year graft survival rates were as follows: CD, 93%, 84%, and 77%; LD, 95%, 91%, and 85%, respectively (Fig. 45-16).

Chronic rejection has become the most common cause of graft failure, accounting for 27% of all graft losses. With improved immunosuppressive treatments, acute rejection accounts for only 15% of failures. Recurrence of the original disease caused graft failure in 6%, and vascular thrombosis accounted for 12% of graft failures. Long-term graft survival after pediatric renal transplantation continues to deteriorate after 10 years despite low patient mortality rates. Death of the recipient with a functioning graft is an uncommon problem. When this occurs, death results primarily from infection (40%) or cardiovascular causes (21%). Young recipients (birth to 1 year of age) and patients with early graft failure are at the highest

	Years post transplant							
	Year 1		Year 3		Year 5		Year 7	
	%	SE	%	SE	%	SE	%	SE
Living donor (1987-1995)	91.2	0.59	84.6	0.76	78.9	0.89	72.2	1.05
Living donor (1996-2007)	95.3	0.41	90.9	0.62	85.4	0.91	78.9	1.40
Deceased donor (1987-1995)	80.7	0.81	70.5	0.96	62.4	1.06	56.2	1.16
Deceased donor (1996-2007)	93.4	0.57	83.8	0.99	77.3	1.31	65.3	2.05

**Figure 45-16.** Renal allograft survival over 5 years from a living donor compared with a cadaveric donor. (From 2008 North American Pediatric Renal Transplant Cooperative Study Report.)

risk. Progressive loss of renal function may be secondary to complications of hypertension, hyperfiltration, hypercholesterolemias, chronic indolent immunologic damage leading to chronic rejection, and progressive primary renal disease. All of these contribute to long-term graft loss.<sup>154,168</sup> Methods to circumvent this progressive graft loss will greatly improve the long-term prognosis.

The overall half-life of pediatric renal transplants is about 25 years for LD grafts and 16 years for CD grafts. Many recipients require second transplants in their lifetime. Overall graft survival for second transplants using LDs was equivalent to primary CD allografts. The factor exerting negative influence on survival in CD grafts was donor age younger than 6 years. Better donor-recipient matching has improved graft survival. The rapidity of first allograft loss, immunologic protocol at retransplant, and race of recipient are not significant factors. Thus, use of cadaveric kidneys from young donors for these procedures is not recommended.

---

## PANCREAS TRANSPLANTATION

Children have rarely been candidates for pancreas transplantation. In the past, the results after pancreas transplantation have not justified the risks associated

with immunosuppression and operation. However, recent improvements in the operative procedure and follow-up have occurred. Overall 1-year patient survival rate exceeds 90%, and graft survival with complete insulin independence exceeds 70% in patients in whom combined kidney and pancreas transplantation is undertaken. The survival rate is approximately 50% in isolated pancreas transplantation.<sup>169,170</sup>

The addition of pancreas transplantation with kidney replacement for diabetic nephropathy does not subject the patient to additional immunosuppressive risks, and it is better accepted. The use of isolated pancreas transplantation is reserved for patients who have extremely labile glucose control or experience hypoglycemic unawareness syndrome.<sup>169</sup> As the results of this procedure improve in the future, the role of this operation in children will need to be reviewed.

Pancreatic islet transplantation has also become possible in children. However, its role in the treatment of juvenile diabetes in childhood is still limited. This procedure has been undertaken in children after pancreatic resection when the cellular autotransplant does not require immunosuppressive treatment. Results have been excellent. Further expansion of this treatment option awaits firm documentation that hypoglycemic correction retards the systemic complications of diabetes.

## ANATOMY AND EMBRYOLOGY

The pancreas originates in week 4 of gestation as paired evaginations of the foregut.<sup>1</sup> The dorsal pancreatic bud gives rise to the body and tail of the pancreas, the minor duct (Santorini) and minor papilla, and the continuation of the main duct (Wirsung) into the body and tail. The dorsal pancreas arises as a diverticulum from the dorsal aspect of the duodenal anlage. The ventral pancreatic bud arises from the biliary diverticulum and swings around the dorsal aspect of the duodenal anlage during gut rotation to give rise to the head of the pancreas, as well as the proximal portion of the main pancreatic duct (Fig. 46-1).

The two pancreatic buds fuse to form one pancreas at approximately 7 weeks' gestation, although it appears that complete fusion of the two ducts to form the main pancreatic duct is delayed until the perinatal period.<sup>2</sup> The endocrine component of the pancreas, the islets of Langerhans, starts to differentiate before

evagination of the pancreatic buds from the wall of the foregut.<sup>3</sup> The islets make up 10% of the pancreas during early embryonic and fetal life, but that figure decreases to less than 1% in the adult. Fetal pancreatic islets appear to play an important role in fetal homeostasis. Pancreatic acini begin to form at 12 weeks and begin to accumulate organelles and zymogen granules characteristic of acinar cells. These cells do not secrete appreciable amounts of enzyme until the time of birth.<sup>1</sup>

The pancreas is retroperitoneal and is light pink in children. The acini can be seen with low-power loupe magnification, as can the septa dividing the lobulations. The head of the pancreas lies in the C-loop of the duodenum while the uncinate process, emanating from the posteromedial portion of the head, projects under the superior mesenteric artery and vein. The neck of the pancreas is defined as that portion of the pancreas anterior to these vessels.<sup>4</sup> The body and

**Figure 46-1.** Pancreatic embryology. **A**, Stomach (a), gallbladder (b), and ventral (c) and dorsal (d) pancreatic buds develop separately at embryologic week 4. The pancreas develops as an evagination of the developing foregut. The dorsal bud evaginates directly off of the duodenal anlage. **B**, The ventral bud evaginates from the biliary bud and then swings around to the left, with gut rotation occurring simultaneously. **C**, The main pancreatic duct of Wirsung and the minor accessory duct of Santorini are shown.

**Figure 46-2.** CT scan showing the cross-sectional anatomy of the pancreas. The pancreas (P) lies convexly across the lumbar spine with the tail of the pancreas next to the spleen (Sp) and the hilum of the left kidney. The head of the pancreas lies to the right of the spine near the hilum of the right kidney. L, Liver; S, stomach; C, colon. (From Maher MM, Hahn PF, Gervais DA, et al: Portable abdominal CT: Analysis of quality and clinical impact in more than 100 consecutive cases. *AJR Am J Roentgenol* 183:663-670, 2004.)

tail, to the left of these vessels, angle sharply upward toward the hilum of the spleen. The main pancreatic duct runs along the posterior aspect of the gland and curves downward in the head to run alongside the common bile duct, which runs in a groove posterior to the pancreas or within the substance of the posterior gland. The main pancreatic duct and common bile duct may fuse to form a “common channel” before entry into the duodenum.

The pancreas is quite convex, with its midportion being reflected over the anterior surface of the upper lumbar vertebrae and aorta and the lateral portions falling posteriorly toward each kidney (Fig. 46-2). The arterial supply of the pancreas is from the celiac and superior mesenteric arteries, which form the pancreaticoduodenal arcade. The pancreas also has anastomoses from the splenic artery.

## CONGENITAL ANOMALIES

Ectopic pancreatic rests are frequently encountered along foregut derivatives, such as the stomach and the duodenum, as well as along the jejunum, ileum, and colon.<sup>5</sup> These lesions are found in approximately 2% of autopsy series and represent the most common anomaly of the gastric antrum. Moreover, they may cause gastric outlet obstruction.<sup>6</sup> Their origin is unknown, but one possible explanation is aberrant epithelial-mesenchymal interactions, leading to the transdifferentiation of heterotopic embryonic epithelium into pancreatic epithelium. Some recent studies have implicated defects in “hedgehog” signaling, which may antagonize normal pancreatic development, as the cause of the formation of ectopic pancreatic tissue.<sup>7,8</sup> Ectopic rests are typically asymptomatic and are encountered incidentally at laparotomy. They can be identified as pancreatic tissue because the

surface has the same granular acinar appearance as the normal pancreas. These ectopic pancreatic rests usually do not become inflamed, possibly because they contain numerous small drainage ducts rather than a large single duct, which might become obstructed more easily. Occasionally, an ectopic pancreatic rest produces obstruction or bleeding. When encountered at laparotomy, ectopic rests should probably be excised unless the excision would entail significant risk of morbidity.

Annular pancreas is thought to result from faulty rotation of the ventral pancreatic bud in its course around the posterior aspect of the duodenal anlage. The duodenum is encircled and often obstructed by normal pancreatic tissue containing normal-functioning acini, ducts, and islets of Langerhans.<sup>9,10</sup> The prevailing theory of pathogenesis is that half of the ventral bud migrates anteriorly and half migrates posteriorly. Abnormal endodermal expression patterns of Sonic hedgehog (Shh) and Indian hedgehog, potent intercellular signaling proteins that demarcate a molecular boundary between the pancreas and the adjacent gastrointestinal tract, may be responsible for the formation of annular pancreas.<sup>7,8</sup> The ductal drainage of this system is variable and complex. Duodenal atresia and stenosis, intestinal malrotation, and trisomy 21 can often be found in combination with annular pancreas.<sup>11</sup> The clinical significance relates primarily to duodenal obstruction, typically with bilious vomiting. Radiographic studies may reveal the classic finding of a “double-bubble” sign.<sup>12</sup> Management consists of surgical bypass of the obstructing lesion with a duodenojejunostomy. If such a bypass is not technically feasible, a duodenojejunostomy can be performed. Resection or division of the annular pancreas should not be done.

Cystic fibrosis is an autosomal recessive condition, seen primarily in the white population, and is found in about 1 in 2500 live births.<sup>13</sup> It is caused by mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene that encodes a protein expressed in the apical membrane of exocrine epithelial cells. Cystic fibrosis leads to significant pancreatic insufficiency. The pancreatic secretions generally have a reduced amount of bicarbonate, a lower pH, and a lower overall exocrine fluid volume. The inspissated secretions lead to blockage of the ducts, with subsequent duct dilatation and obstruction of pancreatic exocrine flow. The acinar cells degenerate, leading to pancreatic fibrosis. The result is impaired digestion of fats and proteins.<sup>14</sup>

## PANCREATITIS

### Acute Pancreatitis

Acute pancreatitis is an acute inflammation of the pancreas, varying in severity from mild abdominal pain that may go undiagnosed to fulminant necrotizing pancreatitis and death. Episodes of acute inflammation may completely resolve and then recur. In such

cases the term *acute relapsing pancreatitis* is applied to the clinical course. It is thought that complete interval resolution of morphology and function occurs as opposed to the occurrence of irreversible changes in the pancreas in cases of chronic pancreatitis.

The causes of acute pancreatitis include trauma, biliary tract stone disease, choledochal cyst, ductal developmental anomalies, drugs, metabolic derangements, and infections. Most commonly the cause is not apparent and it is termed *idiopathic*.

Because the pancreas is fixed against the lumbar spine, trauma to the upper abdomen (classically a bicycle handlebar) fractures the pancreas or injures the major duct at that point (Fig. 46-3). Biliary stone disease, as in adults, may lead to pancreatitis from transient pancreatic duct obstruction, with or without bile reflux. Choledochal cysts produce pancreatitis by pancreatic duct compression or bile reflux resulting from a long common biliary-pancreatic duct within the head of the pancreas.

Pancreas divisum is an anomaly present in 10% of the population and is thought to result from failure of the dorsal duct to fuse with the ventral duct. In pancreas divisum, the majority of the exocrine secretions of the pancreas, including those from the entire body and tail, must drain through the small minor duct of Santorini into the duodenum. The resulting relative obstruction may cause recurring episodes of pancreatitis.<sup>15</sup> These symptomatic patients should undergo a sphincteroplasty of the minor papilla. Endoscopic stenting with or without sphincterotomy has been described but requires particular skill with the endoscope cannulating the small ducts encountered in children.<sup>16</sup> Other rare ductal anomalies may result in obstruction and recurring bouts of pancreatitis. Biliary tract stones are not as common in children, but when present they may lead to pancreatitis. Data extrapolated from the adult literature indicate that removal of impacted stones in gallstone pancreatitis in children

**Figure 46-3.** A teenager sustained blunt trauma to his epigastrium and was found to have complete transection of his pancreas (arrow). He underwent distal pancreatectomy and has recovered uneventfully.

should be performed endoscopically.<sup>17,18</sup> Choledochal cysts may produce pancreatitis from transient pancreatic duct compression or from bile reflux. Drugs that are thought to induce pancreatitis include asparaginase and valproic acid.<sup>19,20</sup> Systemic illnesses and metabolic conditions, such as cystic fibrosis with inspissation of pancreatic secretions in the ducts, Reye syndrome, Kawasaki disease, hyperlipidemias, and hypercalcemia, may cause pancreatitis. Infections with viruses (e.g., coxsackievirus and rotavirus) and generalized bacterial sepsis also can cause pancreatitis.<sup>21</sup>

Clearly, the pathogenesis of acute pancreatitis entails the inappropriate activation of proenzymes, leading to autodigestion of the pancreas. The cellular mechanisms leading to acute pancreatitis are not known, but they are the subject of intense scientific investigation. Pancreatic enzymes can cause destruction at distant sites either by vascular dissemination or by release from the pancreas of cytokines such as tumor necrosis factor- $\alpha$ , free radicals such as superoxide, and vasoactive substances such as histamine and kallikrein.

The mechanism by which inappropriate activation of pancreatic enzymes occurs is not known. Possibilities include (1) reflux of duodenal enterokinase into the pancreas to activate trypsin, which then inappropriately activates other proenzymes in the pancreas; (2) ductal obstruction with extravasation of enzyme-rich ductal fluid into the parenchyma of the pancreas; or (3) fusion of lysosomes with zymogen granules inside acinar cells to allow lysosomal enzyme activation of the proenzymes. Once activated, elastase, phospholipase, and superoxide free radicals are thought to be the principal mediators of tissue damage.

Acute pancreatitis usually is initially seen with the sudden onset of midepigastriac pain associated with back pain, severe vomiting, and low-grade fever.<sup>22,23</sup> The abdomen is diffusely tender with signs of peritonitis, and distention occurs with a paucity of bowel sounds. In severe cases of necrotizing or hemorrhagic pancreatitis, hemorrhage may dissect from the pancreas along tissue planes, appearing as ecchymosis either in the flanks (Grey Turner's sign) or at the umbilicus (Cullen's sign) (Fig. 46-4). These ecchymoses typically take 1 to 2 days to develop.

Elevated amylase levels are helpful in the diagnosis, although normal serum amylase levels do not exclude pancreatitis from the differential diagnostic possibilities. The degree of serum amylase elevation does not correlate with severity of the disease. Amylase is excreted in the urine, but, as is true with glucose, tubular reabsorption results in amylase levels in the urine only after significant hyperamylasemia occurs.<sup>24</sup> In addition, the half-life of amylase is approximately 10 hours. Thus, moderately elevated levels of serum amylase may not be detectable in the urine.

Hyperamylasemia or hyperamylasuria may be caused by conditions other than pancreatitis, most notably salivary inflammation or trauma; intestinal disease including perforation, ischemia, necrosis, or inflammation; renal failure; and macroamylasemia. Alterations in renal excretion are accounted for by

**Figure 46-4.** Positive Cullen's sign, with periumbilical ecchymosis (arrow), in a patient with hemorrhagic pancreatitis.

measuring the ratio of the clearance of amylase to that of creatinine. The ratio requires measurement of simultaneous spot levels of serum amylase and creatinine and urine amylase and creatinine:

$$(U_{\text{amy}}/\text{Serum}_{\text{amy}})(\text{Serum}_{\text{Cr}}/\text{Urine}_{\text{Cr}}).$$

Ratios greater than 0.03 are significant. Lipase levels have been proposed as a more specific test of pancreatic tissue damage, although intestinal perforation does cause an elevation of lipase through reabsorption via the peritoneum. Lipase is produced only in the pancreas, and its measurement is particularly helpful for distinguishing pancreatic trauma from salivary trauma.<sup>25</sup>

Imaging the abdomen is important as part of the evaluation of the patient with abdominal pain. In the patient with pancreatitis, plain abdominal radiographs may reveal an isolated loop of intestine in the vicinity of the inflamed pancreas, the so-called sentinel loop. Other findings suggesting pancreatitis include local spasm of the transverse colon with proximal dilation, known as the colon cut-off sign. Pancreatic calcifications suggest chronic pancreatitis. Plain chest radiographs should be performed in all patients with acute pancreatitis to look for evidence of pleural effusion and pulmonary edema.

Abdominal ultrasonography may show a decrease in echogenicity of the pancreas due to pancreatic edema, but such a finding is not reliable in determining the diagnosis or severity.<sup>26</sup> The main utility of ultrasonography is to demonstrate gallstones as a possible cause of pancreatitis and to look for improvement in edema or peripancreatic fluid collections. Abdominal computed tomography (CT) offers much better resolution than ultrasonography in determining the size of the pancreas, the degree of edema, and the presence of fluid collections.<sup>27</sup> The size of the pancreatic duct can often be estimated much more accurately with CT than with ultrasonography, and the presence

of complications such as pancreatic abscess or pseudocyst may be delineated. The use of dynamic CT pancreatography has been advocated because of its ability to differentiate perfused from nonperfused (necrotic) pancreas. By using a bolus of contrast with rapid scanning in fine cuts through the pancreas, a precise assessment of the percentage of the pancreas that is either underperfused or nonperfused can be made. If necessary, CT can also be used for interventional procedures for diagnosis or drainage of fluid collections. Endoscopic retrograde cholangiopancreatography (ERCP) may also be used in children with acute pancreatitis. The literature would suggest that the complication rates in children are higher than those in the adult patient population.<sup>28</sup> However, it may be potentially helpful in children with severe refractory biliary pancreatitis who may have a stone impacted in the ampulla, as well as in trauma patients in whom a ductal injury is suspected or a pancreatic pseudocyst has formed. Magnetic resonance cholangiopancreatography (MRCP) is a relatively new, noninvasive technique for evaluating the biliary tree and the pancreatic duct. This technique is particularly attractive because the procedure is noninvasive and spares the patient the potential complications of ERCP. In addition, the study is less expensive and does not require radiation or contrast administration, which are routinely needed with ERCP. One disadvantage of MRCP is that it does not allow therapeutic interventions. However, it may help direct the type of therapeutic intervention best suited to the patient's pathologic process.<sup>29</sup> Another problem is that MRCP tends to overestimate the stenosis of the main pancreatic duct in patients with pancreatitis. Regardless, MRCP is now the initial imaging study of choice in the evaluation of pancreatic ductal anatomy in children with unexplained or recurrent pancreatitis.<sup>16</sup>

Key features in treating patients with acute pancreatitis are aggressive fluid replacement to maintain a good urine output (2 mL/kg/hr), usually measured with the aid of an indwelling urinary catheter, and a very low threshold for transferring the patient to an intensive care unit.<sup>30,31</sup>

Acute pancreatitis causes diffuse tissue damage throughout the body as a result of the release of active mediators, including phospholipase A<sub>2</sub>, elastase, histamines, kinins, kallikreins, and prostaglandins. Extracellular fluid losses can be enormous. Constant monitoring is necessary to avoid the development of severe hypovolemia. Patients with acute pancreatitis should be kept at bowel rest with nasogastric suction. Most patients receive histamine-2 (H<sub>2</sub>) receptor antagonists to prevent exposure of the duodenal secretin-producing cells to gastric acid, which is a potent stimulator of pancreatic secretion. These antagonists also may help prevent the stress ulceration seen in patients with pancreatitis. This therapeutic regimen is logical but empirical, because no studies have shown improvement in outcome with these interventions. Clinical trials have, however, shown an improved outcome in acute pancreatitis by using long-acting somatostatin analogs. It is probably reasonable to use these analogs in moderate-to-severe cases of pancreatitis.<sup>32</sup>

Adequate analgesia is critical to minimize the additional stress from pain. Meperidine (Demerol) is thought to be a better analgesic in pancreatitis because morphine causes spasm of the sphincter of Oddi. In turn, this sphincter spasm increases pancreatic duct pressure and potentially worsens the pancreatitis. To date, the superiority of meperidine over morphine in acute pancreatitis has not been proved in an outcome-based comparison. In fact, morphine may actually provide a longer period of analgesia with a lower seizure risk.<sup>33</sup> An important caveat is that the diagnosis of pancreatitis must be certain before giving the patient significant doses of narcotics because the ability to diagnose serious nonpancreatic problems, such as intestinal ischemia or perforated ulcer, may be lost.

As cases of severe pancreatitis progress, patients need to be monitored closely for signs of the development of multisystem organ failure. Pleural effusions and pulmonary edema can progress to severe adult respiratory distress syndrome with hypoxia, requiring endotracheal intubation. The tense abdominal distention associated with pancreatitis frequently contributes to the hypoventilation. Hypocalcemia, hypomagnesemia, anemia from hemorrhage, hyperglycemia, renal failure, and late sepsis can be seen in these patients and require close monitoring. Disagreement exists concerning the use of prophylactic antibiotics. In general, mild or moderate cases probably do not benefit from antibiotics. More severe cases of pancreatitis, however, may benefit because of the high rate of sepsis, although confirmatory data in such patients are lacking. Some advantage has been demonstrated with the use of imipenem, with reduction in the incidence of pancreatic sepsis in patients with necrotizing pancreatitis.<sup>17</sup>

Nutrition is critically important in patients with pancreatitis. An early positive nitrogen balance has been shown to improve survival rates. This need for aggressive nutrition should come in the form of early parenteral hyperalimentation. The hyperalimentation should include lipid formulations, despite the known association of hyperlipidemia and pancreatitis, although a close monitoring of the serum lipid levels should be maintained to avoid triglyceride levels greater than 500 mg/dL. In general, the resumption of enteral nutrition should be cautious, usually after complete resolution of the abdominal pain and preferably after normalization of the serum enzyme levels.

Surgical intervention in acute pancreatitis is usually not necessary. Other than surgery for pancreatic pseudocyst or papillotomy in the case of pancreas divisum, surgical intervention for acute pancreatitis is restricted to patients with severe necrotizing pancreatitis needing debridement or to patients with a pancreatic abscess.<sup>34,35</sup> In some instances, pancreatitis is discovered when laparotomy or laparoscopy is performed for a preoperative diagnosis of appendicitis (Fig. 46-5). In this circumstance, the best course is to palpate the gallbladder for stones. If the pancreatitis is mild and gallstones are present, cholecystectomy is reasonable. If the pancreatitis is severe, the safer course may be to perform a cholecystostomy, which allows later access to the biliary stones. If no gallstones are present, but

**Figure 46-5.** Severe peritoneal and omental fat saponification, seen as white fatty deposits (arrow) in a patient with acute pancreatitis. The preoperative diagnosis was acute appendicitis.

the patient has severe necrotizing pancreatitis, limited debridement is acceptable. Also, simply leaving large sump drains in place may be adequate. Early pancreatic lavage, pancreatic drainage, and pancreatic resection have not been shown to improve survival rates in cases of severe pancreatitis.

A pancreatic abscess may result from infection of the necrotic pancreatic tissue or infection of a peripancreatic fluid collection. Pancreatic abscess increases the mortality from pancreatitis threefold and is an absolute indication for surgical therapy.<sup>36,37</sup> Differentiating a pancreatic abscess from an uninfected pancreatic fluid collection is important because pancreatitis itself can make the patient appear “septic.” The diagnosis of pancreatic abscess is established by Gram stain and culture of the suspected abscess by CT-guided needle aspiration. The indication for aspiration is fever and leukocytosis persisting more than 7 to 10 days after onset of the pancreatitis. Patients shown to have pancreatic necrosis by dynamic CT pancreatography are candidates for aspiration because pancreatic necrosis usually precedes the development of a pancreatic abscess. The surgical therapy for a pancreatic abscess is debridement of clearly necrotic tissue and placement of large sump suction drains. Some mechanism must be in place for ongoing removal of the infected material postoperatively, either by reoperation or by the sump drains. In some cases it is impossible to differentiate an infected pancreatic pseudocyst from an abscess. In this case, a laparotomy or laparoscopy should be performed with sump drainage of the fluid collection.

Pancreatic pseudocyst is a complication of trauma or pancreatitis that entailed damage to the pancreatic ductal system. The extravasated pancreatic enzymes and digested tissue are contained by the formation of a cavity composed of fibroblastic reaction and inflammation, but without an epithelial lining. Pseudocysts may be acute or chronic. The acute pseudocyst has an irregular wall on CT scan, is tender, and usually develops shortly after an episode of acute

**Figure 46-6.** CT scan of an acute pseudocyst in a patient after a severe motor vehicle accident. The wall (arrows) is irregular with nonoccluded fluid inside.

pancreatitis or trauma (Fig. 46-6). Chronic pseudocysts are usually spherical with a thick wall and are commonly seen in patients with chronic pancreatitis. The distinction between these two types of pseudocysts is important because 50% of acute pseudocysts resolve without therapy, whereas chronic pseudocysts rarely spontaneously resolve. An acute pseudocyst develops a thick fibrous wall in 4 to 6 weeks. Pseudocysts smaller than 5 cm in diameter usually disappear without intervention. When compared with those in adults, pseudocysts in children tend to resolve more frequently with medical therapy alone.<sup>38</sup> Some evidence exists that somatostatin may help resolve pancreatic pseudocysts in children.<sup>39</sup>

Pancreatic pseudocysts that persist require either internal drainage (preferred), excision (distal pseudocysts only), or external drainage (infected or immature cysts). A minimally invasive approach to cystogastrostomy has been described in which intragastric laparoscopic ports were used.<sup>40</sup> Other minimally invasive strategies for pancreatic pseudocysts include transesophageal endoscopic cystogastrostomy and percutaneous drainage.<sup>41</sup> These endoscopic procedures should be performed at institutions with significant experience with these techniques.<sup>42,43</sup> Percutaneous drainage is the treatment of choice for infected pseudocysts because these cysts typically have thin, weak walls that are not amenable to internal drainage.

The three major complications of pancreatic pseudocysts are hemorrhage, rupture, and infection. Hemorrhage is the most serious complication and usually results from pressure and erosion of the cyst into a nearby visceral vessel (e.g., splenic, gastroduodenal). These patients require emergency angiography with embolization. Rupture or infection of a pseudocyst is uncommon. In both cases, external drainage is indicated.

Pancreatic ascites in children usually follows trauma or pancreatic surgery.<sup>44</sup> These patients may be seen with ascites or with pancreatic pleural effusions. Free fluid results from the uncontained leakage of a major pancreatic duct. Treatment initially consists of bowel

rest with hyperalimentation and use of long-acting somatostatin analogs. In many cases, ascites resolves spontaneously with this treatment. If not, ERCP or MRCP should be performed to determine the site of the ductal injury.<sup>45</sup> For distal duct injuries, simple distal resection is adequate, but proximal duct injury requires Roux-en-Y jejunal onlay anastomosis to preserve an adequate amount of pancreatic tissue.

Pancreatic fistula is a postoperative complication. Most low-output fistulas close spontaneously but may drain for several months. Long-acting somatostatin analogs decrease the fistula output and accelerate the rate of closure, but they do not appear to induce closure of fistulas that would not have otherwise closed. Managing a pancreatic fistula centers around (1) maintaining adequate nutrition, with hyperalimentation if enteral feeding results in high-volume output, and (2) making sure the fistula tract does not become obstructed. In fistulas that do not close, surgical intervention with a Roux-en-Y jejunostomy to the leak point is recommended.<sup>46</sup>

## Chronic Pancreatitis

Chronic pancreatitis is distinguished from acute pancreatitis by the irreversibility of the changes associated with the inflammation.<sup>47</sup> Chronic pancreatitis is either calcifying or obstructive. The calcifying form, most commonly caused by hereditary pancreatitis, is more common than the obstructive form in children and is associated with intraductal pancreatic stones, pseudocysts, and a more aggressive scar formation with more significant damage (Fig. 46-7). The obstructive type of chronic pancreatitis, which is associated with anatomic obstructions (most commonly pancreas divisum), is generally less severe with less scar formation than calcifying pancreatitis. The pancreatic architecture in the obstructive type may be partially reversible with correction of the obstruction.<sup>48</sup>

Chronic pancreatitis is distinctly uncommon in children. The most common cause in North America is hereditary or familial pancreatitis.<sup>49</sup> The inheritance is autosomal dominant with incomplete penetrance. The genetic mutations responsible for hereditary pancreatitis have been isolated to chromosome 7q35. The majority of these patients express one of two mutations in the cationic trypsinogen (*PRSSI*) gene. It has been suggested that these mutations lead to an alteration in the trypsin recognition site that prevents deactivation of trypsin within the pancreas. Autodigestion occurs, resulting in pancreatitis. In certain cases of idiopathic pancreatitis, it may be worthwhile to perform genetic screening for the cationic trypsinogen gene mutation.<sup>50,51</sup> The clinical presentation is typically one of recurrent attacks resembling acute pancreatitis. Familial pancreatitis has no distinguishing characteristics other than pancreatic calcification and its occurrence in other family members. These patients typically begin to have symptoms at about age 10 years, and pancreatic insufficiency, both exocrine and endocrine, slowly develops. Other complications include diabetes mellitus, ascites with pleural effusion, portal

**Figure 46-7.** CT scan of a pancreas with chronic calcifying pancreatitis. A dilated duct can be seen within the pancreas, further supporting the diagnosis of chronic pancreatitis. Calcified stones (arrows) can be seen in the dilated duct.

hypertension, dilatation of the pancreatic ducts, and thrombosis of the portal and splenic vein.<sup>17</sup> Pseudocysts tend to occur more often in patients with hereditary pancreatitis. Such patients have a 40% lifetime risk of developing adenocarcinoma of the pancreas.<sup>51</sup>

In some patients with familial pancreatitis who have severe, intractable pain, ERCP or MRCP may help locate surgically correctable lesions, such as large stones or a stricture with distal ductal dilation. Surgical options in this form of pancreatitis include excision of the localized pancreatitis, subtotal pancreatectomy, lateral pancreaticojejunostomy (modified Puestow procedure), and sphincteroplasty. Although the results of surgical therapy in these patients are generally disappointing, evidence exists that complicated cases of hereditary pancreatitis treated with a modified Puestow procedure may experience an improved quality of life, with subsequent improvement in pancreatic function and nutritional status (Fig. 46-8). Unlike adults with hereditary pancreatitis, some reversal of the steatorrhea may be seen in children.<sup>52</sup>

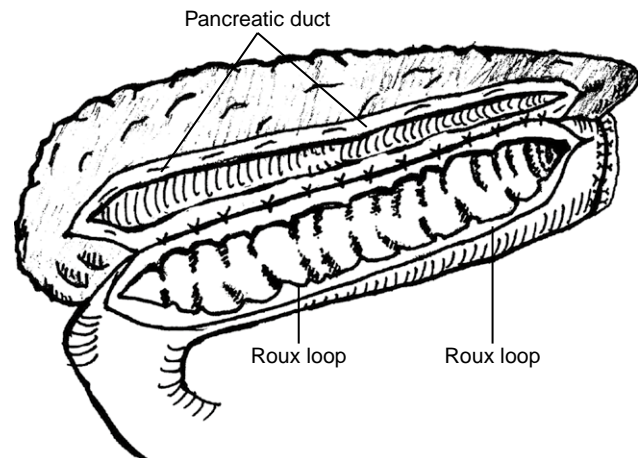

Obstructive pancreatitis due to pancreas divisum or choledochal cyst is best treated by relieving the obstruction. The association between pancreas divisum and chronic pancreatitis remains controversial. Some patients with ductal dilation clearly improve with sphincterotomy or sphincteroplasty. Other cases may be difficult to diagnose, and functional tests of duct pressure after secretin stimulation have been suggested. Surgical results in patients with functional obstruction are often not satisfying.

The diagnosis of chronic pancreatitis does not depend on amylase or lipase determination. Even though mild serum enzyme elevations are commonly seen during an exacerbation, they are inconsistent and frequently are normal. The diagnosis of chronic pancreatitis relies on a characteristic pain, diminished pancreatic function, and changes in radiographic appearance.

Increased stool fat, diabetes mellitus, and steatorrhea are signs of pancreatic insufficiency. Frequently on CT scan the pancreas has microcalcifications throughout the parenchyma and calcified stones in the duct (see Fig. 46-7). Additionally, pancreatic pseudocysts or inflammation may be seen on CT scan. ERCP offers the best view of ductal anatomy and can confirm the diagnosis of pancreas divisum as a probable cause of chronic pancreatitis. MRCP provides a less invasive alternative to better define the pancreatic ductal anatomy.<sup>29</sup> Papillotomy may be accomplished endoscopically as well.

Therapy for chronic pancreatitis is directed toward palliation of symptoms. Initial therapy for acute exacerbation is pain control and hydration. Steatorrhea indicates the need for pancreatic enzyme replacement. In general, these patients do better with small, frequent meals. The diabetes mellitus that results from chronic pancreatitis seems to be unusually brittle, with a propensity for severe hypoglycemic episodes after even low doses of insulin. This hypersensitivity to insulin may be due to loss of entire islets. Unlike autoimmune diabetes mellitus, in which specific destruction of the insulin-producing beta cells of the islets of Langerhans occurs, entire islets, including the glucagon-producing alpha cells, are destroyed in chronic pancreatitis. Thus, the important insulin-opposing effects of glucagon are lost in these patients.

Surgical or endoscopic therapy is indicated for bile or pancreatic duct obstruction or for pancreatic pseudocyst complications (Fig. 46-9).<sup>53</sup> Patients with intractable pain who do not have an identifiable anatomic problem will likely not benefit from surgical intervention. Relief of obstruction may be achieved by endoscopic sphincterotomy, ductal stenting, or open surgical drainage with Roux-en-Y lateral pancreaticojejunostomy (a modified Puestow procedure) (see Fig. 46-8). Pancreatic resection, starting with distal resection only, but extending to subtotal or even total pancreatectomy,

**Figure 46-8.** Modified Puestow procedure. The pancreatic duct is opened longitudinally and a side-to-side anastomosis to a Roux loop of jejunum is performed. (Adapted from Mayo-Smith WW, Iannitti DA, Dupuy DE: Intraoperative sonographically guided wire cannulation of the pancreatic duct for patients undergoing a Puestow procedure. *AJR Am J Roentgenol* 175:1639-1640, 2000.)

**Figure 46-9.** Endoscopic retrograde cholangiopancreatography in a patient with chronic pancreatitis with dilation of the biliary and pancreatic ducts (arrow).

has been advocated for intractable pain. These patients trade the sequelae of further, and perhaps complete, pancreatic insufficiency for anticipated pain relief.

## FUNCTIONAL PANCREATIC DISORDERS

The causes of persistent hypoglycemia in children vary greatly with age. In newborns and young infants, the major causes are:

1. Persistent hyperinsulinemic hypoglycemia of infancy (PHHI), previously called nesidioblastosis
2. Lack of substrate for gluconeogenesis (e.g., glycogen storage disease)
3. Inadequate gluconeogenic hormones (e.g., hypothyroidism or growth hormone deficiency)

In children with the onset of hypoglycemia after 1 year of age, the causes are different, with insulinoma being the most common.

### Persistent Hyperinsulinemic Hypoglycemia of Infancy

Nesidioblastosis comes from the Greek *nesidio*, meaning “island,” and *blast*, meaning “new formation.” Nesidioblasts are thought to be progenitor cells in the wall of the pancreatic ducts, normally giving rise to islets in physiologic states requiring more islets, such as during pregnancy or after pancreatic resection. It has been postulated that these nesidioblasts overproliferate in patients with PHHI.<sup>54</sup> This postulate was based on what

had been thought to be atypical pathology of nesidioblastosis. However, it has been shown that the proliferation of nesidioblasts in the periductular regions of the pancreas is actually a normal variant in neonates.<sup>55</sup>

The defect in patients with PHHI appears to be related to four genes that are responsible for the ability of the beta cell to regulate insulin secretion through the adenosine triphosphate (ATP)-sensitive potassium channels, which normally consist of heteromultimers of the sulfonylurea receptors (SURs).<sup>56-58</sup> More specifically, the four genes are the sulfonylurea receptor (*ABCC8*), the potassium channel (*KCNJ11*), glutamate dehydrogenase (*GULDI*), and glucokinase (*ADPGK*) located on chromosome 11p15.1.<sup>59</sup> Some PHHI patients have been found to have a truncation mutation of the second nucleotide-binding fold on the *ABCC8* of the ATP-sensitive potassium channel. Mutations in this receptor channel prevent the normal feedback regulation of insulin production by serum glucose. Oral hypoglycemic agents act by binding the sulfonylurea receptor and activating insulin release.

The two forms of PHHI are a focal and a diffuse type. Because both forms have the same clinical presentation, the difference between the two types can be seen only after histologic analysis. The focal type is associated with the loss of a maternal allele from chromosome 11p15, with inheritance of a paternal mutation of *ABCC8*. It is characterized by a localized tumor-like aggregation of islets and also is referred to as focal adenomatous islet-cell hyperplasia. The accumulation of the large islet clusters are separated by thin rims of acinar cells or strands of connective tissue.<sup>60</sup> It represents about one third of the cases of PHHI. The diffuse type of PHHI represents a recessively inherited mutation of the *ABCC8/KCNJ11* protein that presents as a diffuse pancreatic beta cell functional abnormality. The distinction between the two forms of PHHI is important because patients with focal PHHI may be spared the extensive pancreatic resection required in patients with diffuse PHHI.<sup>61,62</sup>

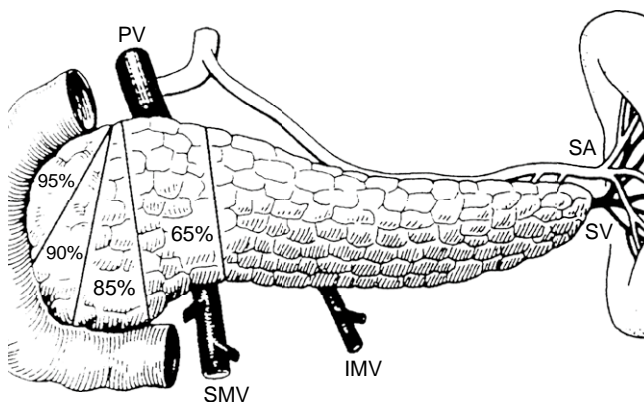

PHHI patients typically have hypoglycemia shortly after birth, although adult cases have been reported (probably not of the same origin).<sup>63</sup> Symptoms are those of hypoglycemia, with behavioral changes such as jitteriness and seizures. It is critical to measure serum insulin and glucose levels simultaneously because the absolute insulin level may be normal but the ratio of insulin to blood glucose is not normal. These patients differ from insulinoma patients in that adenoma patients usually have high absolute insulin levels. In addition, the hyperinsulinemia of PHHI is more easily suppressed with somatostatin and somatostatin analogs.

Initial treatment of PHHI should be frequent feeding, or even a drip-feeding regimen, with the addition of intravenous glucose as needed. Central venous access is advised because adequate venous access is lifesaving, and high concentrations of glucose infusion may be necessary. When the glucose infusion rate necessary to prevent hypoglycemia is more than 15 mg/kg/hr, PHHI is likely. When onset occurs after the newborn period, the patients may have only intermittent hypoglycemia

and the diagnosis may be more difficult. Owing to the much higher incidence of insulin-producing adenoma, patients older than 1 year at the onset of hypoglycemia should undergo evaluation, which may include exploratory laparotomy or laparoscopy.

Initial medical treatment of PPHI should include a long-acting somatostatin analog such as octreotide or an antisecretory drug such as diazoxide. Diazoxide acts primarily by activating the potassium ATP channel through ABCC8 to inhibit insulin secretion. Octreotide activates beta cell potassium channels to inhibit insulin secretion. The main drawback of octreotide is that it requires subcutaneous injection. Other medical therapy includes glucocorticoids to promote insulin resistance and streptozotocin (beta cell-specific toxin) to decrease the number of insulin-secreting cells. In addition, glucagon can be used as a temporizing agent to control hypoglycemia.<sup>64</sup> These drugs seem to be most effective for treating milder cases or older children with PPHI. Medical failure to control hypoglycemia necessitates surgical resection.

In patients with diffuse-type PPHI, adequate surgical treatment consists of a 90% to 95% pancreatectomy, which entails leaving a residual remnant of pancreas on the common bile duct along the C-loop of the duodenum (Fig. 46-10).<sup>65</sup> It is important, especially in patients out of the newborn period, to inspect the pancreas closely for evidence of an insulin-producing adenoma, because finding an adenoma would allow significant preservation of pancreatic tissue and obviate potential endocrine and exocrine insufficiency. Postoperatively, these patients are often transiently hyperglycemic. All patients after resection of a large part of the pancreas are at significant risk for developing diabetes mellitus in later years. A 95% pancreatectomy has approximately a 75% rate of eventual diabetes mellitus.<sup>66</sup> For this reason, some strategies have been suggested to minimize the effects of a near-total pancreatectomy. These strategies include a non-surgical approach using long-term hyperalimentation, continuous gastric tube feeding, and octreotide

**Figure 46-10.** Various degrees of pancreatectomy may be indicated for persistent hyperinsulinemic hypoglycemia of infancy. Typically, a 95% pancreatectomy, as shown here, leaves behind a cuff of pancreas along the C-loop of the duodenum. IMV, inferior mesenteric vein; PV, portal vein; SA, splenic artery; SMV, superior mesenteric vein; SV, splenic vein.

administration; a 75% pancreatectomy with a plan for a near-total pancreatectomy in the future if symptoms persist; and a near-total pancreatectomy in all patients, with isolation of the islets from the excised pancreas and cryopreservation for later autotransplantation to control diabetes.

In contrast, patients with focal-type PPHI may be treated with a more topographically guided pancreatic resection. The difficulty lies in distinguishing between focal and diffuse types. Recent series have shown that arterial calcium stimulation with venous sampling and transhepatic portal venous sampling can help distinguish between focal and diffuse PPHI. After a more localized exploration during laparotomy or laparoscopy and with the addition of frozen-section analysis, the pancreatic resection may be limited to the region of involvement.<sup>61,62</sup> In this manner, the complications of extensive pancreatic resection can be avoided in patients with focal-type PPHI.

The long-term outlook for these patients depends primarily on the age at onset, which relates to severity of disease, and on an expeditious diagnosis, because a late diagnosis results in a higher incidence of neurologic deficits.<sup>67</sup> Most patients seem to “grow out of the disease” after several years, implying diminished activity of the beta cells. This natural history may explain the development of diabetes mellitus in some of these patients during their school-age years.

## Glycogen Storage Disease

Glucose-6-phosphatase deficiency (glycogen storage disease type I) classically appears as severe hypoglycemia in neonates and infants and is caused by the inability to dephosphorylate glycogen subunits into glucose.<sup>68</sup> The hypoglycemia becomes apparent when the time between feedings increases, requiring the liver to generate glucose from glycogen stores. Diagnosed clinically by the low insulin levels and hepatomegaly, ketosis and cutaneous xanthomas develop as a result of compensatory high lipid levels. Such patients often have fasting glucose levels less than 20 mg/dL. Central venous access is needed to allow continuous infusion of highly concentrated glucose. An increased incidence of hepatic adenoma is found in patients who survive to adulthood, with a 10% risk of malignant transformation.<sup>69</sup> Liver transplantation has become the treatment of choice for these patients.

## PANCREATIC TUMORS AND CYSTS

### Pancreatic Endocrine Tumors

The endocrine cells of the mature human pancreas are confined to the islets of Langerhans (Fig. 46-11), although pancreatic neurons are known to secrete locally active peptide hormones such as vasoactive intestinal peptide (VIP). Four main hormones are produced by the islets: insulin from the centrally located beta cells, which make up more than 90% of the islet; glucagon from the peripheral mantle of alpha cells;

**Figure 46-11.** Mature islet in the pancreas. Immunohistochemical stain shows the peripheral location of the glucagon cells (alpha cells, arrows). The insulin-producing cells (beta cells) are located in the central portion of the islet. (From Fawcett DW [ed]: *Textbook of Histology*. New York, Chapman & Hall, 1994, p 699.)

and somatostatin and pancreatic polypeptide from the delta cells and pancreatic polypeptide (PP) cells scattered throughout. A small population of endocrine cells accounts for the production of ghrelin, gastrin, and other peptide hormones. Currently, it is believed that pancreatic endocrine tumors arise from cells located in the islets, although some evidence indicates that precursor cells in the pancreatic ducts or acini may give rise to these tumors as well.<sup>70</sup> Only insulinoma, gastrinoma, and VIPoma are known to occur in children.

Insulinoma is the most common pancreatic endocrine tumor in children, although it is still quite rare, with an estimated incidence of one case per 250,000 patient-years. Only 10% of insulinomas are malignant, and these metastasize to surrounding tissues.<sup>71,72</sup> This tumor causes symptoms of hypoglycemia, including dizziness, headaches, sweating, and seizures. The classic Whipple's triad was described in patients with insulinoma and consists of the following: symptoms of hypoglycemia with fasting, glucose level less than half of normal when fasting, and relief of symptoms with glucose administration.

Patients are typically older than 4 years, although neonates have been described with insulinoma. The lesions are usually solitary, except in multiple endocrine neoplasia type 1 (MEN 1) in which multiple insulinomas may be found.

Insulinoma is diagnosed by demonstrating an insulin-to-glucose ratio of more than 1.0 (microunits of insulin per milliliter/milligrams of glucose per deciliter). Normal should be less than 0.3. Levels of insulin C-peptide should always be measured because its absence indicates exogenous administration of insulin. The distinction between benign and malignant lesions is difficult and is based on tumor size (<2 cm tend to be benign) and the presence of metastases.

Tumor localization preoperatively can be difficult.<sup>73</sup> Extrapancreatic insulinomas are rare, and thin-slice CT of the pancreas will identify more than half of the tumors. Small hypervascular tumors may be visualized by angiographic blush, but angiography is probably not warranted with the advent of newer imaging techniques. Magnetic resonance imaging (MRI) and endoscopic ultrasonography allow visualization of very small tumors. Selective portal venous sampling may help localize the tumor for blind pancreatic resections. All patients should undergo surgical resection. The tumors are pink and firm, appear encapsulated, and are usually amenable to simple enucleation. At operation, occult tumors may be localized by intraoperative ultrasonography.<sup>74</sup> Failure to localize the tumor by any of the aforementioned techniques is unlikely, but because insulinomas tend to be located in the tail of the pancreas, distal pancreatectomy is the best "blind" procedure. Patients with MEN 1 and multiple adenomas require a 95% pancreatectomy. Malignant insulinomas require chemotherapy, usually with the beta cell-toxic drug streptozotocin. When malignant tumors have metastasized to the liver, chemoembolization is widely used and should be combined with somatostatin analogs. The overall prognosis for these latter patients is very poor.

Fetal gastrin-producing cells in the pancreas are believed to give rise to pancreatic gastrinoma. The pancreas is the primary source of gastrin in the fetus. After birth, the gastric antrum becomes the principal gastrin source. The Zollinger-Ellison syndrome consists of gastric hypersecretion with severe peptic ulcer disease and a gastrin-producing tumor, which classically is located in the pancreas. The pancreas is the most common site for gastrinomas, which are malignant in 65% of cases and usually produce the 17-amino-acid form of gastrin. Unlike adults, children with gastrinoma have not been reported to have MEN 1.<sup>75,76</sup>

The diagnosis of a gastrinoma is based on hypergastrinemia and gastric hypersecretion. Gastrin levels are usually greater than 500 pg/mL, but equivocal cases can be diagnosed by using 2 U/kg of IV secretin as a stimulation test. A gastrinoma responds with a 200 pg/mL or more increase in serum gastrin. Localization of gastrinomas can be difficult because these tumors may be outside the pancreas. CT, MRI, endoscopic ultrasonography, and selective portal venous sampling have all been used to help localize the tumors. Occult tumors have been shown most often to be located in the duodenum and may require a duodenotomy.

The medical treatment for gastrinoma is omeprazole, the inhibitor of acid secretion that selectively blocks the ATP-dependent hydrogen-potassium proton pump necessary for acid secretion. All patients with potentially resectable disease should undergo exploration, although most pancreatic tumors are not resectable. Only patients who undergo complete resection are cured.

## Non-neoplastic Cysts

Although most cystic lesions of the pancreas are pseudocysts and are acquired, congenital cysts may be first seen at an early age as a symptomatic mass with

compression of surrounding structures.<sup>77</sup> Alternatively, these congenital cysts may be noted incidentally on physical examination or radiographic studies. Congenital cysts contain cloudy straw-colored fluid with normal pancreatic enzyme levels. The cysts are most often found in the distal pancreas and are amenable to local resection with a rim of normal pancreas. Lesions in the head of the pancreas should be internally drained with a Roux-en-Y cystojejunostomy. Congenital duplications of the intestine also may be sequestered in the pancreas. They have a gastric mucosal lining but maintain pancreatic ductal communication. The gastric acid may cause episodes of pancreatitis. The mass is usually small and identified only on CT. Surgical resection is necessary, either in the form of enucleation, distal pancreatectomy, or even pancreaticoduodenectomy.

Acquired non-neoplastic cysts of the pancreas are called retention cysts and seem to represent ectasia of the pancreatic ducts (Fig. 46-12). The cysts contain fluid rich in pancreatic enzymes. The preoperative distinction of a retention cyst from other types of cysts or pseudocysts may be difficult. ERCP or MRCP may demonstrate a communication with the ductal system and may help in determining the surgical approach (resection versus Roux-en-Y cystojejunostomy).

### Pancreatic Exocrine Tumors

The pancreatic exocrine system consists of the pancreatic ducts, centroacinar cells, and acini. Tumors arising from this system include pseudopapillary tumors, ductal adenocarcinomas, acinar cell carcinomas, or pancreatoblastomas. Cystic tumors of the pancreas, which include serous cystadenoma, mucinous cystadenoma, and cystadenocarcinoma, are well characterized in the adult population. In children, however, rare cases

**Figure 46-12.** Large pancreatic cyst (retention cyst) emanating from the pancreatic parenchyma. The cyst was filled with clear fluid. (Courtesy of Howard B. Ginsburg, MD.)

have been described in the literature, but overall they are poorly characterized.<sup>77</sup> A recent review of the literature suggests that no documented case of cystadenocarcinoma has been described in children. Moreover, with one exception, the few cases of cystadenoma are dissimilar to the adult lesions. These cases of cystadenomas may represent a developmental malformation and not neoplasms.<sup>78</sup>

### Adenocarcinoma/Pancreatoblastoma

In general, pancreatic cancers are rare in children. Children with malignant pancreatic exocrine tumors generally have a much better overall prognosis after surgical resection than malignant pancreatic exocrine tumors in adults. Ductal adenocarcinoma is the most common adult form of pancreatic cancer. It has been described in children, but most of the reported cases are in the older literature. As the pancreatic tumors of childhood have become better characterized, these previous diagnoses of ductal adenocarcinoma have been questioned. Because these lesions have become rare in recent years, it appears that many of these tumors may have been previously misdiagnosed.<sup>78</sup> Acinar cell adenocarcinoma is more often seen in children and tends to have a less aggressive behavior with a better prognosis. Treatment is complete surgical resection for both ductal adenocarcinoma and acinar cell carcinoma.

Another variant of adenocarcinoma seen in infants and younger children has been termed *pancreatoblastoma* and represents the most common exocrine tumor of the pancreas in childhood. It is seen more often in boys than in girls and is thought to be of embryonic origin, similar to Wilms' tumor and hepatoblastoma. An allelic loss occurs on chromosome 11p, suggesting a common genetic relationship among pancreatoblastoma, Beckwith-Wiedemann syndrome, and related embryonal malignancies.<sup>79</sup> Pancreatoblastomas are of low malignancy and often arise in the head of the pancreas (two thirds). They may represent a tumor of immature duct cells.<sup>80,81</sup> Even large tumors have a relatively benign course. Metastases are reported in one third of the patients, with the liver and lung being the most common sites.  $\alpha$ -Fetoprotein levels may be elevated in pancreatoblastoma and may be used to monitor patients for recurrence.<sup>82</sup> The prognosis is relatively good with complete resection of the tumor. Recurrence is common, so close follow-up is mandatory.

A Frantz tumor is a papillary-cystic tumor, also referred to as solid pseudopapillary tumor, seen in girls and young women. It is derived from exocrine cells. Histologically, no acinar or ductal structures appear to be present. Degenerative changes result in the formation of pseudopapillae, and a fibrous capsule is usually seen.<sup>83</sup> Solid pseudopapillary tumor is less malignant than pancreatoblastoma, and metastases are rarely present. The prognosis is good even with just local resection. Although solid pseudopapillary tumor is a relatively indolent tumor, at the present time aggressive resection is advocated, given that the tumor is curable.<sup>84</sup>

# SPLENIC CONDITIONS

Frederick J. Rescorla, MD

The role of the spleen as an important functional organ in health and disease has been well documented. An early observation was the recognition by King and Schumacher in 1952 of the susceptibility of splenectomized infants to infection.<sup>1</sup> The essential role of the spleen led pediatric surgeons to introduce nonoperative management of splenic injuries in children, which evolved into the preferred method for treating not only children but also adults.<sup>2</sup> Currently, the primary role of surgery for the spleen involves the management of hematologic disorders. Perhaps the most significant change has been the introduction of laparoscopic splenectomy in adults by Delaitre and Maignon and subsequently in children by Tulman and Holcomb.<sup>3,4</sup> The laparoscopic approach has quickly emerged as the preferred technique for the management of splenic disorders.

## EMBRYOLOGY, ANATOMY, AND PHYSIOLOGY

The splenic primordium develops as a mesenchymal bulge in the dorsal mesogastrium between the stomach and the pancreas, initially observed at the 8- to 10-mm embryo stage. A true epithelium is noted at the 10- to 12-mm stage as sinusoids communicate with capillaries. The spleen produces white and red cells by the fourth month of fetal life, although this function ceases later in gestation. The anatomic arrangement of the spleen is consistent with the various functions of the spleen. The splenic artery branches into segmental vessels, which further branch into trabecular arteries. After further bifurcations, small arteries enter the white pulp, which consists of lymphocytes and macrophages arranged as a germinal center around the central artery. The central artery delivers particulate material into the white pulp, an arrangement that may facilitate antibody formation in response to particulate antigens.<sup>5-8</sup> The red pulp consists of the endothelial cords of Billroth, which are functionally distal to the white pulp. The function of the spleen consists of red blood cell maintenance, immune function, and a reservoir.

The red pulp serves to destroy old and defective cells. The spleen also removes Howell-Jolly bodies (nuclear

remnants), Heinz bodies (denatured hemoglobin), and Pappenheimer bodies (iron granules). These particles are noted on the peripheral smear after splenectomy. The immune response occurs in the white pulp as antigens come in contact with macrophages and helper T cells. T cells respond with cytokine synthesis, and activated T cells circulate to modulate the response. A humoral response occurs as macrophages and helper T cells come in contact with antigens.<sup>9</sup>

Splenic function also involves removal of particulate matter as well as production of nonspecific opsonins, which further activate the complement system. In addition, the spleen serves as a biologic filter. If little antibody is available for opsonization of bacteria, the spleen assumes a greater role. This may be a factor in the age-related differences in post-splenectomy infections in young children who can lack an adequate antibody response.<sup>6</sup> The spleen also serves as a reservoir for platelets and factor VIII.

## ANATOMIC ABNORMALITIES

### Asplenia and Polysplenia

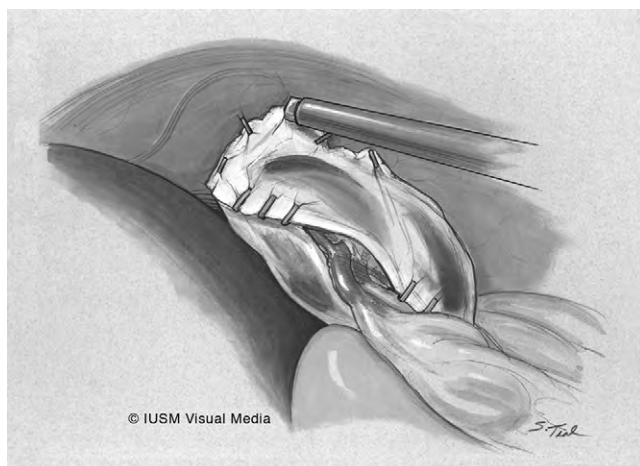

Asplenia is often noted with complex congenital heart disease as well as bilateral “right-sidedness” such as bilateral three-lobed lungs and a right-sided stomach and central liver.<sup>10</sup> Intestinal malrotation has also been observed with asplenia.<sup>11</sup> These infants are at a risk for overwhelming infection and should receive antibiotics for prophylaxis.

Polysplenia usually consists of a cluster of very small splenic masses and is often associated with biliary atresia. Other associated conditions can include preduodenal portal vein, situs inversus, malrotation, and cardiac defects.<sup>10</sup> These children have adequate splenic immune function.

### Wandering Spleen

This condition is characterized by a lack of ligamentous attachments to the diaphragm, colon, and retroperitoneum, resulting in a mobile spleen. This is

**Figure 47-1.** Drawing of a laparoscopic splenopexy with placement of the spleen between two sheets of absorbable mesh with fixation in the left upper quadrant. (© IUSM Visual Media.)

likely due to failure of development of the ligaments from the dorsal mesentery.<sup>12</sup> Children are occasionally noted with an abdominal mass and episodic pain but can also present with torsion and infarction.<sup>13-17</sup> Pancreatitis has also been noted as a presenting sign.<sup>18</sup> Splenopexy is the preferred method of treatment and can be performed with placement of the spleen into a mesh basket, suture splenopexy, colonic displacement with gastropexy, placement in an omental basket, or placement in an extraperitoneal pocket.<sup>17,19-22</sup> The laparoscopic approach is the preferred method, and the use of an absorbable or nonabsorbable mesh with fixation in the left upper quadrant is demonstrated in [Figure 47-1](#).<sup>23,24</sup> Placement of the spleen in an extraperitoneal pocket is seen in [Figure 47-2](#). Torsion with infarction requires splenectomy. Cases of chronic torsion have also been reported with massive splenomegaly,<sup>25</sup> which may necessitate splenectomy.

## Accessory Spleens

Accessory spleens have been noted in 15% to 30% of children, with a recent series noting a 19% rate.<sup>23</sup> Accessory spleens likely originate from mesenchymal remnants that fail to fuse with the main splenic mass, with most (75%) located near the splenic hilum ([Fig. 47-3](#)). Other locations that must be evaluated during surgery include the lesser sac along the splenic vessels, omentum, and retroperitoneum. If an accessory spleen is noted, 86% are single, 11% have two, and 3% have three or more.<sup>26,27</sup> A missed accessory spleen at the time of planned total splenectomy can lead to recurrence of the primary disease process, which in cases of immune thrombocytopenic purpura is early and with hereditary spherocytosis is later.<sup>28-30</sup>

## Splenic Gonadal Fusion

This condition in which the left gonad and the spleen are attached is a result of early fusion between the two structures before descent of the testis.<sup>31</sup> The remnant can be a continuous band or discontinuous with splenic tissue attached to the gonad. A remnant of spleen has also been noted totally separate in the left scrotum as an accessory splenic remnant type of abnormality.<sup>32</sup>

## Splenic Cysts

Cysts of the spleen are most frequently primary splenic cysts containing an epithelial lining and are also referred to as epithelial or epidermoid cysts ([Fig. 47-4](#)). Post-traumatic pseudocysts are also occasionally seen. Inclusion of surface mesothelium into the splenic parenchyma is the most likely etiology of the epithelial cysts. They may present as symptoms related to their size with gastric compression or pain, an abdominal mass, rupture, or infection with abscess.<sup>33-35</sup> Simple cysts less than 5 cm may be observed, but cysts that are enlarging, symptomatic, or larger than 5 cm

**Figure 47-2.** **A**, The upper pole of the spleen was placed in the retroperitoneal pouch, and the upper aspect of the pouch (*dotted arrow*) was closed with interrupted sutures. Note the splenic vessels (*solid arrow*) coursing into the spleen. A generous opening was left in the pouch for these vessels so that the vessels would not be compressed by closure of the pouch. **B**, One of the interrupted silk sutures is being placed to approximate the peritoneal flaps over the spleen. At this point, most of the spleen has been placed into the extraperitoneal pouch. (From Upadhyaya P, St. Peter SD, Holcomb GW III: Laparoscopic splenopexy and cystectomy for an enlarged wandering spleen and splenic cyst. *J Pediatr Surg* 42:E23-E27, 2007. Reprinted with permission.)

**Figure 47-3.** An accessory spleen (arrow) is seen in the lienocolic ligament in this patient.

require treatment. Most symptomatic cysts are larger than 8 cm.<sup>33</sup> Percutaneous aspiration and sclerosis utilizing alcohol or other agents have been reported with variable success.<sup>36,37</sup>

Marsupialization is commonly performed (Fig. 47-5) but has been associated with a high recurrence rate if an adequate segment of cyst is not removed.<sup>38,39</sup> In addition, a recent report noted a high recurrence rate with laparoscopic partial excision.<sup>40</sup> However, others have had good success with this technique, and many also recommend partial splenectomy associated with cyst resection.<sup>41-45</sup> Our group has reported good results with

partial splenectomy, emphasizing a margin of normal spleen so that the cut surfaces of the cyst cannot be in opposition which might lead to recurrence.<sup>23</sup>

## INDICATIONS FOR SPLENECTOMY

### Hereditary Spherocytosis

Hereditary spherocytosis, an autosomal dominant condition, is the most common inherited red cell disorder among Northern European descendants, with approximately 25% of affected children representing new mutations. Defects in red cell proteins ankyrin or spectrin result in poorly deformable spherocytes. Most affected children have anemia, an elevated reticulocyte count, and a mild elevation in bilirubin concentration. The degree of hemolysis can vary, with some having only a mild anemia. Spherocytes on peripheral smear along with a positive osmotic fragility test confirms the diagnosis. Affected children may develop an aplastic crisis associated with parvovirus B19 infection with suppression of bone marrow red cell production and a very low hemoglobin concentration due to ongoing splenic red cell destruction.<sup>46</sup> Splenectomy is usually performed for moderate to severe anemia. If possible, splenectomy is delayed until 5 to 6 years of age to decrease the likelihood of post-splenectomy infection. Splenomegaly is common with this condition. Associated gallstones are also common, and an ultrasound evaluation of the gallbladder should be performed before splenectomy. A recent study noted the presence

**Figure 47-4.** A, A large epithelial splenic cyst (arrow) is seen on the CT scan. B, At laparoscopy, the large cyst is seen to occupy most of the spleen.

**Figure 47-5.** A, The wall of the large epithelial splenic cyst seen in Figure 47-4 is being excised. B, The cyst was marsupialized and the remnant lining of the cyst was ablated with the argon beam coagulator.

**Figure 47-6.** Laparoscopic partial splenectomy with preservation of blood flow to the spleen through the most superior short gastric vessel is depicted. Note division of the parenchyma about 1 cm to the right of the devascularized margin. (© IUSM Visual Media.)

of gallstones in children undergoing splenectomy to be 27% in those younger than age 10 years compared with 56% in those 10 years of age or older.<sup>23</sup> Partial splenectomy is an attractive alternative to a total splenectomy in an attempt to remove enough spleen to alleviate the anemia while preserving enough spleen to prevent overwhelming post-splenectomy infection (Fig. 47-6). This may be particularly useful in young children requiring splenectomy, but the long-term results are not known.

### Immune Thrombocytopenic Purpura

Immune thrombocytopenic purpura (ITP) occurs due to antiplatelet autoantibodies binding with platelets and subsequently undergoing destruction in the spleen. In most children, it is primary (idiopathic), whereas in some it may be secondary to lupus, human immunodeficiency virus, malignancy, or hepatitis C infection. Most children (80%) have acute ITP that resolves with simple observation or medical management. Most treatment plans aim at decreasing platelet destruction. These include corticosteroids, which may have their effect by inhibiting the reticuloendothelial binding of platelet/antibody complexes; intravenous immunoglobulin (IVIG), which inhibits the Fc receptor binding of platelets by macrophages; or Rho(D) immunoglobulin in Rh-positive children, which bind red cells that then saturate the splenic receptors, allowing the platelets to avoid destruction. Response to corticosteroids, IVIG, or both, predicts excellent outcome with splenectomy.<sup>47,48</sup> Some children fail to respond to medical treatment or, more commonly, develop relapse when the treatment is stopped. In some cases, further therapy may include rituximab, a monoclonal antibody against CD20-positive B cells. This depletes the B cells and is somewhat of a “medical splenectomy.” Other treatment modalities have included azathioprine, cyclophosphamide, danazol, and mycophenolate mofetil.<sup>49</sup> Platelet production may be decreased in ITP. Thus, the use of thrombopoietic agents has emerged<sup>49</sup> and

successful therapy with agents such as AMG 531 (Amgen Inc., Thousand Oaks, CA) has been reported.<sup>50</sup>

Children with thrombocytopenia for longer than 6 months are considered to have chronic ITP and are candidates for splenectomy. The response to splenectomy is usually excellent in children who have responded to medical management. In adult patients, the response is not as high. Accessory spleens or residual splenic tissue has been identified in up to 50% of these patients with ITP, thus emphasizing both the importance of accessory spleen detection at exploration as well as the need to avoid parenchymal disruption.<sup>28</sup>

### Sickle Cell Disease

Sickle cell disease results from an amino acid substitution in the  $\beta$  chain of normal hemoglobin A, which results in hemoglobin S. Children may be homozygous (sickle cell disease) or have less severe heterozygous types such as sickle-C or sickle-thalassemia. These cells become rigid as they pass through the hypoxic environment of the spleen, leading to splenic sequestration. Although in most children autoinfarction and atrophy lead to a functional asplenic state, some develop symptomatic sequestration. If the sequestration is severe, these children develop anemia and splenomegaly with associated thrombocytopenia known as acute splenic sequestration crisis. Because of the associated morbidity and mortality, severe or recurrent episodes merit consideration of splenectomy.

### Thalassemia

The thalassemias are characterized by abnormal production of  $\alpha$  or  $\beta$  chains of hemoglobin. Thalassemia major ( $\beta$ -thalassemia) is associated with the most severe clinical anemia among this group. Splenomegaly causes further red cell sequestration and the need for transfusion. Total or partial splenectomy has been used to decrease the need for transfusions in children with severe anemia.

### Gaucher's Disease

Gaucher's disease is characterized by a deficiency of the enzyme  $\beta$ -glucocerebrosidase, resulting in excessive glucocerebroside in the macrophages of the spleen, liver, bone marrow, and lungs. Splenomegaly may be severe, and both partial and total splenectomy have been utilized to alleviate the symptomatic hypersplenism and decrease destruction of red cells, leukocytes, and platelets.<sup>51</sup> However, massive bleeding and death has been reported several months postoperatively in a child with Gaucher's disease who underwent partial splenectomy.<sup>52</sup>

## SPLENECTOMY

### Open Splenectomy

The open technique through a left upper quadrant incision is usually reserved for massive splenomegaly or partial splenectomy. The initial division of the

splenorenal, splenocolic, and splenophrenic ligaments allows the spleen to be mobilized from the left upper quadrant and out of the abdominal cavity. The short gastric vessels are initially divided, followed by the hilar vessels. A careful search must be undertaken for accessory spleens. A lateral muscle-splitting approach has been reported with a 2.7-day length of stay, comparable to some early laparoscopic series but longer than more recent series.<sup>23,53-56</sup>

## Laparoscopic Splenectomy

Laparoscopic splenectomy has evolved over the past 5 to 10 years to become the preferred technique for management of splenic disorders.<sup>3,4</sup> Less pain, shorter hospitalization, and smaller scars are the main advantages over open splenectomy. It is associated with longer operative time and can be difficult in cases of splenomegaly. The main technical advances have been the result of smaller instrumentation and advanced energy sources such as the Harmonic Scalpel (Ethicon Endosurgery Inc, Cincinnati, OH) and Ligasure (Valley Lab, Tyco Healthcare Group, Boulder, CO). At our institution, we primarily utilize the Ligasure because it allows division of vessels up to 7 mm.

Preoperative splenic artery embolization has been recommended in some adult series for spleens between 20 and 30 cm. However, complications such as pain, abscess, and retroperitoneal necrosis have been reported.<sup>57,58</sup> Although we have not found preoperative embolization necessary, on occasion we have been forced to divide the spleen in the abdomen to facilitate its removal. Hand-assisted procedures have been used in adults, but the large incision appears to eliminate the benefits of the laparoscopic approach in children.<sup>59,60</sup> Splenomegaly in children is usually associated with hereditary spherocytosis, but most cases are still amenable to the laparoscopic approach. A recent report

confirmed the benefit of the laparoscopic technique in adults for spleens between 15 and 25 cm.<sup>61</sup>

The most significant initial concern of the laparoscopic approach related to accessory spleen detection. However, in adult studies, and comparison pediatric series, similar rates of accessory spleen detection at laparoscopic and open splenectomy have been noted.<sup>28,29,54-56,62-64</sup> For the laparoscopic operation, most surgeons utilize a lateral approach with slight elevation of the left flank. One technique to improve the ease of port placement is to have the patient's left side initially elevated approximately 45 degrees rather than the true lateral position. The operating table is tilted to the patient's left to achieve a flat position for the port placement and is then tilted to the patient's right to achieve a lateral position for the procedure (Fig. 47-7). In young children and with small spleens, the upper midline instruments can be inserted without cannulas because these instruments are not removed during the procedure (Fig. 47-8). The first assistant holds the two upper midline instruments and provides elevation of the spleen and traction on surrounding tissues. The surgeon holds the camera (5-mm, 30-degree telescope) in the left hand and the energy source in the right.

Initially, the splenocolic ligament is divided with the energy device, allowing the splenic flexure to fall away from the spleen. The inferior portion of the gastrosplenic ligament is divided, and the surgeon works in a cephalad direction dividing the short gastric vessels and opening the lesser sac (Fig. 47-9). The most superior short gastric vessels are often very short, and care must be taken to avoid injury to the stomach or diaphragm. The lesser sac should be inspected for the presence of accessory spleens. The splenophrenic ligament is divided to fully mobilize the upper pole. At this point, the hilum can be approached. It is often easiest at this time to divide the splenorenal ligament

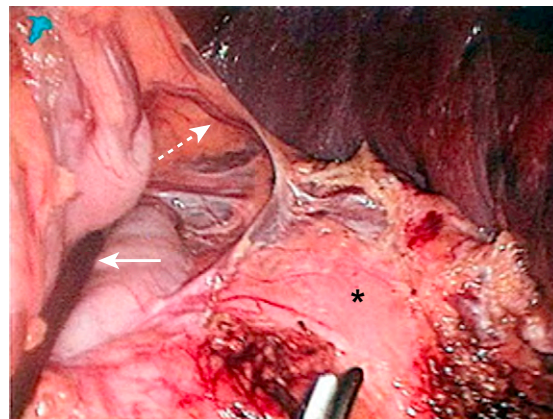

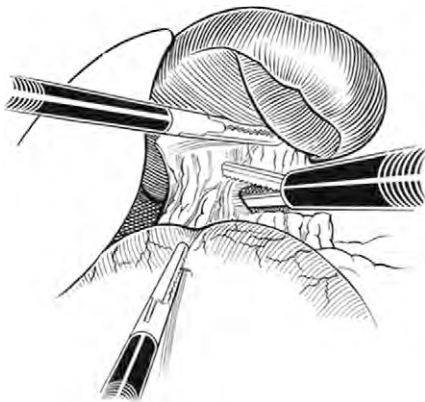

**Figure 47-7.** A, Initial positioning of the patient before any movement of the table. B, The table has been tilted to the patient's left to obtain a near supine position of the patient for port placement. C, The table is then rotated back to the patient's right to achieve a right lateral decubitus position for the operation. (From Rescorla FJ: Laparoscopic splenectomy. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 121-126. Reprinted with permission.)

**Figure 47-8.** Placement in a child of 3-mm midline instruments without the use of cannulas. The umbilical port is 12 mm, and the left lower quadrant port is 5 mm.

because this allows the option to use the endovascular stapler on the hilum. The hilar vessels can be divided with clips, stapler, or the energy device (Fig. 47-10). One study comparing the endoscopic stapler to the Ligasure demonstrated safety and efficiency of both with a lower blood loss and conversion rate with the Ligasure.<sup>65</sup> At our hospital, we utilize the Ligasure to divide the individual segmental vessels, usually with one treatment applied toward the pancreas side without division and a second toward the spleen

**Figure 47-9.** After division of the short gastric vessels using the ultrasonic scalpel, the lesser sac is entered. In the operative photograph, the stomach is being retracted by the assistant's instrument (*solid arrow*). The ultrasonic scalpel, at the bottom of the photograph, is approaching one of the intact short gastric vessels (*dotted arrow*). The pancreas is marked with an *asterisk*. (From Rescorla FJ: Laparoscopic splenectomy. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 121-126. Reprinted with permission.)

with division. Other reported adjuncts include use of a suction cup grasper to manipulate the spleen, a wall-lifting device, or umbilical tape around the hilum for splenic mobilization.<sup>66-68</sup>

The Endocatch II bag (Covidien, Norwalk, CT) is introduced through the 15-mm umbilical port with the telescope moved to the left lower quadrant site. This bag has a 13-cm diameter opening with a 23-cm depth and can accommodate most pediatric spleens. A smaller bag and umbilical cannula may be used for smaller spleens. The neck of the bag is delivered through the umbilical site, and either a finger or ring forceps is introduced to disrupt the capsule and remove the spleen piecemeal (Fig. 47-11). Use of an ultrasonic morcellator and liposuction has been reported but is usually unnecessary.<sup>69</sup> A coring device to remove portions of the spleen to decrease the size has also been described for children with sickle cell disease and splenomegaly.<sup>70</sup> This should not be utilized for hereditary spherocytosis because splenosis can lead to recurrent anemia.

These basic techniques are also utilized for the treatment of splenic cysts with excision and partial splenectomy as well as splenopexy for a wandering spleen. This approach is usually not applicable to traumatic splenic injuries because most of these children have unstable conditions and are in need of rapid control of the bleeding. However, a recent report described laparoscopic splenectomy after splenic artery embolization in a 15-year-old girl with a traumatic injury.<sup>71</sup>

### Partial Splenectomy

Concerns of post-splenectomy infection have led to the concept of partial splenectomy. This is primarily utilized in children with hereditary spherocytosis but has also been utilized with Gaucher's disease, hypersplenism with cystic fibrosis, splenic hamartomas, and as previously noted for splenic cysts.<sup>51,72,73</sup> The principle of partial splenectomy in hereditary spherocytosis is to remove enough spleen to minimize hemolysis

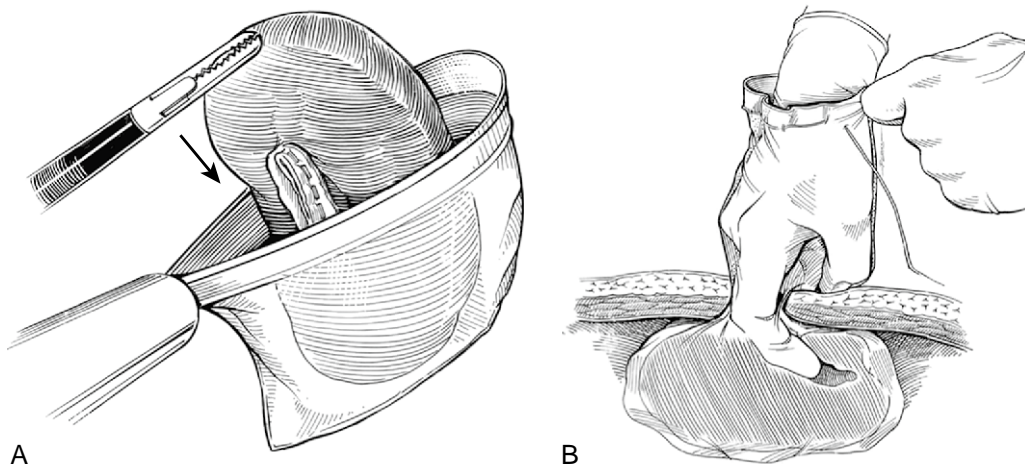

**Figure 47-10.** Once the spleen has been mobilized and is attached only through the hilar vessels, the camera is rotated to the left lower quadrant port and the stapler is introduced through the umbilical port. It is then placed across the hilar vessels, taking care not to incorporate a portion of the pancreas in the tissue to be divided. In the operative photograph, note that the splenic artery has been ligated with clips (*arrow*) before hilar division because the spleen was extremely large. (From Rescorla FJ: Laparoscopic splenectomy. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 121-126. Reprinted with permission.)

while preserving enough spleen to protect against overwhelming post-splenectomy infection. This generally involves removal of 85% to 95% of the spleen with preservation of approximately 25% of the normal splenic size. In this approach, the remnant spleen is supplied by one or two short gastric vessels with division of all of the hilar vessels (see Fig. 47-6). An alternative approach, depending on the anatomy of the segmental vessels, is to leave the uppermost segmental vessel as the only blood supply. Although most have been performed through an open technique, the laparoscopic approach is gaining popularity.<sup>23,74,75</sup>

The splenic parenchyma can be divided with a stapler, cautery, or energy device. Our institution recently reported 12 laparoscopic partial splenectomies.<sup>23</sup> In all cases, a combination of an energy device (Ligasure) and cautery were utilized, occasionally with a topical agent placed over the cut surface. After splenic vessel division, a clear line of demarcation is usually noted. We divide the spleen 1 cm onto the ischemic side to

minimize bleeding. The upper splenorenal and splenophrenic ligaments are left in place in an attempt to avoid torsion. Another report of seven laparoscopic partial splenectomies utilized the harmonic scalpel for parenchymal division and also completely mobilized the spleen.<sup>76</sup> The authors utilized splenopexy to prevent torsion.

Most series have noted an increase in red cell half-life, higher hemoglobin levels, and lower reticulocyte and bilirubin levels after partial splenectomy for spherocytosis.<sup>74,77</sup> Lack of Howell-Jolly bodies on peripheral smear and a decreased number of pitted red cells is evidence of preservation of splenic phagocytic function. Normal levels of IgM- and IgG-specific antibody titers after *Streptococcus pneumoniae* have been observed. Splenic regeneration occurs in all patients although the degree of regrowth does not correlate with hemolysis.<sup>75</sup> The development of cholelithiasis varies from 7% to 22%, indicating ongoing hemolysis. Moreover, the need for total splenectomy has been reported.<sup>74,78</sup> Rice and

**Figure 47-11.** A, After complete mobilization, the spleen is dropped into an endoscopic retrieval bag. B, The neck of the bag is then exteriorized through the umbilicus, and the surgeon's finger is used to fracture the splenic capsule. A combination of ring forceps and the surgeon's finger is then used to remove the splenic fragments. (From Rescorla FJ: Laparoscopic splenectomy. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 121-126. Reprinted with permission.)

colleagues have popularized this procedure and recently summarized their experience in 29 children undergoing partial splenectomy.<sup>75</sup> They noted decreased transfusion requirements, elimination of splenic sequestration, as well as higher hematocrits and lower reticulocyte counts and bilirubin levels. An alternative technique has been described that leaves a 10-cm<sup>3</sup> remnant as a small cylinder supplied off one vessel.<sup>79</sup>

## Complications and Controversies of Laparoscopic Splenectomy

### Accessory Spleen Detection

The identification of residual splenic function in up to 50% of some selected adult patients after laparoscopic splenectomy has led to concern of the ability of laparoscopy to adequately detect accessory spleens.<sup>28</sup> Parenchymal disruption at the time of laparoscopic splenectomy has also been associated with a higher rate of residual splenic function.<sup>28</sup> Although preoperative computed tomography and splenic scintigraphy have been utilized, most surgeons have abandoned this approach.<sup>80,81</sup>

There are reports of equivalent detection rates of accessory spleens with laparoscopy.<sup>28,82</sup> A review of several comparative pediatric series demonstrated an accessory spleen rate of 20.3% with open splenectomy compared with 20.2% with laparoscopy.<sup>54-56,62-64</sup> A recent report of over 200 pediatric laparoscopic splenectomies noted an accessory spleen rate of 19%.<sup>23</sup> Laparoscopic removal of missed accessory spleens has been reported with good success.<sup>83</sup> Some have been identified years after splenectomy.<sup>84</sup>

### Conversion to Open Splenectomy

Splenomegaly and bleeding are the main reasons for conversion from laparoscopy to an open operation and is reported in 1.3% to 2.8% of patients.<sup>62,80,85-87</sup> The largest pediatric series has a 1.7% rate.<sup>23</sup> Higher conversion rates have been noted with larger spleens, less surgeon experience, and obese patients.<sup>57,87,88</sup>

### Operative Time

The laparoscopic approach has uniformly been associated with somewhat longer operative times than open splenectomy.<sup>54-56,62-64</sup> A recent report noted a decrease in time with experience from a mean of 110 ± 36 minutes in the early period to 86 ± 35 minutes in the later period.<sup>23</sup> This operative time is compared with 83 minutes for open splenectomy in a previous report from the same institution.<sup>64</sup>

### Postoperative Hospitalization

Pediatric comparative studies have consistently demonstrated a lower duration of hospitalization with the laparoscopic compared with the open technique, ranging from 2.5 to 4.9 days for the open operation and 1.3 to 3.6 days for the laparoscopic approach.<sup>54-56,62-64</sup>

Recent studies have noted a length of stay of 1.5 to 1.8 days.<sup>23,62,63</sup> Our recent series of over 200 cases noted the length of hospitalization to vary by diagnosis, with hereditary spherocytosis requiring 1.23 days, ITP, 1.20 days, and sickle cell disease, 2.37 days.<sup>23</sup> The increased length of hospitalization in sickle cell disease is secondary to the higher incidence of complications in these patients, such as acute chest syndrome. Splenomegaly itself, which is common in hereditary spherocytosis, does not appear to affect the length of stay. An unreported benefit of the shorter length of hospitalization is the effect on the parent's ability to return to work. One study noted children return to full activity faster with laparoscopy compared with open splenectomy.<sup>56</sup>

## Complications

Most pediatric series have had relatively few complications with laparoscopic splenectomy. A meta-analysis of adult and pediatric studies reported between 1991 and 2002 noted a complication rate of 15.5% for laparoscopic and 26.6% for open splenectomy ( $P < .0001$ ).<sup>89</sup> The laparoscopic group had fewer pulmonary, wound, and infectious complications but more hemorrhagic complications when conversions for bleeding were included. A large adult comparative study noted equivalent grade I and II complications (minor, potentially life threatening) but higher grade III and IV (residual or lasting disability, death) with the open technique compared with laparoscopy.<sup>90</sup> Our recent review of over 200 pediatric laparoscopic splenectomies reported an overall complication rate of 11% with no wound infections or deaths.<sup>23</sup> Postoperative ileus, acute chest syndrome, and bleeding requiring transfusion were the most common complications. The complication rate was 22% among the children with sickle cell disease and only 8.3% among those with other conditions ( $P = .0083$ ). This report had one symptomatic portal vein thrombosis.

Splenic vein or portal vein thrombosis is a rare complication after splenectomy but may be more common than is clinically appreciated and is particularly common in cases of splenomegaly.<sup>91,92</sup> A recent small adult study identified a 50% incidence of portal or splenic vein thrombosis, with splenic weight being the strongest predictor of thrombosis.<sup>93</sup> Another prospective study in adults identified an incidence of 4.79% and noted spleen weight over 650 g and a platelet count over 650,000/mm<sup>3</sup> to be associated with portal system thrombosis.<sup>94</sup> A pediatric prospective series noted an incidence of 5.88% with the same risk factors.<sup>95</sup> Most authors recommend treatment with antithrombotic and antiplatelet therapy. Of the patients with total splenic vein thrombosis, over 50% were symptomatic with fever and abdominal pain, emphasizing the need to evaluate for this condition in symptomatic patients.

### Post-splenectomy Sepsis

Overwhelming post-splenectomy infection (OPSI) was initially reported by King and Shumacher in a group of five infants undergoing splenectomy for hereditary

spherocytosis.<sup>1</sup> The actual risk of OPSI is difficult to determine because most of the data was accumulated before routine vaccinations. Data from the 1990s note the rate of OPSI between 0.13% and 8.1% in children and adolescents younger than 15 years of age compared with 0.28% to 1.9% in adults.<sup>96-98</sup> Most authors quote the current rate between 3.5% and 4.4%.<sup>75,97,98</sup> Some have also noted a higher mortality in children younger than 4 years of age (8.1%) compared with a lower rate (3.3%) in older children. Most deaths occur within 4 years of splenectomy.<sup>99,100</sup> The causative organism is primarily *Streptococcus pneumoniae* which has been found in 50% to 90% of all infections.<sup>101-104</sup> Moreover, pneumococcus is responsible for 60% of all fatal infections followed by *Haemophilus influenzae*, meningococcus, and group A *Streptococcus*.<sup>105</sup> Vaccinations have been shown to decrease the risk of bacteremia.<sup>105,106</sup> Most studies and centers utilize post-splenectomy antibiotics, usually with penicillin.

A single institution study compared two time periods.<sup>97</sup> The first one was prior to immunizations and antibiotics. The second era (with a 70% immunization rate and 100% antibiotic prophylaxis rate) noted a decrease in OPSI (6% to 3.8%) and mortality (3.9% to 0.9%). This study noted an age difference with a rate of infection of 13.8% for those children younger than 6 years of age compared with 0.5% for older children. Although older studies noted mortality rates of 50% with OPSI, more recent studies have reported a rate of around 10%.<sup>97,107-109</sup> Routine immunization against *S. pneumoniae*, *H. influenzae*, and meningococcus as well as postoperative antibiotic prophylaxis are recommended by most authors. Although the optimal length of antibiotic prophylaxis is unclear, the highest rate of infection appears to occur within the first 2 years.<sup>110</sup>

## CONGENITAL ABDOMINAL WALL DEFECTS

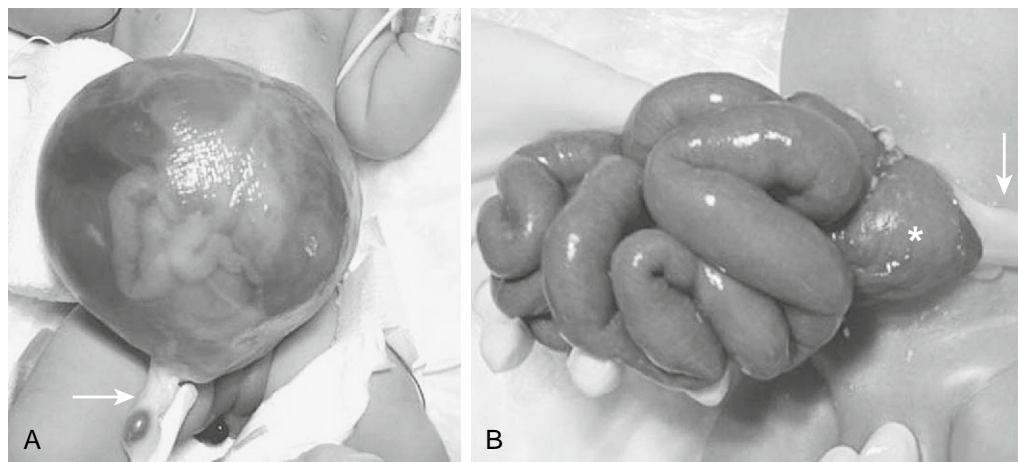

Cassandra Kelleher, MD • Jacob C. Langer, MD

**G**astroschisis and omphalocele are the two most common congenital abdominal wall defects. These two conditions are often diagnosed on prenatal ultrasonography and are easily differentiated by the location of the defect and the presence or absence of a sac surrounding the eviscerated bowel. There is a differential rate of associated anomalies between infants with omphalocele and gastroschisis. The risk of an associated cardiac or genetic abnormality in an infant with omphalocele approaches 50% but is much lower in neonates with gastroschisis. The long-term outcome for neonates with omphalocele is often determined by these associated anomalies. Differences between gastroschisis and omphalocele are illustrated in [Figure 48-1](#) and summarized in [Table 48-1](#).

Gastroschisis occurs in 1 in 4000 live births.<sup>1</sup> The majority of pregnancies complicated by gastroschisis are diagnosed sonographically by 20 weeks' gestation.<sup>2</sup> Often an ultrasound evaluation is performed because of an abnormal maternal serum  $\alpha$ -fetoprotein level, which is universally elevated in the presence of

gastroschisis. Detection of bowel loops freely floating in the amniotic fluid and a defect in the abdominal wall to the right of a normal umbilical cord insertion are diagnostic of gastroschisis.<sup>3</sup> An increased incidence of gastroschisis in mothers younger than 21 years of age has been widely documented.<sup>4</sup> There has also been a significant increase in the overall incidence of gastroschisis in all age groups over the past 2 decades.<sup>5,6</sup> Preterm delivery is more frequent in infants with gastroschisis, with an incidence of 28% compared with 6% of normal deliveries.<sup>7</sup>

Concomitant bowel atresia is the most common associated anomaly in patients with gastroschisis, with rates ranging from 6.9% to 28% in recently reported series ([Table 48-2](#)).<sup>8,9</sup> Gastroschisis is also one of a constellation of disorders in the limb-body wall defect syndrome, also known as the amniotic band syndrome. In this rare syndrome, thoracic wall anomalies or gastroschisis are found associated with limb abnormalities, meningocele, abnormal genitalia, variable intestinal atresias, and umbilical cord abnormalities.<sup>10,11</sup>

**Figure 48-1.** These two photographs nicely depict the differences between an omphalocele and gastroschisis. **A**, In an omphalocele both the liver and bowel can be herniated. A sac is always present and the umbilical cord (*arrow*) inserts onto the sac. Moreover, this is always a midline defect. **B**, With a gastroschisis, the liver is never herniated and a sac is absent. The location of the fascial defect is to the right of the umbilicus, and the umbilical cord (*arrow*) is attached to the umbilicus. In addition to the large and small intestine, the stomach (*asterisk*) can sometimes be herniated as well.

Characteristic	Omphalocele	Gastroschisis
Herniated viscera	Bowel ± liver	Bowel only
Sac	Present	Absent
Associated anomalies	Common (50%)	Uncommon (<10%)
Location of defect	Umbilicus	Right of umbilicus
Mode of delivery	Vaginal/cesarean	Vaginal
Surgical management	Nonurgent	Urgent
Prognostic factors	Associated anomalies	Condition of bowel

Elevation of maternal serum  $\alpha$ -fetoprotein is also present in many pregnancies complicated by fetal omphalocele, although not as commonly as with gastroschisis. The prenatal diagnosis of omphalocele can be made by 2D ultrasonography during the routine 18-week gestation ultrasound evaluation for dates.<sup>2</sup> Early first-trimester detection is possible if 3D ultrasonography is utilized. The incidence of omphalocele seen on ultrasonography at 14 to 18 weeks is as high as 1 in 1100.<sup>12</sup> Due to both spontaneous intrauterine fetal death and pregnancy termination, the incidence in live births is approximately 1 in 4000.<sup>1</sup>

Ultrasound evaluation is very useful for the detection of associated anomalies in infants with an omphalocele. An 18% to 24% incidence of cardiac anomalies is found and can be detected on fetal echocardiography.<sup>1,12</sup> Pulmonary hypoplasia is also commonly associated with omphalocele and may result in early respiratory distress requiring intubation and ventilatory support at the time of delivery. Recognized syndromes such as cloacal exstrophy and the pentalogy of Cantrell are diagnosed mainly on the basis of the physical examination. Chromosomal abnormalities occur in up to 48% of neonates with omphalocele.<sup>13</sup> Trisomy 13 and trisomy 18 are the most common. However, Down syndrome is also associated. The risk of a chromosomal abnormality is more common in infants with a central omphalocele and those containing only bowel, when compared with neonates with epigastric omphaloceles or those containing liver and bowel.<sup>13</sup> Infants with multiple anomalies are also more likely to have chromosomal abnormalities.

The delivery of an infant with a congenital abdominal wall defect requires prompt neonatal intervention. Immediate evaluation of respiratory and circulatory status, establishment of intravenous access, and resuscitation should be undertaken at birth. If pediatric surgical care is not available at the institution of delivery, urgent transfer should be arranged.

## EMBRYOLOGY

The abdominal wall forms during the fourth week of gestation from differential growth of the embryo causing infolding in the craniocaudal and mediolateral directions. The lateral abdominal folds of the embryo meet in the anterior midline and surround the yolk sac, eventually constricting the yolk sac into a yolk stalk that becomes the site of the umbilical cord. During the sixth week of gestation, rapid growth of the intestine causes herniation of the midgut into the umbilical cord. Elongation and rotation of the midgut occurs over the ensuing 4 weeks. By week 10, the midgut has returned to the abdominal cavity and the first, second, and third portions of the duodenum and the ascending and descending colon assume their fixed, retroperitoneal positions.

An omphalocele occurs if the intestines fail to return to the abdominal cavity. Varying amounts of bowel may be contained within the omphalocele sac. Other intra-abdominal viscera including liver, bladder, stomach, ovary, and testis can also be found within the sac. The sac consists of the covering layers of the umbilical cord, which include amnion, Wharton's jelly, and peritoneum. The umbilical cord is attached to the sac itself.

The etiology of gastroschisis is less clear. One theory suggests that gastroschisis results from failure of the mesoderm to form in the anterior abdominal wall. A second theory posits that failure of the lateral folds to fuse in the midline leaves a defect to the right side of the umbilicus.<sup>14</sup> DeVries and associates and Hoyme and colleagues proposed that thrombosis of the right omphalomesenteric vein (umbilical vein) causes necrosis of the surrounding abdominal wall, leading to the right-sided defect.<sup>15,16</sup> This theory is supported by the observation that gastroschisis is sometimes associated with intestinal atresia, a condition that is also thought to be associated with an ischemic etiology.<sup>17,18</sup> Additionally, retrospective data have shown an increased

Study	No. Patients	Drop in	Anastomosis	Stoma
Amoury et al, 1977 <sup>93</sup>	6		3	3
Pokorny et al, 1981 <sup>94</sup>	5	1		4
Gornall, 1989 <sup>95</sup>	5	1	3	1
Shah and Woolley, 1991 <sup>96</sup>	4	3		1

Fleet and de la Hunt, 2000 <sup>56</sup>	10	6		4

risk of gastroschisis and intestinal atresia with maternal use of vasoconstrictive drugs such as ephedrine, pseudoephedrine, or cocaine, as well as with smoking.<sup>19</sup> In-utero rupture of an omphalocele has also been proposed as a mechanism of gastroschisis formation.<sup>20,21</sup> Most patients with congenital abdominal wall defects have some form of rotation abnormality, because the herniated bowel does not undergo the normal process of rotation and is not fixed in the appropriate retroperitoneal position during development.

## GASTROSCHISIS

### Perinatal Care

The optimal mode of delivery for fetuses with gastroschisis has been debated for many years. Proponents of routine cesarean delivery argue that the process of vaginal birth results in injury to the exposed bowel. However, the literature would suggest that both vaginal delivery and cesarean section are safe.<sup>22</sup> A recent meta-analysis by Segel and coworkers failed to demonstrate a difference in outcomes for infants delivered by cesarean section or vaginally.<sup>23</sup> Therefore, the delivery method of a neonate with gastroschisis should be at the discretion of the obstetrician and the mother, with cesarean section reserved for obstetric indications or fetal distress.

Early delivery of the fetus with gastroschisis has been advocated to limit exposure of the bowel to amniotic fluid in an attempt to reduce the inflammatory peel on the surface of the bowel. Poor motility of the bowel is thought to be related to exposure to the amniotic fluid and altered bowel wall cellular and extracellular matrix composition.<sup>24,25</sup> Interleukin-6, interleukin-8, and ferritin are elevated in the amniotic fluid in fetuses with gastroschisis when compared with controls.<sup>26</sup> Amniotic fluid cytokines and other proinflammatory mediators have been shown to damage the myenteric nerve plexus and interstitial cells of Cajal in animal models of gastroschisis.<sup>27,28</sup> Damage to the pacemaker cells and nerve plexuses may contribute to the profound dysmotility and malabsorption seen in the patients with gastroschisis. Bowel edema and peel formation increase as pregnancy progresses, most significantly if the gastroschisis defect constricts venous outflow from the herniated bowel.<sup>29</sup> Early delivery may mitigate these effects, but the literature is mixed in terms of the benefit of preterm delivery. A recent randomized trial showed a shorter time to full enteral feeding or shorter hospital stay after induced early delivery.<sup>30</sup> Low birth weight does seem to impact outcome, with neonates weighing less than 2 kg having increased time to full enteral feeding, an increased number of ventilated days, and an increased length of parenteral nutrition compared with those weighing more than 2 kg.<sup>31</sup>

Some authors advocate selective preterm delivery based on the appearance of bowel distention and thickening on prenatal ultrasonography. The presence of dilated fetal bowel has been shown to correlate with

poorer outcome, including fetal distress and demise in some series but not in others.<sup>32-36</sup> One confounding factor in the use of bowel dilatation to predict outcome is the lack of a common definition of “dilated,” with values ranging from 7 to 25 mm being considered abnormal. The timing of fetal ultrasonography and bowel measurements also lack standardization. The presence of bowel atresia has also been correlated with worsening outcome by some authors but not by others.<sup>37,38</sup> Among those who advocate preterm delivery, there are some who suggest that delivery be done by routine cesarean section. Others attempt induction of labor at 36 to 37 weeks’ gestation. We have found that labor can be successfully induced in gastroschisis pregnancies in a high percentage of cases, probably because of the inherent tendency toward preterm labor.<sup>11</sup> Most authors advocate delivery at a tertiary perinatal center so as to provide immediate access to neonatal and pediatric surgical expertise.

### Neonatal Resuscitation and Management

Neonates with gastroschisis have significant evaporative water losses from the open abdominal cavity and exposed bowel. Appropriate intravenous access should be obtained and fluid resuscitation begun before transport to a tertiary referral center, if necessary. Nasogastric or orogastric decompression is important to prevent undue distention of the stomach and intestine. The herniated bowel should be wrapped in warm saline-soaked gauze and placed in a central position on the abdominal wall. The child should be positioned on the right side to prevent kinking of the mesentery and resultant bowel ischemia. The bowel should be wrapped with plastic wrap or the infant placed with the bowel and legs in a plastic bag to reduce evaporative losses and improve temperature homeostasis (Fig. 48-2). Although gastroschisis most often is an isolated anomaly, thorough examination of the neonate should be undertaken to exclude the coexistence of other

**Figure 48-2.** Photograph of a neonate with gastroschisis who has been transported wrapped with a bowel bag. The bag has been untied to allow inspection of the herniated bowel.

anomalies. In addition, the bowel must be carefully examined in a search for evidence of intestinal atresia, necrosis, or perforation.

## Surgical Management

Surgical management of gastroschisis varies from center to center. The primary goal is to return the viscera to the abdominal cavity while minimizing the risk of damage to the viscera due to direct trauma or to increased intra-abdominal pressure. Options include silo placement, serial reductions, and delayed abdominal wall closure, primary reduction with operative closure, and primary or delayed reduction with umbilical cord closure. In addition, the timing and location of surgical intervention is controversial, ranging from immediate repair in the delivery room, to reduction and closure in the neonatal intensive care unit, to surgical closure in the operating room.<sup>39,40</sup> In all cases, inspection of the bowel for obstructing bands, perforation, or atresia should be undertaken. Bands crossing the bowel loops should be lysed before silo placement or primary abdominal closure to avoid subsequent bowel obstruction.

Because intestinal hypomotility is almost universally present in children with gastroschisis, central venous access should be established early. Options include a cuffed Broviac catheter or a peripherally inserted central catheter line.

### Primary Closure

Historically, urgent primary closure of gastroschisis was advocated in all cases. This method of treatment is still commonly practiced for neonates in whom full reduction of the herniated viscera is thought to be possible. The procedure has traditionally been done in the operating room, but more recently some authors have advocated primary closure at the bedside without general anesthesia.<sup>40</sup> Multiple methods of closure have been described for children in whom primary fascial closure cannot be achieved. Many of these incorporate the umbilicus as an allograft.<sup>41,42</sup> Prosthetic options include nonabsorbable mesh or bioprosthetic materials such as dura or porcine small intestinal submucosa (Surgisis, Cook, Inc., Bloomington, IN). Once the fascial closure is completed, skin flaps can be mobilized to cover the abdominal wall closure. Breakdown of these flaps due to tension can occasionally occur. Thought can be given to leaving a skin defect and allowing healing by secondary intention.

Traditionally, most surgeons have excised the umbilicus during gastroschisis repair. However, many cases can be repaired with preservation of the umbilicus with an excellent cosmetic result (Fig. 48-3).<sup>43</sup> Another option in selected cases is to reduce the bowel and place a piece of Silastic sheeting under the abdominal wall to prevent evisceration (Fig. 48-4). This technique is useful in infants when the surgeon is concerned about worsening the pulmonary function with fascial and skin closure. The Silastic sheet is removed in 4 to 5 days, and the abdominal wall and skin are closed.

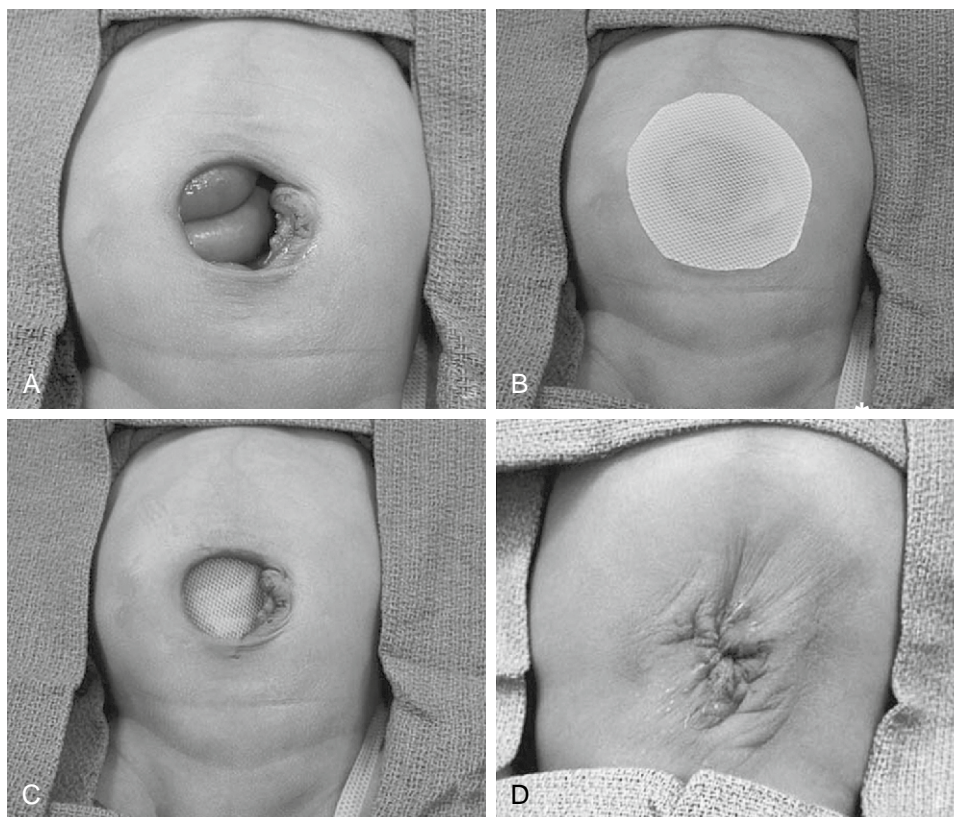

**Figure 48-3.** Nice cosmetic result after gastroschisis repair in which the umbilicus was preserved.

Intra-abdominal pressure, measured either as intravesical pressure using a bladder catheter or as intragastric pressure using the nasogastric tube, can sometimes be used to guide the surgeon during reduction. Pressures higher than 10 to 15 mm Hg indicate an elevated intra-abdominal pressure and are correlated with decreased perfusion to the kidneys and bowel.<sup>44</sup> Pressures higher than 20 mm Hg can lead to renal failure and bowel ischemia with ensuing infarction.<sup>45</sup> Similarly, an increase in central venous pressure greater than 4 mm Hg has been correlated with the need for silo placement or patch closure during attempted primary repair.<sup>46</sup> In the situation in which bladder pressure is higher than 20 mm Hg before or during visceral reduction, some authors advocate placing a silo or patch to maintain pressures less than 20 mm Hg.<sup>47,48</sup> Splanchnic perfusion pressure, defined as the difference between mean arterial pressure and intra-abdominal pressure, has also been used to guide surgeons during reduction, with a splanchnic perfusion pressure less than 44 mm Hg indicating decreased blood flow and the need for silo placement.<sup>49</sup>

### Staged Closure

For many years, primary closure of gastroschisis was attempted in all cases. Multiple retrospective reviews of primary versus staged closure can be found in the literature, most of which documented better outcomes in those patients who underwent primary closure. However, this finding probably represents selection bias because those patients with the most intestinal damage were the most likely to require staged closure

**Figure 48-4.** In selected cases, it may be possible to reduce the bowel back into the abdominal cavity (A), but the surgeon is concerned about worsening pulmonary function if the fascia and skin are closed. Therefore, one technique is to cut a circular piece of Silastic sheeting (B) and place it in the abdomen and on top of the reduced intestine (C). Four to 5 days later, after the neonate has become more stable and the pulmonary function has improved, the Silastic sheet is removed and the fascia and the skin are closed (D).

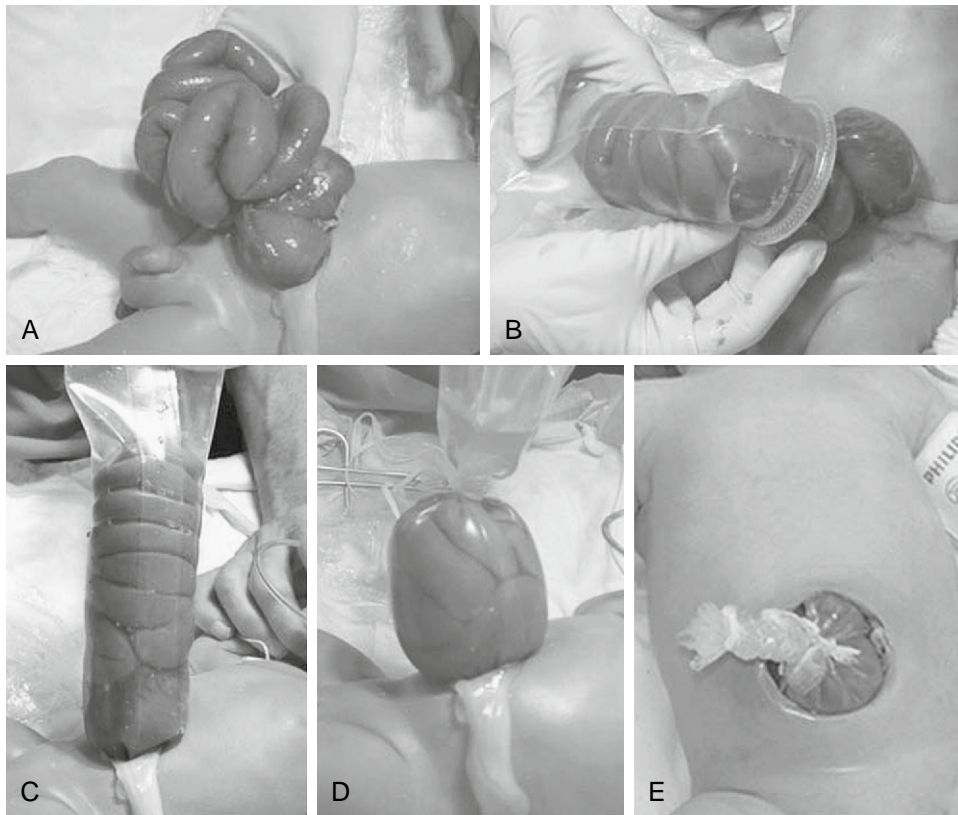

and were also the most likely to have a poor outcome. Recent data from the Canadian Pediatric Surgeons Network (CAPSNet) database confirm these thoughts, suggesting that infants who are able to undergo immediate primary reduction and closure have a shorter length of parenteral nutrition use and total length of stay when compared with those who required staged reduction and delayed repair.<sup>37</sup>

Originally, staged closure consisted of placing the bowel into a silo constructed of Silastic sheets sewn together and sutured to the abdominal wall. More recent introduction of a prefabricated silo with a circular spring that can be placed into the fascial opening, without the need for sutures or general anesthesia, has made it possible to insert the silo in the delivery room or at the bedside in the neonatal unit (Fig. 48-5). In either case, the bowel is reduced once to twice daily into the abdominal cavity as the silo is shortened by sequential ligation. When the eviscerated contents are entirely reduced, the definitive closure can be performed. This process usually takes between 1 and 14 days, depending on the condition of the bowel and the infant.

Over the past 2 decades, the routine use of a preformed silo with delayed closure of the abdominal wall defect has increasingly come into favor, with the theory being that avoidance of high intra-abdominal pressure will avoid ischemic injury to the viscera and permit earlier extubation. One study reported

fewer days on mechanical ventilation for patients undergoing staged silo reduction when compared with primary closure.<sup>50</sup> However, there was no difference found in time to full feeds or days on parenteral nutrition. Another report showed a similar time to full enteral feedings but also showed that primary closure was associated with the need for higher mean airway pressures, oxygen requirement, vasopressor requirement, and decreased urine output in patients treated with primary closure.<sup>51</sup> In a prospective study using historical controls, our group demonstrated that the routine use of a spring-loaded silo was associated with a shorter time on the ventilator, lower postoperative airway pressures, shorter hospital stay, lower cost, and lower risk of complications.<sup>52</sup> In a recent randomized multicenter trial, the routine use of the spring-loaded silo was associated with a trend toward fewer days on the ventilator, with a similar incidence of other outcomes.<sup>53</sup> The main advantage of this approach would therefore appear to be repair of the defect in a more controlled and elective environment.

Definitive closure in the operating room consists of raising skin flaps around the fascial defect and primary fascial closure in the horizontal direction. Closure of the skin in a linear fashion creates a “keyhole” appearance with a horizontal scar to the right of the umbilicus. Some surgeons advocate a purse-string suture of the skin around the umbilicus to create a circular scar with improved cosmesis. Recently, the “plastic

**Figure 48-5.** The use of a spring-loaded prefabricated silo is shown in these photographs. **A**, The gastroschisis defect is seen. **B**, An appropriate-sized spring-loaded silo is then placed over the eviscerated intestine. **C**, The ring of the silo has been positioned under the fascial defect and attached to an overhead support to keep the bowel from torquing, which may result in intestinal ischemia. **D**, Gradual reduction of the silo is performed. **E**, Finally, the bowel has been completely returned to the abdominal cavity and the neonate is ready for transport to the operating room for closure of the fascia and skin.

closure” method has been introduced in which the umbilical cord, if not too macerated or dried out, is tailored to fill the gastroschisis defect and is then covered with an adhesive dressing.<sup>54</sup> If the umbilical cord is not salvageable, the bowel can be directly covered with the dressing. In-growth of granulation tissue and epithelialization occurs over time. With this technique, an operation can be avoided entirely in many infants. Residual ventral hernia rates are reported to be 60% to 84%, the majority of which close spontaneously.<sup>55</sup>

### **Management of Associated Intestinal Atresia**

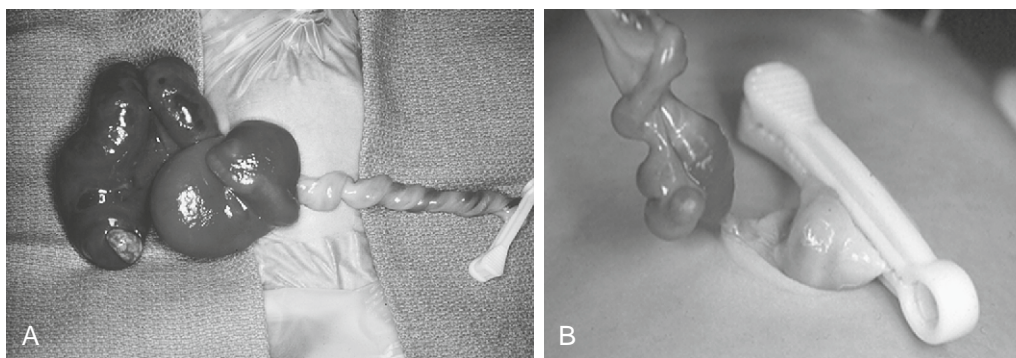

Up to 10% of neonates with gastroschisis will have an associated atresia, most commonly jejunal or ileal. In a recent review of 4344 infants with gastroschisis, a 5% incidence of small bowel atresia and a 2% incidence of large bowel atresia was found.<sup>8</sup> These atresias can be treated at the time of abdominal wall closure with resection and primary anastomosis. If the condition of the bowel makes primary anastomosis inadvisable, the bowel can be reduced with the atresia intact and repair can be undertaken 4 to 6 weeks after the initial abdominal wall closure. Some surgeons have chosen to create a stoma in cases of atresia, particularly in the case of distal atresias.<sup>56</sup> If perforation is encountered, the perforated segment can be resected with primary

anastomosis if the bowel inflammation is minimal. Alternatively, an ostomy can be created and primary closure undertaken with closure of the ostomy at a later date. In cases in which perforation has occurred and primary closure is impossible, a silo can be applied and the area of perforation exteriorized through a hole in the silo. Once the bowel has been reduced, a formal stoma can be created at the time of abdominal wall closure. There is no consensus in the literature about the optimal management of these complicated problems (see Table 48-2).

Intestinal atresia should be differentiated from “vanishing bowel” in infants with gastroschisis. This condition is usually associated with a very small abdominal wall defect and is characterized by necrosis and disappearance of some or all of the intestine (Fig. 48-6). Although this is a rare finding, it usually results in short bowel syndrome.

### **Postoperative Course**

Gastroschisis is associated with abnormal intestinal motility and nutrient absorption, both of which gradually improve over time in most patients. Introduction of enteral feeding is often delayed for weeks while awaiting return of bowel function. During the period of dysmotility, nasogastric decompression and parenteral nutrition is required. When the nasogastric output is

**Figure 48-6.** A and B, These two photographs show different neonates with the prenatal diagnosis of gastroschisis. In each instance, the herniated intestine has died. At exploration, each patient was found to have short bowel syndrome due to very little small intestine.

no longer bilious and bowel activity has begun, enteral feeds can be started and slowly advanced. Often there is initial intolerance with the need for slow progression of feeds. Holding feeds and restarting them a few days later due to feeding intolerance is often needed as well. Because progression to full enteral feeding can take weeks, secure central venous access is important. We also advocate early oral stimulation, because the sucking-swallowing reflex can be lost while awaiting bowel function.

The treatment of gastrointestinal dysmotility with prokinetics is often used to hasten initiation of feeding or time to full feeding. However, there is little documentation in the literature to support their use. Commonly utilized prokinetics include erythromycin, metoclopramide, domperidone, and cisapride. In a rabbit model of gastroschisis, only cisapride improved contractility of newborn intestine, whereas erythromycin improved motility in control adult tissue only.<sup>57</sup> A randomized controlled trial of erythromycin versus placebo similarly showed that enterally administered erythromycin did not improve time to achieve full enteral feedings over placebo.<sup>58</sup> However, a similar randomized trial examining the use of cisapride in postoperative neonates, most of whom had gastroschisis, did show a beneficial effect.<sup>59</sup> Cisapride is available on a compassionate use basis in North America. We have had success with its use in infants with severe dysmotility who had not responded to other agents.

A number of authors have recently attempted to stratify patients with gastroschisis according to risk, finding that intestinal damage predicts a more prolonged hospital course and increased morbidity and mortality. In one review of 103 infants with gastroschisis, the authors were able to document a significant increase in complications and mortality in those infants with a complex anomaly defined as the presence of atresia, volvulus, necrotic bowel segment or perforation. In the complex group, length of mechanical ventilation, time to the initiation and to full enteral feedings, infectious complications, and mortality (28% vs. 0%) were all increased when compared with the infants with simple conditions.<sup>60</sup> Using a classification of simple and complex conditions, one group showed similar increased morbidity and mortality in infants with complex gastroschisis in a review of

4344 patients.<sup>8,61</sup> Also, another study found a similar increased incidence of central venous catheter-related sepsis, a longer time to full enteral feeding, and a longer hospital stay in infants with gastroschisis complicated by atresia or necrotic bowel.<sup>62</sup> In a single institutional review, another group found that a significantly increased number of patients with complex gastroschisis required long-term enteral access for feeding difficulties.<sup>63</sup> In an additional analysis of 2003 inpatient data, the authors verified a risk stratification index that identifies patients with gastroschisis who are at the highest risk for death.<sup>64</sup> Infants with gastroschisis complicated by intestinal atresia, necrotizing enterocolitis, cardiac disease, or pulmonary hypoplasia/bronchopulmonary dysplasia are at a 2- to 14-fold increased risk of death, respectively. The ability to risk-stratify gastroschisis patients with respect to increased morbidity and mortality has utility in counseling families, predicting hospital utilization, and identifying a group of patients who would benefit from further strategies to improve outcomes.

### Long-Term Outcomes

Long-term outcomes for patients born with gastroschisis are generally excellent. The presence of bowel atresia is the most important prognostic determinant for a poor outcome.<sup>8,62,65</sup> Patients with bowel atresia are significantly more likely to require prolonged parenteral nutrition with the associated risks of total parenteral nutrition-related cholestatic liver disease and central line-related sepsis. These complications lead to a 20-fold increased risk of death when compared with a patient without associated atresia.<sup>62</sup>

Necrotizing enterocolitis has been encountered in full-term infants with gastroschisis in higher than expected frequencies (up to 18.5%).<sup>66,67</sup> Significant bowel loss from necrotizing enterocolitis can predispose patients to short bowel syndrome and its associated hepatic and septic complications. On the other hand, another group found that in the patients with necrotizing enterocolitis after gastroschisis the clinical course was often uncomplicated.<sup>66</sup> There is a report suggesting that infants fed with breast milk have a lower incidence of necrotizing enterocolitis after gastroschisis repair than those infants fed with formula.<sup>67</sup>

Cryptorchidism is associated with gastroschisis with an incidence of 15% to 30%.<sup>68,69</sup> However, it is unclear from the literature if this is due to the testis being outside the abdomen through the abdominal wall defect, leading to testicular maldescent, or if the prematurity associated with gastroschisis is responsible.<sup>68</sup> Several retrospective analyses have shown that replacement of the herniated testis into the abdominal cavity will result in normal testicular descent into the scrotum in the majority of cases.<sup>69,70</sup> Our current practice is to allow a trial of spontaneous testicular descent after placement of the testis into the abdominal cavity. We then proceed with orchidopexy if the testis remains undescended by 1 year of age.

The majority of patients with gastroschisis will achieve normal growth and development after an initial catch-up period in early childhood.<sup>9,71</sup> If the umbilicus is sacrificed during the repair of the gastroschisis defect, up to 60% of children report psychosocial stress from the lack of an umbilicus.<sup>71</sup> Umbilical reconstruction can be undertaken when the child is healthy, if it is desired by the child or parents.

## OMPHALOCELE

### Perinatal Care

The delivery of patients with omphalocele, like those with gastroschisis, should be dictated by obstetric considerations, because neither vaginal delivery nor cesarean section has been shown to be superior.<sup>72</sup> However, despite the lack of data, most practitioners choose to deliver neonates with giant omphaloceles by cesarean section because of the fear of liver injury. In addition, most authors advocate delivery at a tertiary perinatal center to allow immediate access to neonatal and pediatric surgical expertise.

### Neonatal Resuscitation and Management

After delivery, a thorough search for associated anomalies should be undertaken. The high risk of associated cardiac defects mandates a directed cardiac evaluation, including auscultation, four-limb blood pressures, and peripheral pulse examination. If there is suspicion of a cardiac defect, echocardiography should be obtained. Renal abnormalities can be detected on abdominal ultrasonography. Neonatal hypoglycemia should alert the practitioner of the possibility of Beckwith-Weidemann syndrome. Blood samples for genetic evaluation should be obtained, if indicated.

In preparing infants with omphalocele for transport, risks arising from associated anomalies should be specifically addressed. Adequate intravenous access should be obtained and fluid resuscitation begun. Infants with omphalocele do not have as significant fluid and temperature losses as those with gastroschisis but the losses are higher than those with an intact abdominal wall. The omphalocele itself can be dressed with saline-soaked gauze and an impervious dressing to minimize

**Figure 48-7.** Neonate with an omphalocele sac that ruptured during delivery. Treatment was similar to that for gastroschisis, and a silo was constructed.

these losses. A nasogastric or orogastric tube should be inserted and placed to suction or gravity drainage. In some cases, the omphalocele sac may have ruptured either prenatally during delivery or postnatally (Fig. 48-7). In this situation, the surgical management should be the same as described for the infant with gastroschisis.

## Surgical Management

### Primary Closure

Treatment options in infants with omphalocele depend on the size of the defect, gestational age, and the presence of associated anomalies. In infants with small defects, the loss of abdominal domain may not be excessive and primary closure may be appropriate. This option is predicated on the ability of the patient to withstand an operation if associated cardiac disease is present. Primary closure consists of excision of the omphalocele sac and closure of the fascia and skin over the abdominal contents. It is not unusual for an omphalomesenteric duct remnant to be associated with a small omphalocele (Fig. 48-8). When dealing with a medium-sized omphalocele, care must be taken when excising the portion of the sac covering the liver, because the hepatic veins are located just under the epithelium/sac interface in the midline and can be inadvertently injured. Also, the sac is often adherent to the liver itself and significant hemorrhage can result from tears in Glisson's capsule. In this situation, it is best to leave part of the sac on the liver. The inferior portion of the sac covering the bladder can be quite thin, and excision of the sac in this area can lead to inadvertent bladder injury. As with gastroschisis, intra-abdominal pressure can be elevated during reduction, leading to abdominal compartment syndrome. Measurement of intra-abdominal pressure can be very useful to guide the surgeon. When reducing the contents, attention must be given to the position of the hepatic veins because kinking will result in acute obstruction.

**Figure 48-8.** In patients with small omphaloceles (A), it is not unusual for an omphalomesenteric duct remnant to be found (B). C, The diverticulum was excised primarily and the fascia and skin closed. This neonate recovered uneventfully.

In many cases, the defect is large and the loss of domain in the peritoneal cavity prevents primary closure without an undue increase in intra-abdominal pressure (Fig. 48-9). Multiple methods have been proposed to obtain primary fascial closure of the abdominal wall in this setting. In the 1950s, Kearns and Clarke described a “cutis graft” composed of dermis and anterior rectus fascia.<sup>73</sup> Bilateral flaps that mobilize the muscle, fascia, and skin of the abdominal wall toward the midline and allow midline fascial closure have been used successfully.<sup>74,75</sup> Component separation at the level of the external oblique has also been described.<sup>76</sup> More recent approaches include the use of tissue expanders that are placed inside the abdominal cavity to reduce abdominovisceral disproportion.<sup>77</sup> Volume is added to the tissue expander over time until a primary fascial closure can be performed.

Some surgeons prefer to place a patch in the abdominal wall and close the skin over the patch. Experience with nonabsorbable materials such as Marlex, polypropylene mesh, and Gore-Tex have resulted in high rates of infection requiring removal of the mesh.<sup>78</sup> Recent introduction of bioabsorbable materials such as small intestine submucosa, dura, or human acellular dermis may represent promising alternatives.<sup>79,80</sup>

**Figure 48-9.** This neonate was born with a large omphalocele. As is evident, the abdominal cavity is quite small. Primary closure is not possible in such a patient.

### Staged Closure

Historically, children with large omphaloceles were managed using skin flaps that were mobilized to cover the exposed viscera, leaving a large ventral hernia that would be closed in the future.<sup>81,82</sup> In 1967, Schuster first described the use of a silicone plastic “silo” to provide staged reduction for children with omphalocele.<sup>83</sup> With this approach, the infant is taken to the operating theater and the sac of the omphalocele is excised. Once the omphalocele sac has been removed, a Silastic silo can be sewn to the rectus fascia (Fig. 48-10A). In most instances, a short circumferential skin flap is raised so that the silo is sewn to the fascia only. Alternatively, the silo can be sewn to the full thickness of the abdominal wall. In our experience, the use of preformed spring-loaded silos in this setting is usually unsuccessful, owing to the relatively large size of the defect that prevents the silo from remaining in place. For moderate-sized omphaloceles with a relatively thick sac, sequential ligation of the sac itself can be used for gradual reduction of the viscera. Serial reductions, similar to that for gastroschisis, are performed on a once- to twice-daily schedule until definitive closure can be obtained. At this time, the infant is returned to the operating theater for definitive closure of the defect. If the fascial edges cannot be approximated at this time, prosthetic closure can be utilized (see Fig. 48-10B, C).

“Escharotic therapy,” which results in gradual epithelialization of the omphalocele sac, is another form of staged closure that can be used for neonates who cannot tolerate operation due to prematurity, pulmonary hypoplasia, congenital heart disease, or other anomalies. Historically, mercurochrome was used as both a scarificant and a disinfectant (Fig. 48-11). Reports of deaths due to mercury poisoning led to abandonment of this treatment option.<sup>84</sup> Other options have included iodine, polymer membrane, silver sulfadiazine, and Nystatin powder. It usually takes many months for the sac to granulate and epithelialize (Fig. 48-12). Once that has occurred and the infant is stable enough to undergo anesthesia and surgery, the remaining ventral hernia can be repaired by one of the previously mentioned methods, usually requiring use of prosthetic mesh with skin flap coverage, especially

**Figure 48-10.** A, A Silastic silo has been sewn to the rectus fascia in this neonate with a large omphalocele. B, Serial reductions have been performed once or twice daily until the bowel has been reduced into the abdominal cavity. C, At that time, the silo is removed and fascia and skin are closed (if possible). If not, the skin is closed and the fascial defect is left open.

at the upper end of the defect. Again, tissue expanders have been used to create an abdominal cavity big enough to house the viscera (Fig. 48-13).<sup>85</sup>

### Postoperative Course

If primary closure has been accomplished, the majority of patients will require mechanical ventilation for a number of days postoperatively. During this time, the abdominal wall and bowel wall edema will resolve and the intra-abdominal pressure will decrease. A nasogastric tube should be utilized for gastric decompression. Feeding can begin when the nasogastric tube output is no

longer bilious, the volume is minimal, and bowel activity has occurred. Abdominal distention should have resolved by the time bowel function has returned. Antibiotics are administered postoperatively for 48 hours unless there are signs of wound infection, in which case they are continued. If a hernia develops, closure is usually possible after 1 year of age. A prosthetic mesh may be necessary in cases of large fascial defects.

The method of closure (primary, staged with delayed primary closure or prosthetic mesh) has not been shown to affect length of hospital stay. The time to resumption of enteral feeding, however, may be shorter with primary closure.<sup>86</sup> In a review of omphalocele treatment at one institution, the authors reported a 12% incidence of complications of increased intra-abdominal pressure after closure, including acute hepatic congestion requiring reoperation, renal failure requiring dialysis, and bowel infarction.<sup>87</sup> In this retrospective review, wound complications including skin and fascial dehiscence occurred in up to 25% of patients undergoing operative closure. It is likely that careful attention to avoiding excessive elevation in intra-abdominal pressure can minimize these types of complications.

### Long-Term Outcomes

Most infants with a small omphalocele recover well and do not have any long-term issues. A number of long-term medical problems occur in patients with larger omphaloceles. These include gastroesophageal reflux, pulmonary insufficiency, recurrent lung infections or asthma, and feeding difficulty with failure to thrive.<sup>88</sup> In 23 patients with omphalocele, 43% were found to have gastroesophageal reflux disease by esophageal biopsy or pH monitoring. Patients younger than 2 years old had an increased rate of reflux compared with those older than 2 years of age. Patients with large defects also had an increased rate of reflux.<sup>89</sup> Only one of these children required a fundoplication, suggesting that reflux improves as the child ages. In children who are managed with escharotic therapy and who have persistent severe reflux, the fundoplication should be done at the time of definitive abdominal wall closure.

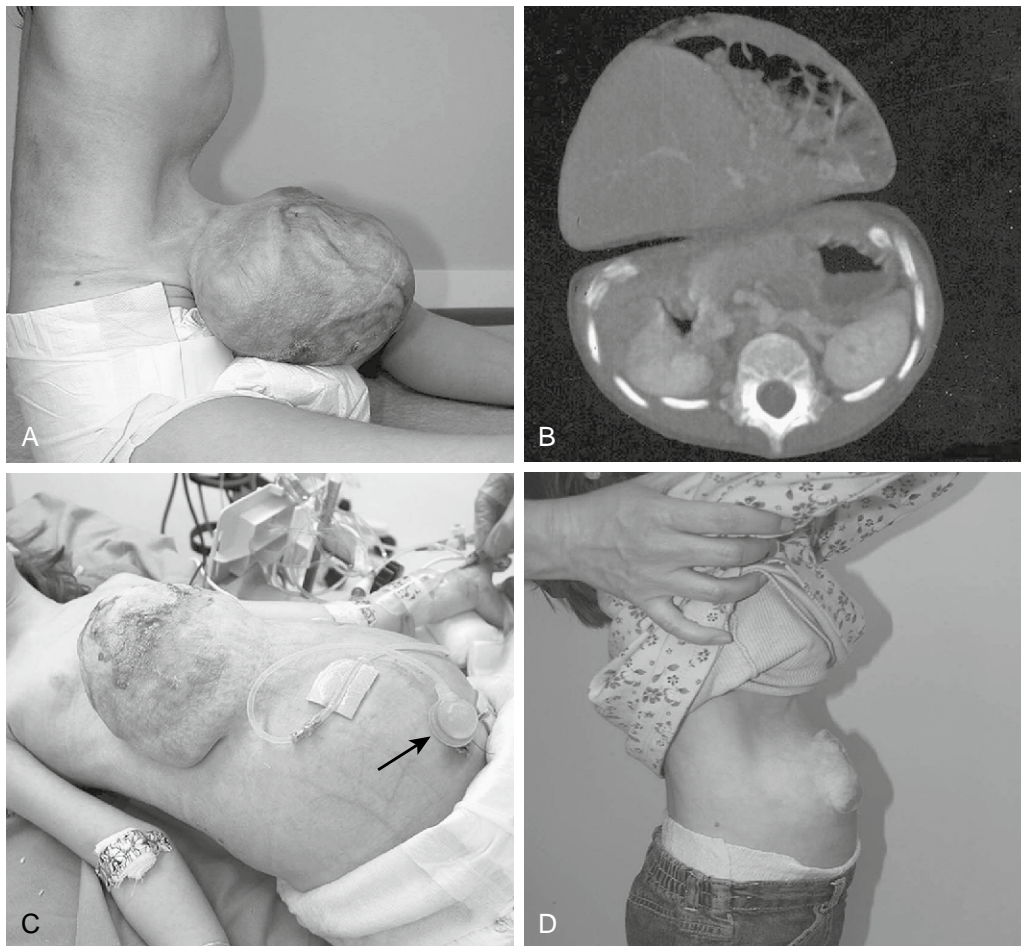

Feeding difficulties can occur in 60% of infants with a giant omphalocele.<sup>88</sup> Many of these children

**Figure 48-11.** Photograph of an infant with a large omphalocele that was treated by scarification using mercurochrome. Note the intense inflammation on the abdominal wall surrounding the scarred sac. Reports of death due to mercury poisoning led to abandonment of this method.

**Figure 48-12.** A, Options for scarification of the omphalocele sac include iodine, nystatin powder, polymer membrane, and sulfadiazine (shown above). B, Although it may take many months for the sac to granulate and epithelialize, eventually this does occur. C, The remaining ventral hernia can be repaired in multiple stages.

**Figure 48-13.** A 4-year-old girl was born with a number of anomalies including a diaphragmatic hernia, pulmonary hypoplasia and pulmonary hypertension, atrial septal defect, and a large omphalocele. She underwent repair of the diaphragmatic hernia shortly after birth, but no attempt was made to repair the large omphalocele because of its massive size and the disproportion between the extra-peritoneal viscera and the peritoneal cavity. A and B, At 4 years of age, she was found to have loss of abdominal domain, a narrow neck to the omphalocele sac, and most of the viscera in the sac. C, She underwent placement of an intraperitoneal tissue expander in the pelvis. As an outpatient, the tissue expander was gradually filled to 900 mL of volume, through a catheter emanating from the expander (arrow). Over time, it was possible to expand the peritoneal cavity to the point that the abdominal muscles and fascia could be approximated. However, a biosynthetic patch was needed to complete the fascial closure. D, She has recovered uneventfully and has a very reasonable appearing abdomen. (A and B reprinted with permission from Foglia R, Kane A, Becker D, et al: Management of giant omphalocele with rapid creation of abdominal domain. *J Pediatr Surg* 41:704-709, 2006. Photos courtesy of Dr. Robert Foglia.)

**Figure 48-14.** This upper gastrointestinal study in an infant born with a large omphalocele shows the stomach to be situated in the middle of the abdomen with a longitudinal rather than a horizontal orientation.

may require gastrostomy feeding. These difficulties seem to resolve by childhood, with height and weight measurements becoming similar to those of their peer group.<sup>90</sup> The respiratory insufficiency associated with giant omphaloceles may be secondary to abnormal thoracic development with a narrow thorax and small lung area leading to pulmonary hypoplasia.<sup>91</sup> Prolonged respiratory difficulties can occur in up to 20% of infants with giant omphaloceles, leading to increased time of mechanical ventilation and the need for supplemental oxygen during the neonatal period.<sup>91</sup> In a study looking at the long-term cardiopulmonary consequences of large abdominal wall defects, lung volumes and oxygen consumption were found to be normal.<sup>92</sup> Exercise tolerance, however, was reduced, possibly owing to a more sedentary lifestyle.

Many of the intra-abdominal organs in infants with omphalocele will be abnormally positioned. The liver sits in a medial position with the hepatic veins in variable locations. The stomach is also usually in the middle of the abdomen with a longitudinal rather than a horizontal orientation (Fig. 48-14). Rotation abnormalities of the bowel will also be present. When reoperation is necessary in patients with a previous omphalocele repair, the atypical organ position should be anticipated.

# UMBILICAL AND OTHER ABDOMINAL WALL HERNIAS

Thomas R. Weber, MD

## UMBILICAL HERNIA

Umbilical hernia is a common disorder in children that pediatric and general surgeons are frequently asked to evaluate and treat. Although the hernia defect is present at birth, unlike other hernias of childhood an umbilical hernia may resolve without the need for an operation. However, these hernias do not always resolve, and complications can develop that require an emergency operation. An understanding of the embryology, anatomy, incidence, natural history, and complications is important to any surgeon managing umbilical hernias in children.

### Embryology

The 5-week embryo has a body stalk and yolk sac that enter the ventral aspect of the developing abdominal wall at the site of the umbilical cord. The omphalomesenteric duct forms from the yolk sac, whereas mesenchyme from the stalk forms the umbilical vessels. These structures enter the abdomen through the umbilical ring. The umbilical cord usually consists of two arteries, one vein, the omphalomesenteric duct and urachal remnants, and connective tissue.

After birth, closure of the umbilical ring is the result of complex interactions of lateral body wall folding in a medial direction, fusion of the rectus abdominis muscles into the linea alba, and umbilical orifice contraction aided by elastic fibers from the obliterated umbilical arteries. Fibrous proliferation of surrounding lateral connective tissue plates and mechanical stress from rectus muscle tension may also aid in closure.

### Anatomy

Although “direct” and “indirect” umbilical hernias have been described, suggesting the existence of congenital and acquired lesions, virtually all pediatric umbilical hernias are congenital and form as a hernia through a persistent umbilical ring. The hernia sac is peritoneum, which is frequently adherent to the dermis of the

umbilical skin. The actual fascial defect can range from several millimeters to 5 cm or more in diameter. The extent of the skin protrusion is not indicative of the size of the fascia defect. Frequently, small defects can result in alarmingly large “proboscis”-like protrusions (Fig. 49-1). Thus, it is important to palpate the actual fascia defect by reducing the hernia manually to assess whether operative or nonoperative treatment is appropriate.

### Incidence

The incidence of umbilical hernia in the general population varies with age, race, gestational age, and coexisting disorders. In the United States, the incidence in African-American children from birth to 1 year old ranges from 25% to 58%, whereas white children in the same age group have an incidence of 2% to 18.5%.<sup>1,2</sup> Premature and low birth weight infants have a higher incidence than full-term infants, reported to be up to 75% in infants weighing 500 to 1500 g at birth.<sup>3</sup> Infants with certain other conditions, such as Beckwith-Wiedemann syndrome, Hurler’s syndrome, various trisomy conditions (trisomy 13, 18, and 21), and congenital hypothyroidism, also have an increased incidence of umbilical hernia, as do children requiring peritoneal dialysis.<sup>4,5</sup>

### Treatment

It has been known for many years that umbilical hernias will close spontaneously, and it seems very safe to simply observe the hernia until age 3 to 4 years to allow closure to occur. Pressure dressings and other devices to keep the hernia reduced do not speed the resolution and may result in skin irritation and breakdown and are therefore not advisable. Prospective studies in both white and African-American populations have shown spontaneous resolution rates of 83% to 95% by 6 years of age.<sup>6-10</sup> Another study has shown 50% of hernias still present at age 4 to 5 years will close by age 11 years.<sup>9</sup> One study suggests that hernias with fascial defects greater than 1.5 cm are unlikely to close by age 6 years,

**Figure 49-1.** This 5-year-old child has a large proboscis-like umbilical hernia.

whereas other series suggest that even large defects will spontaneously resolve without operation.<sup>8,11,12</sup>

The primary danger associated with observation therapy is the possibility of incarceration or strangulation. Studies have shown these complications to be quite rare, with an incidence of less than 0.2%.<sup>8,12,13</sup> Patients with small fascial defects (0.5 to 1.5 cm in diameter) appear more prone to incarceration.<sup>14</sup> Strangulation with or without bowel infarction is even more rare. In general, informing the adult caregivers in the family regarding the signs and symptoms of incarceration, along with periodic follow-up, should ensure a safe observation period while waiting for spontaneous closure.

The operative closure of an umbilical hernia uses standard techniques, is generally straightforward, and can usually be completed as an outpatient procedure. Although a “minimally invasive” technique has been described using injection of a sclerosing agent,<sup>15</sup> most of these abnormalities are repaired using more traditional suture closure of the defect. Methods used commonly in the adult, such as prosthetic placement, are almost never needed in the child.

The most common method of repair is shown in Figures 49-2 and 49-3. A small transverse infraumbilical incision is made, usually placed in the redundant skin, which is inverted at the conclusion of the procedure, thereby burying the closed incision. The hernia sac is identified and dissected free from the dermis, underlying the umbilical cicatrix. Our technique includes excision of the sac to the fascial edges, although other authors have described a more limited excision or simple inversion of the sac through the fascial opening. Interrupted sutures of nonabsorbable or long-lasting absorbable sutures are placed and tied, closing the fascial defect in a transverse fashion. We leave the needle attached to the center fascia suture, which is then used to tack the underside of the umbilical cicatrix to the fascia. The skin incision is closed with an absorbable subcuticular suture, and a dressing is applied. Pressure dressings are generally unnecessary.<sup>16</sup>

Excision of the redundant skin is usually not performed because it tends to return to normal appearance after the

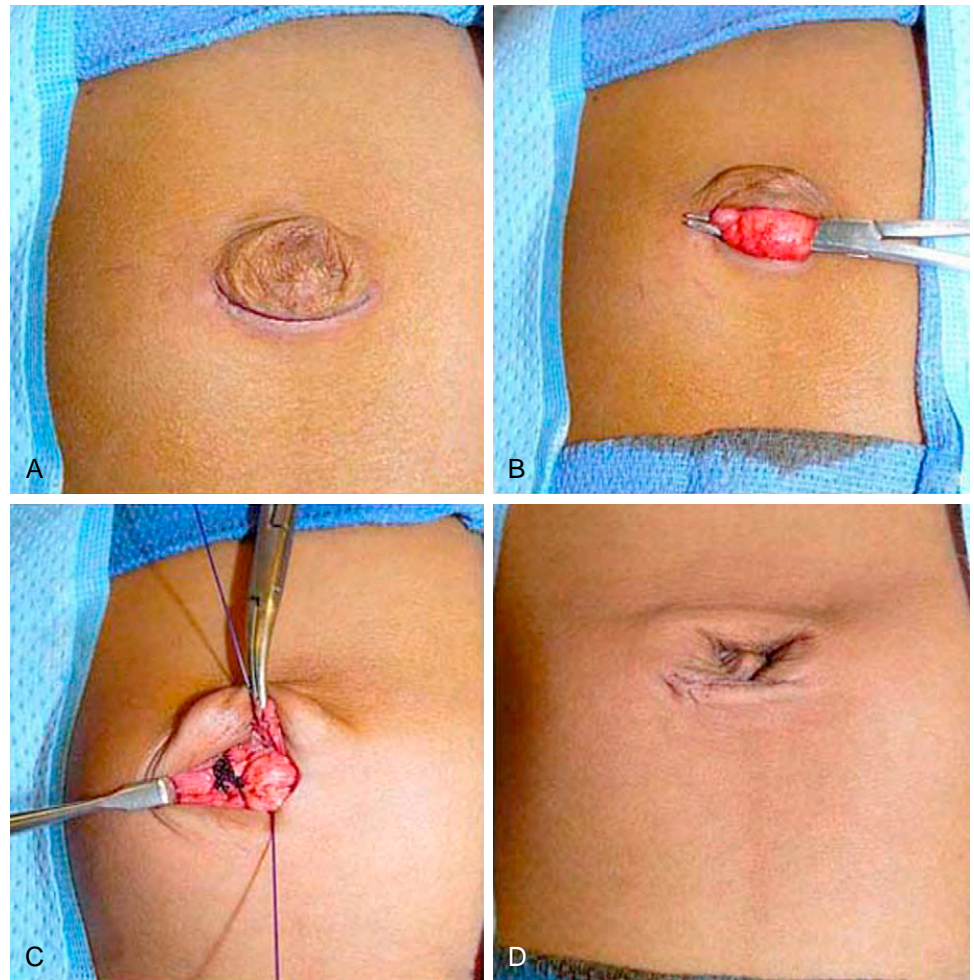

**Figure 49-2.** Diagram of technique for operative repair for umbilical hernia. **A**, An infraumbilical skin crease incision is made. **B**, The hernia sac is opened, leaving a portion of the sac attached to the umbilical skin for ease of subsequent umbilicoplasty. **C**, The umbilical sac has been completely divided and excised to strong fascia. **D**, The fascial defect is closed in a transverse fashion with interrupted, simple nonabsorbable sutures. **E**, The remaining umbilical sac, which is attached to the umbilical skin, is secured to the fascia with interrupted, absorbable sutures. **F**, The skin incision is closed with a subcuticular suture.

hernia is repaired. This can take up to 12 months to occur, and the family should be reassured appropriately. If the umbilicus fails to return to an acceptable appearance after 1 to 2 years, there are a number of techniques described to restore it to a more normal configuration.<sup>17-19</sup>

The complications of umbilical hernia repair are few and include seroma or hematoma formation, which are usually self-limited and resolve spontaneously. Wound infections can generally be treated with local care and antibiotics, whereas a recurrent hernia, occurring in less than 1%, is treated with reoperation.<sup>14</sup>

## EPIGASTRIC HERNIA

Hernias of the abdominal wall through the midline linea alba, also termed *epigastric hernias*, are common in the pediatric age group. These hernias present as

**Figure 49-3.** The steps depicted in the operative diagram in Figure 49-2 are shown. **A**, An infraumbilical incision is made. **B**, The umbilical hernia sac has been encircled with a hemostat. **C**, The umbilical hernia sac is excised, and transverse closure of the fascial defect is accomplished with interrupted long-lasting absorbable sutures. **D**, The umbilicus has been tacked to the fascial closure, and the skin is approximated with a subcuticular closure.

small masses, usually with incarcerated properitoneal fat, between the umbilicus and xiphoid process. An epigastric hernia should not be confused with diastasis recti, which is a generalized weakness in the linea alba from umbilicus to xiphoid and virtually always resolves by age 10 years. Incarcerated epigastric hernias can be painful. These hernias can also be multiple and associated with an umbilical hernia. Epigastric hernias do not resolve and should be repaired.

A small midline incision over the hernia is generally used, with suture repair of the defect after the contents (properitoneal fat) are reduced or excised. The site of the hernia should always be marked before anesthesia because the defect may be difficult to find with muscle relaxation. Recurrence is extremely rare.

### SPIGELIAN HERNIA

Spigelian hernias are quite rare in children and can be difficult to detect and diagnose. The actual defect occurs at the intersection of the linea semicircularis, linea semilunaris, and the lateral border of the rectus abdominis muscle. It usually involves absence or attenuation

of the transversus abdominis and internal oblique muscles. These hernias are more frequently found in girls and more commonly occur on the right side below the umbilicus.<sup>20</sup> They are also occasionally associated with skeletal abnormalities.<sup>21</sup> Pain in the area with a feeling of “fullness” or an actual mass are the most common symptoms. Ultrasonography may aid in the diagnosis. In extreme cases, computed tomography may be needed.

Repair consists of a transverse incision over the defect with excision of the sac and closure of the defect. Frequently, the sac is found below the external oblique muscle and may require prosthetic placement for secure repair if the defect is large. A tension-free closure is important to prevent recurrence in this area that has a high level of muscle tension.

### LUMBAR HERNIA

Lumbar hernias are usually visible shortly after birth as a “bulge” in the area bordered by the 12th rib, sacrospinalis muscle, and internal oblique muscle. Occasionally, they extend inferiorly to the iliac crest. These hernias tend to develop at the site of penetration of the intercostal nerves and vessels or of the ilioinguinal, iliohypogastric, and lumbar nerves. The “bulge”

is usually properitoneal fat. Therefore, the physical findings include a soft mass that is easily reducible. Although frequently asymptomatic, repair is advisable because the defect never resolves spontaneously and incarceration is possible.

Repair sometimes requires prosthetic reinforcement of the fascia or muscle closure because the tissue available for repair is usually thin and weak. We favor

using absorbable mesh in the growing child that will not cause later scoliosis, which has been associated with the need for permanent prostheses. Recurrence is not uncommon because of the weak tissues involved. Repeat operations may be needed. Bilateral hernias can be repaired with either staged or simultaneous closures, depending on the surgeon's and family's preferences.

# LAPAROSCOPY

George W. Holcomb III, MD, MBA

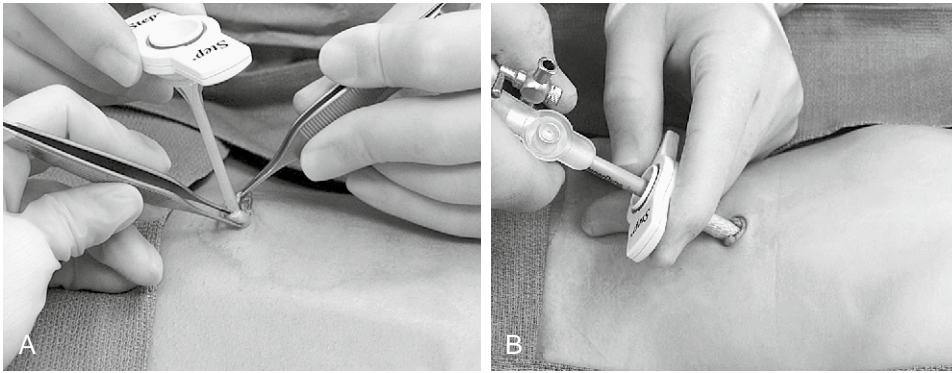

As opposed to 15 years ago, the benefits of the laparoscopic approach for infants and children are readily recognized today, and most training programs have, at the very least, one person who is adept with this technology. Also, laparoscopy is utilized commonly and almost exclusively for a number of common surgical conditions, such as appendectomy, cholecystectomy, fundoplication, pyloric stenosis, and splenectomy. Moreover, there are a number of reports describing this approach for relatively less common problems, such as excision of a choledochal cyst, cystogastrostomy for a pancreatic pseudocyst, colectomy for ulcerative colitis or polyposis syndromes, and gastric mobilization for a gastric pull-up operation. It has almost become the standard of care as part of the management for Hirschsprung's disease. Finally, many surgeons are utilizing this approach for high imperforate anus repair.

## CONCERNS IN CHILDREN

Almost every abdominal operation performed by pediatric surgeons today has been accomplished using the laparoscopic approach. Regardless of the operation to be performed, a number of concerns are important for children. One major concern is the pliability and laxity of the abdominal wall, especially in young children. Because of this pliability, it is quite easy to introduce a cannula with a sharp trocar through the abdominal wall and into an underlying visceral or vascular structure, turning a routine operation into an emergency procedure. Therefore, it is imperative that the surgeon recognize this issue of the pliability of the abdominal wall and take great care not to injure the underlying structures when introducing a sharp trocar. One technique to avoid this problem is to direct the sharp stylet more in a transverse direction above the viscera once it has penetrated the peritoneum rather than continuing in an oblique or downward direction toward the viscera and major vessels. Injuries can occur with these sharp stylets whether or not a safety shield is attached to the trocar. Another technique used by many pediatric surgeons for safety reasons is the Step

system (Covidien, Norwalk, CT). With this technique, after a small skin incision, a Veress needle with an expandable sheath is introduced through the abdominal wall into the peritoneal cavity. The Veress needle is then removed, and a cannula with a blunt-tipped trocar is introduced through the expandable sheath. It is unlikely that the blunt trocar will injure the underlying vasculature, and the expandable sheath stabilizes the cannula in the abdominal wall. This same Veress needle technique is used by some pediatric surgeons for the initial cannula entry, usually through the umbilicus. With this approach, an incision (3 mm, 5 mm, 10 mm, or 12 mm) is made in the umbilical skin and the Veress needle and sheath are introduced through the umbilical fascia and into the peritoneal cavity. Great care must be taken when introducing the Veress needle and cannula with this approach. Often it is helpful to grasp the abdominal wall manually and elevate it away from the underlying structures when introducing this Veress needle. A blind man's cane technique is then used by moving the Veress needle side to side, such as a blind man testing the surface in front of him before taking the next step. Once the surgeon is satisfied that the Veress needle is inside the abdominal cavity, insufflation is initiated, followed by removal of the Veress needle and introduction of a cannula with a blunt trocar through the expandable sheath. Other surgeons prefer a more direct cutdown approach by incising the umbilical skin and fascia, followed by introducing the cannula through the umbilical fascia into the peritoneal cavity. One modification of this approach is to insert only the expandable sheath (without the needle) through the umbilical fascial and peritoneal incision, followed by insertion of the cannula with the blunt-tipped trocar through the expandable sheath (Fig. 50-1). In experienced hands, all of these techniques for initial entry into the peritoneal cavity are safe, and few recent reports exist describing injuries to underlying viscera with careful introduction of cannulas in infants and children.

Once the initial cannula has been inserted and a pneumoperitoneum established, accessory instruments are introduced. Some surgeons prefer the use

**Figure 50-1.** When introducing the initial umbilical cannula for laparoscopy, one approach is a direct umbilical cutdown technique, with insertion of the expandable Step sheath (A) followed by introduction of the cannula with a blunt trocar through the sheath (B). In this way, injuries from the use of the Veress needle technique are avoided.

of additional cannulas through which the instruments are inserted and removed from the peritoneal cavity. These accessory cannulas are either reusable, “reposable” (part reusable, part disposable), or completely disposable. The main disadvantage of the completely disposable cannula is the cost for one-time use. These ports vary in size from 2 to 15 mm, depending on the operation. For many procedures in children, 3-mm instruments are preferred, whereas for laparoscopic appendectomy in which the 12-mm stapler is used, a 12-mm port is necessary. Similarly, for laparoscopic splenectomy in which a 15-mm endoscopic retrieval bag is used, a 15-mm port is required. Whereas some surgeons prefer the use of cannulas for introduction of these accessory instruments, another technique is to introduce the instruments directly through the abdominal wall without the use of cannulas (Fig. 50-2).<sup>1</sup> With this technique, a stab incision is made with a No. 11 blade (Becton Dickinson, Franklin Lakes, NJ) through the skin and abdominal wall under telescopic visualization. The blade is removed, and the 3- or 5-mm instrument is inserted through the path created by the blade (Fig. 50-3). This technique is especially applicable for infants and young children when 3- and 5-mm instruments are used. It also is applicable for older children and adolescents with relatively thin abdominal walls for procedures in which instruments are not moved in and out of the abdominal wall during the operation. If instruments are exchanged frequently throughout the procedure, it is best to use a cannula

at this site. Although a cosmetic advantage exists with this technique, the biggest advantage to the stab technique is the cost savings realized by not using either a reusable or disposable cannula system. In one study of 511 patients undergoing laparoscopic procedures using this stab incision technique, a total of \$187,180 was saved in patient charges over a 3½-year period (Table 50-1).<sup>1</sup>

## DIAGNOSTIC LAParoscopy

Laparoscopy for diagnostic purposes in pediatric patients was reported in the early 1970s for several conditions, including evaluation of a contralateral patent processus vaginalis (CPPV).<sup>2,3</sup> Diagnostic laparoscopy also may be useful in boys with a nonpalpable testis. Moreover, it may be helpful in patients with cancer requiring a second-look procedure to determine the possibility of residual disease after chemotherapy (Fig. 50-4). In the cancer patient, laparoscopy is often used for determination of resectability as well as an adjunct for guided biopsy. Finally, diagnostic laparoscopy can be very useful in selected patients with penetrating trauma whose condition is stable and in whom a question exists of peritoneal penetration (Fig. 50-5). If no injury is found, the patient may be discharged within 24 hours, as opposed to the several days needed for recovery after laparotomy.

**Figure 50-2.** Technique for creating a transabdominal stab incision is shown. A, The No. 11 blade is seen to pass through the abdominal wall and into the peritoneal cavity. B, The No. 11 blade has been removed, and the instrument is directly introduced through the path created by the blade.

**Figure 50-3.** Depiction of the use of stab incisions with introduction of the instruments through the abdominal wall, without the use of accessory cannulas. In each photograph, an umbilical cannula appears through which the telescope is introduced and insufflation is achieved. **A,** A teenager is undergoing a laparoscopic cholecystectomy. Two 5-mm and two 3-mm instruments are placed directly through the abdominal wall. **B,** The patient is undergoing a laparoscopic appendectomy with a 5-mm instrument placed directly through the abdominal wall in the left suprapubic region. **C,** The patient is undergoing a laparoscopic splenectomy. A 12-mm cannula is placed in the umbilicus, and a 5-mm cannula is introduced in the midline epigastrium. Two 3-mm instruments are placed through stab incisions cephalad to the 5-mm cannula. **D,** An adolescent is undergoing a laparoscopic fundoplication. A second cannula has been placed in the patient's left upper abdomen through which the ultrasonic scalpel and needle holder are introduced.

**Table 50-1** A Listing of Savings in Charges to the Patient and Cost to the Hospital Realized by Using the Stab Incision Technique with One or Two Step Cannulas

Procedure	Step Savings (\$)		Ethicon Savings (\$)	
	Patient	Institution	Patient	Institution
Nissen (209)	117,040	51,832	76,912	34,276
Nissen (14)	5,880	2,604	3,864	1,722
Appendectomy (102)	14,208	6,324	9,384	4,182
Pyloromyotomy (77)	21,560	9,548	14,168	6,314
Cholecystectomy (31)	8,680	3,844	5,704	2,542
Splenectomy (22)	5,880	2,604	3,864	1,722
Pull-through (20)	2,800	1,240	1,840	820
Ligation of testicular vessels (UDT) (15)	4,300	1,860	2,760	1,230
Esophagomyotomy (7)	2,940	1,302	1,932	861
Adrenalectomy (6)	1,680	744	1,104	492
Varicocele (5)	1,400	620	920	410
Ovarian (2)	560	248	368	164
Meckel's diverticulum (2)	280	124	184	82
<b>TOTAL: 511 operations</b>	<b>\$187,180</b>	<b>\$82,894</b>	<b>\$123,004</b>	<b>\$54,817</b>

**Note:** If Ethicon cannulas were used, the savings that would have occurred are seen as well (right column). UDT, undescended testis.

**Figure 50-4.** Second-look laparoscopy can be useful after adjuvant therapy in certain circumstances. In this teenage patient who previously had undergone laparotomy and resection of a large germ cell tumor, second-look laparoscopy was performed to determine whether evidence of residual disease existed. **A**, Residual disease is seen along the right pelvic side wall (*arrow*). **B**, This mass is being resected from the pelvic side wall. Note the normal right ovary (*arrow*). **C**, Further dissection of the mass is achieved. **D**, The mass has been completely excised, with hemostasis controlled by cautery.

### Diagnostic Laparoscopy for Contralateral Patent Processus Vaginalis

In the early 1990s, two reports were published describing diagnostic laparoscopy through the umbilicus in children with a unilateral inguinal hernia to determine evidence of a CPPV.<sup>4,5</sup> Several years later, with the advent of 3-mm angled telescopes, it became apparent that this same information could be obtained through the ipsilateral hernia sac.<sup>6</sup> A number of reports have confirmed the efficacy of this technique to determine the presence of a CPPV, which may indicate the need for repair under the same anesthetic.<sup>7-10</sup>

The largest report describing laparoscopy for evaluating a CPPV described 1676 consecutive children presenting with a unilateral inguinal hernia who underwent diagnostic laparoscopy for evaluation for CPPV.<sup>11</sup> In 73 patients (4.49%), the sac was deemed too thin to perform laparoscopy. Therefore, 1603 patients underwent diagnostic laparoscopy. Within this group, 643 (40.1%) patients were found to have a patent processus vaginalis.

Of those patients in whom a CPPV was not seen at laparoscopy, only 5 (0.70%) patients have returned with a symptomatic hernia. Of 446 patients thought to have a CPPV by examination under anesthesia, only 192 (43%) were found to have a CPPV at laparoscopy. On the other hand, 1157 patients were felt not to have CPPV by palpating a thickened cord on examination under anesthesia, but 451 (39%) actually did have a CPPV.

Although the accuracy of this technique approaches 99%, it is not possible to determine which patient with a CPPV will develop a symptomatic hernia. At the same time, it does subselect those patients who should undergo contralateral exploration based on a positive finding rather than subjecting all children with a unilateral inguinal hernia to contralateral exploration, as has been advocated in the past. A few surgeons have taken this approach one step further and are performing various types of laparoscopic hernia repairs in children. Laparoscopic hernia repair remains controversial because the recurrence rate has been cited to be 2% to 4% in several studies.<sup>12-14</sup>

**Figure 50-5.** Laparoscopy can be useful in selected cases of penetrating trauma in which the patient appears to be uninjured, yet there is concern that the sharp object, or perhaps a bullet, has penetrated the abdominal cavity. **A**, An entrance wound from a bullet that entered the peritoneal cavity (*arrow*) is seen. **B**, The bullet is seen to lie on top of the left lobe of the liver just beneath the entry site. This patient did not have other injuries and was discharged the next day. A laparotomy was avoided in this patient.

**Figure 50-6.** At laparoscopy for evaluation of a contralateral patent processus vaginalis, several findings are possible. In each of these photographs, the *dotted white arrow* depicts the testicular vessels and the *solid white arrow* depicts the vas deferens. An additional *black arrow* shows the inferior epigastric vessels. **A**, No evidence is seen for a left patent processus vaginalis. **B**, A large internal opening to a left patent processus vaginalis is found. **C**, A veil of peritoneum (*dotted black arrow*) covers the left testicular vessels and there appears to be a small opening to a patent processus vaginalis. In this setting, however, it is unclear how distal the small patent processus vaginalis extends. **D**, Air bubbles are seen emanating from the internal opening of right patent processus vaginalis when manual pressure is applied over the right inguinal canal.

The technique for evaluating the contralateral inguinal region involves creation of a pneumoperitoneum through the hernia sac, followed by diagnostic laparoscopy with an angled (usually 45- to 70-degree) telescope. Some surgeons insufflate the peritoneum by introducing a cannula into the abdomen through the hernia sac, whereas others use a catheter. Either technique appears to work well.

At laparoscopy, it is usually evident whether a CPPV is present (Fig. 50-6). However, on occasion, a veil of peritoneum may obscure the visualization of the contralateral inguinal ring. At times, the length of the CPPV may not be clear. A technique has been described in which a silver probe is percutaneously introduced on the contralateral side to retract the peritoneal veil to evaluate the length of the CPPV (Fig. 50-7).<sup>15</sup>

## PROCEDURAL LAPAROSCOPY

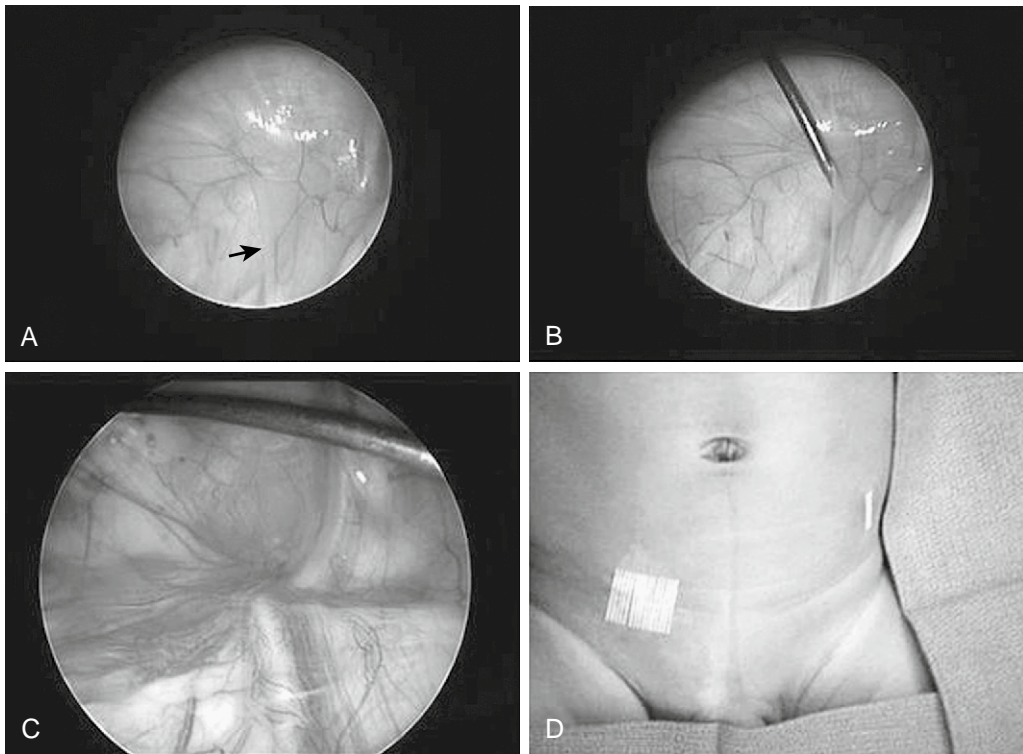

### Stomach and Solid Organs

#### Fundoplication

The laparoscopic operation for fundoplication has become the preferred approach for surgical management of gastroesophageal reflux for most pediatric surgeons. Any

type of fundoplication, including a Nissen, Thal, Toupet, Boix-Ochoa, or other, can be performed by using the laparoscopic approach. It is my experience that the laparoscopic Nissen fundoplication is the easiest operation to perform laparoscopically and yields the best results, but this belief is not shared by all pediatric surgeons. Complications have been minimal, and results are very satisfactory. Transmigration (herniation) of the fundoplication wrap through the esophageal hiatus has been found to develop in 3% to 5% of patients undergoing laparoscopic fundoplication. It is possible that the lack of scarring near the esophageal hiatus after a laparoscopic fundoplication allows retraction of the esophagus and the fundoplication wrap through the esophageal hiatus. Because of this concern, I have taken additional steps in the technique I use to prevent this problem.

A 4- or 5-mm transumbilical cannula is placed in most patients. In adolescents, especially tall patients with a narrow costal margin, it may be more appropriate to place this initial cannula in the midepigastriac region. After pneumoperitoneum, four additional instruments are introduced by using either cannulas or the stab incision technique. The short gastric vessels are divided beginning at a point midway along the greater curvature of the stomach and progressing to the esophageal hiatus (Fig. 50-8). The gastroesophageal junction is initially approached from the patient's

**Figure 50-7.** On occasion, it is not possible to determine accurately whether a significant contralateral patent processus vaginalis (CPPV) exists. **A**, A veil of peritoneum (*arrow*) covers the left internal ring structures, and even with a 70-degree telescope, it is not possible to determine whether a CPPV is present. **B**, A silver probe has been placed through a stab incision in the left lower abdomen. The tip of the silver probe is manipulated to retract the peritoneal veil, which, in **C**, shows a blind end to the internal ring. Thus, no evidence exists of a PPV on the left side. **D**, The Steri-strips are seen placed over the right inguinal crease incision. A single Steri-strip is used to approximate the skin where the silver probe was introduced through the left lower abdominal wall.

**Figure 50-8.** The initial steps for laparoscopic fundoplication are shown. **A**, The short gastric vessels are being ligated and divided by using the Maryland dissecting instrument, which is attached to cautery. **B**, The esophagus has been retracted anteriorly and to the patient's right, exposing the retroesophageal space. Note the right and left diaphragmatic crura (*arrows*). **C**, The patient's right diaphragmatic crus is being separated from the esophagus by using blunt dissection. **D**, A 2-0 silk suture attached to an RB-1 needle (*arrow*) is being placed through the patient's left diaphragmatic crus for approximation of the crura.

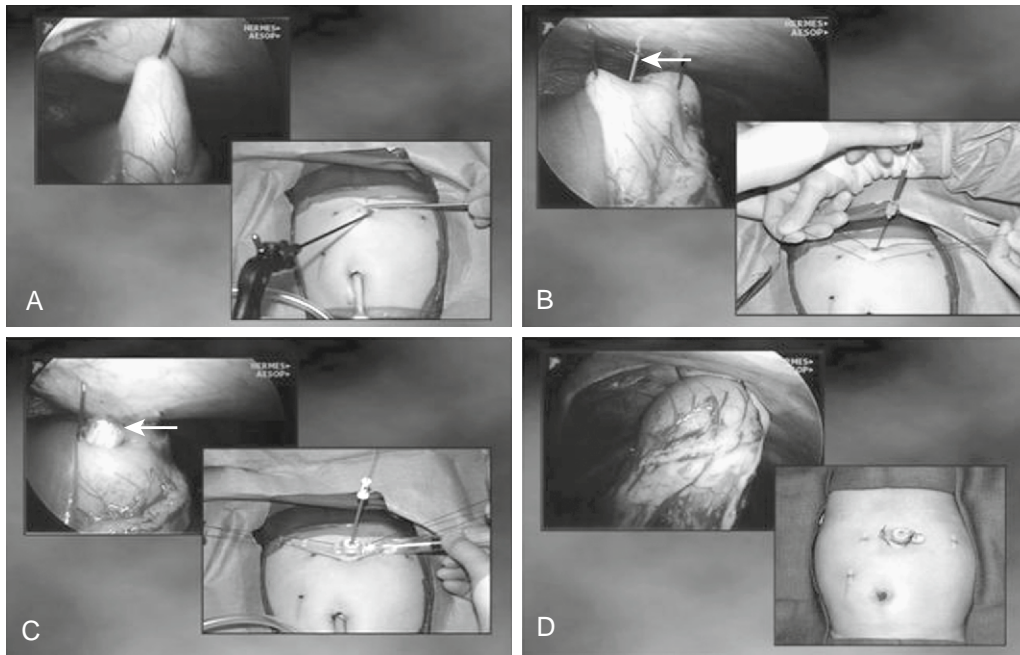

**Figure 50-9.** A, The diaphragmatic crura have been approximated posteriorly with a 2-0 silk suture. Note the small space anteriorly (arrow) that remains after posterior approximation of the crura. B, This space has been obliterated with an anteriorly placed 2-0 silk suture so that the diaphragmatic crura have been approximated both posteriorly and anteriorly (arrows). C, An esophagus-to-crura suture is seen at the 9-o'clock position. In addition, similar sutures are placed at the 3-o'clock position. D, The completed fundoplication.

left side, and the retroesophageal space is identified and opened. The esophagus is then freed from the diaphragmatic crura in all directions by using blunt and sharp dissection to create an adequate portion of intra-abdominal esophagus. After mobilizing the intra-abdominal esophagus, the diaphragmatic crura are usually approximated, at least with one suture, which is placed posterior to the esophagus (see Fig. 50-8). If the hiatus is greatly enlarged, a second suture may be needed anteriorly (Fig. 50-9). After crural repair, the esophagus is sutured to the narrowed hiatus at three or four sites several centimeters above the gastroesophageal junction (see Fig. 50-9). This suture fixation helps to prevent transmigration of the fundoplication wrap through the hiatus. After adding this modification to my technique, the incidence of transmigration of the wrap has markedly diminished. An appropriate-size transesophageal bougie is then introduced into the stomach. The fundus is wrapped around the intra-abdominal esophagus and sutured back to itself in a standard Nissen fundoplication fashion. In a recent study, a fundoplication length of approximately 2 cm was found to be effective in relieving symptoms.<sup>16</sup> Usually, three 2-0 silk sutures are used to create the fundoplication wrap. At this point, with hemostasis ensured, the operation is terminated and the cannulas/instruments are removed. Gastroesophageal reflux is discussed in detail in Chapter 29.

### Gastrostomy

Laparoscopic gastrostomy may be performed either in conjunction with a laparoscopic fundoplication or as a separate procedure. When performed in conjunction

with fundoplication, the site of placement of the gastrostomy button is the site of the main working port for the fundoplication in the left upper abdomen. This incision in the patient's left upper abdomen should be marked before creating the pneumoperitoneum. Otherwise, creation of the pneumoperitoneum will confuse the surgeon as to the appropriate location for the gastrostomy. For laparoscopic gastrostomy alone, the site can be marked as well. If laparoscopic gastrostomy is performed alone, a 4- or 5-mm cannula and telescope are introduced through the umbilicus. If it is performed after fundoplication, the telescope remains in place. A grasping forceps is introduced through the gastrostomy site incision in the left upper abdomen. It is often helpful to ask the anesthesiologist to insufflate the stomach. This maneuver reduces the likelihood that the posterior wall of the stomach will be caught by the fixation sutures, which are introduced next. After grasping a site for the gastrostomy on the anterior gastric wall near the greater curvature, the stomach is pulled anteriorly to approximate its serosa with the abdominal wall (Fig. 50-10). One 2-0 monofilament suture is placed on either side of the gastrostomy site. These sutures are placed in an extracorporeal manner through the skin and abdominal wall cephalad to the gastrostomy site, then through the anterior stomach wall, and then out through the abdominal wall and skin caudad to the gastrostomy. With the use of the Cook Vascular Dilator Set (Cook, Inc., Bloomington, IN), a needle is placed through the gastrostomy incision and into the stomach. A guide wire is inserted and, by using the Seldinger technique, the skin and gastrostomy are sequentially dilated using 8-, 12-, 16-, and 20-Fr dilators, which are introduced over the

**Figure 50-10.** The technique for laparoscopic gastrostomy used by the author is shown. **A**, After fundoplication in this patient, a 3-mm instrument has been introduced through the left upper stab incision and the stomach has been grasped. Extracorporeal sutures are then placed on each side of this planned gastrostomy site. These sutures are introduced through the abdominal wall cephalad to the stomach, through the stomach, and exteriorized through the abdominal wall caudad to the gastrostomy site. **B**, With a suture on each side of the planned gastrostomy, a needle is introduced into the stomach (*arrow*) through the gastrostomy site, followed by advancement of a guide wire through the needle into the stomach. **C**, The tract is then serially dilated and a 14-Fr, 0.8-cm button (*arrow*) is introduced over the guide wire into the stomach. **D**, The balloon is inflated, and the extracorporeal sutures are tied over the button.

guide wire. The 8-Fr dilator is inserted through the gastrostomy button and used to introduce the button into the stomach. The balloon is inflated under telescopic visualization. The dilator is removed, and the sutures are tied over the button. It is important to ensure that the guide wire and the button are definitely inside the stomach. It is helpful to use an angled telescope to inspect the entire circumference of the gastrostomy to confirm that the button is not outside the stomach. The patient may be fed by using the gastrostomy several hours after its placement, if desired. The 2-0 monofilament sutures are removed 4 or 5 days later.

### Esophagomyotomy

In preparation for a laparoscopic esophagomyotomy for achalasia, it is important to give the patient a liquid diet for several days. Usually the lower esophagus will empty itself of solid food during this time. After induction of anesthesia, it is important to suction the esophagus thoroughly to evacuate any retained food particles and to insert an esophageal bougie. In the event of entry into the esophageal lumen during the operation, gross spillage will not occur into the peritoneal cavity.

Placement of incisions for laparoscopic esophagomyotomy is almost identical to that for a laparoscopic fundoplication. In addition, because an anterior partial fundoplication, rather than a full fundoplication, is usually performed, only the most cephalad two or

three short gastric vessels are ligated and divided. After ligation and division of these short gastric vessels, the wall of the anterior lower esophagus is grasped on each side. Through the primary working port in the left upper abdomen, either the ultrasonic scalpel or hook cautery is used to divide the distal esophageal muscle down to the submucosa (Fig. 50-11). Once the submucosa is visualized, the ultrasonic scalpel is used, with the “hot” blade turned anterior, to create the esophagomyotomy for a distance of 4 to 6 cm cephalad. The esophagomyotomy usually extends through the esophageal hiatus for 1 or 2 cm. By using the same technique, the myotomy is extended onto the stomach for 1 or 2 cm to ensure that the circular fibers of the lower esophageal sphincter are completely divided. If any question remains, esophagoscopy can be performed to verify this complete myotomy. Should entry into the lumen occur, it is often easy to see the bougie through the mucosal perforation. A perforation can usually be closed laparoscopically.

After the anterior esophagomyotomy, a partial fundoplication is usually performed. This can be either a partial posterior (Toupet) fundoplication or an anterior (Dor) fundoplication. The advantage of the Dor procedure is that it covers the just-completed esophagomyotomy. For this reason, I prefer this anterior fundoplication. With interrupted 2-0 silk, the cephalad portion of the greater curvature of the fundus is sutured initially to the left edge of the completed myotomy and the left diaphragmatic crus and then to the right edge of the completed myotomy and the

**Figure 50-11.** In a laparoscopic esophagomyotomy and anterior fundoplication, the placement of the ports and instruments is similar to that for a laparoscopic fundoplication. **A**, The muscle of the esophagus has been grasped on the lateral aspects of the esophagus, and a Maryland dissecting instrument is being used to develop a plane between the muscle down through the submucosa. **B**, This plane has been developed, and the ultrasonic scalpel is being used to ligate and divide the muscle. **C**, The longitudinal fibers of the esophageal muscle have been divided. Note the circular fibers (*white arrow*) of the lower esophageal sphincter in the lower aspect of the photograph. In addition, the anterior vagus nerve (*black arrow*) is seen to course vertically along the esophagus. **D**, An anterior (Dor) fundoplication has been performed to help prevent the development of gastroesophageal reflux in the postoperative period.

right crus. Approximately three sutures are taken on each edge of the myotomy along with the diaphragmatic crus. These sutures also help to separate each side of the myotomy to help prevent recurrence of symptoms.

Before initiating a clear liquid diet the next day, a water-soluble contrast study is performed to ensure that the esophageal mucosa is intact. Most patients are ready for discharge either the morning after the operation or on the second postoperative morning. Results with this operation in children have been favorable to date.<sup>17-20</sup> Achalasia is also covered in Chapter 26.

### Pyloromyotomy

Laparoscopic pyloromyotomy is rapidly becoming the preferred approach for pyloromyotomy in infants. A prospective randomized trial comparing the laparoscopic and open approaches was recently completed in 200 infants.<sup>21</sup> The primary outcome variable was the operative time, which differed by 6 seconds. There was statistically significantly less pain medicine utilized in the laparoscopic group, and the length of postoperative hospitalization trended toward significance in the laparoscopic group as well. The authors believed there was a definite cosmetic advantage to the laparoscopic procedure.

A 4- or 5-mm cannula is positioned in the umbilicus, followed by insufflation and insertion of an angled telescope. With stab incisions in both the right and left

upper abdominal quadrants, the duodenum is grasped with DeBakey endoscopic forceps placed through the patient's right upper abdominal stab incision. It is very important to grasp the duodenum securely because a few instances of injury to the duodenum with this technique have been reported.<sup>22</sup> Through the stab incision in the patient's left upper abdomen, an arthroscopy knife is introduced and the knife is extended to the second notch, which represents a 2-mm depth of penetration of the blade (Fig. 50-12). Because the ultrasonographic criterion for pyloromyotomy is 4 mm in depth, using a knife with a 2-mm blade should not allow entry into the mucosa. It is important to incise the serosa and muscle adequately on the initial pass to allow introduction of the pyloric spreader. The knife is then returned to its sheath and extracted, and a pyloric spreader is introduced through the same left upper abdominal stab incision. The pylorus is gently and carefully spread to disrupt the muscular fibers. The submucosa is visualized during this part of the operation to ensure that no evidence of mucosal injury is present. It is important that an adequate myotomy is performed. In one study, no evidence of incomplete pyloromyotomy was found in 171 patients in whom a mean pyloromyotomy incision length of 2.0 cm was achieved.<sup>23</sup> Conversely, in a few instances, an incomplete pyloromyotomy has been described, and it is postulated that inadequate extension onto the stomach was the reason.<sup>22</sup> After what appears to be a completed pyloromyotomy, it is often prudent to insufflate

**Figure 50-12.** In an infant undergoing laparoscopic pyloromyotomy, a 5-mm cannula is inserted through an incision in the umbilical fascia. **A**, The sites of the stab incisions in the left and right upper quadrants are shown (arrows). **B**, With an arthroscopy knife, an incision will be made in the seromuscular portion of the hypertrophied pylorus. **C**, The knife is removed, a pyloric spreader is introduced through this same incision, and the hypertrophied muscle bluntly divided. **D**, The pyloromyotomy incision is usually approximately 2 cm long.

the stomach via a red rubber catheter to ensure that no evidence of unrecognized perforation exists. Placing omentum over the pyloromyotomy, as is commonly done in the open operation, may be advantageous. The instruments are then removed, and the umbilical fascia and skin are closed.

## Splenectomy

The first report of a laparoscopic splenectomy in children was published in 1993.<sup>24</sup> A number of authors have described various techniques for elective removal of a spleen for hematologic diseases.<sup>25-29</sup> The largest report describes the outcomes in patients undergoing laparoscopy for splenic conditions.<sup>30</sup> These diseases are primarily idiopathic thrombocytopenic purpura, hereditary spherocytosis, and, occasionally, splenic sequestration from sickle cell disease. The patient is usually positioned with a roll under his or her left side so that he or she is in a 30- to 45-degree right decubitus position. Placement of the ports for this operation vary from surgeon to surgeon. A common denominator is the need for a 15-mm site through which the Endo-catch II bag (Ethicon Endosurgery, Cincinnati, OH) can be inserted. In addition, a site for introduction of an angled telescope and two other accessory sites are necessary. One approach is to position the 15-mm cannula through a 15-mm incision in the umbilical skin and fascia and orient the accessory ports in the midline.

The advantage of this positioning is that the largest incision is nicely hidden in the umbilicus, yet if conversion is required, the midline incisions can be incorporated in an upper midline incision (see Fig. 50-3). Stab incisions may be used for these accessory sites so that the only cannulas required are the 15-mm one in the umbilicus and a 5-mm port for introduction of the angled telescope. With the orientation described, the main working port is in the umbilicus, through which the ultrasonic scalpel is introduced. After insertion of all instruments, a thorough search is made for accessory spleens. The most common sites for these are in the splenic hilum or in the lienocolic region (Fig. 50-13). It is important to remove accessory spleens either separately or with the specimen. The lienocolic ligament is then incised with the electrocautery, taking great care to identify the transverse colon and splenic flexure. Once the left colon has been mobilized from the spleen, it can be gently pushed caudad, out of the way of future dissection. The dissection then proceeds along the greater curvature of the stomach, carefully ligating and dividing the short gastric vessels with the ultrasonic scalpel. During this part of the operation, it is often helpful to rotate the table to the patient's right, allowing the stomach to gravitate away from the spleen. Sometimes it is not possible to divide the most cephalad short gastric vessels completely until later in the operation. After exposing the splenic hilum, one approach is to dissect the main splenic artery and

**Figure 50-13.** The technique for laparoscopic splenectomy is depicted. **A**, An accessory spleen is seen in a patient with idiopathic thrombocytopenic purpura (*black arrow*). In addition, one of the 3-mm instruments (*white arrow*) is being used to elevate the lower pole of the spleen for access to the lienocolic ligament. After ligation and division of the short gastric vessels, one technique is to isolate the artery and doubly clip it before dissection in the splenic hilum. **B**, Note the two clips (*black arrow*) on the splenic artery along the cephalad portion of the pancreas. **C**, Attachments of the spleen to the diaphragm and other structures have been divided, and an endoscopic vascular stapler is placed across the splenic hilum. The pancreas, noted below the stapler, has not been incorporated into the jaws of the stapler. **D**, The spleen has been removed. Note the intact staple line (*black arrow*) across the hilum of the spleen.

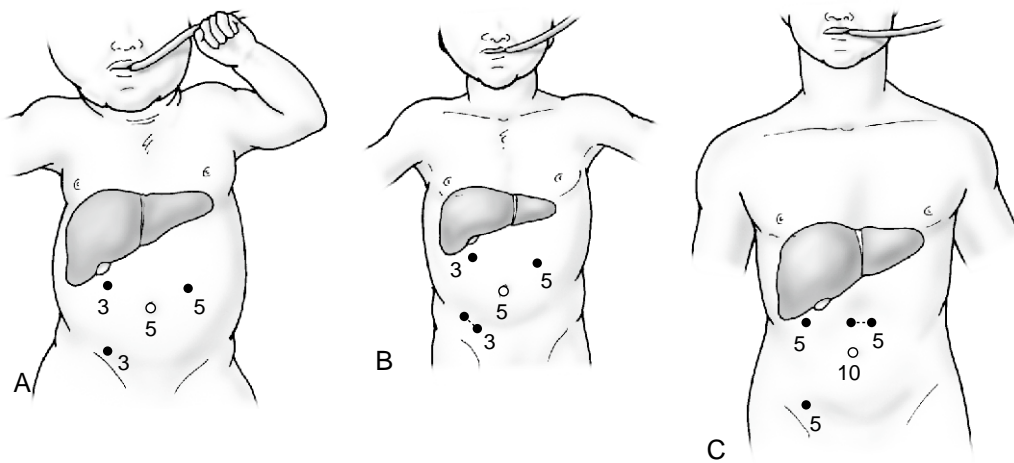

ligate it with an endoscopic clip before any further dissection. It is important to place this clip well away from the splenic hilum so that it does not later interfere with staple occlusion and division of the splenic veins. Occlusion of the arterial supply reduces the risk of dangerous hemorrhage and allows the splenic blood to “autotransfuse” the patient.

Attention is now turned to dissecting the pancreas from the splenic hilum by using the ultrasonic scalpel. Sometimes this is relatively straightforward, but it can be quite tedious. At this time, or perhaps earlier in the dissection, the attachments of the spleen to the lateral peritoneal wall are incised. The avascular cephalad peritoneal attachments to the diaphragm are divided by using scissors. It is important to be aware of the diaphragm, because it is possible to injure it while mobilizing the cephalad aspect of the spleen. Once the tail of the pancreas has been separated and the spleen has been detached from its peritoneal fixation, the spleen can be lifted on either side of the hilum with retracting instruments. A 15-mm articulating stapler is introduced through the 15-mm cannula and positioned across the hilum of the spleen (see Fig. 50-13). It is necessary to ensure that the pancreas is not incorporated in the stapler and to confirm that the stapler is completely across the splenic vessels. Once positioned, the stapler should be closed for 20 seconds, after which the stapler can be fired and then gently released. When releasing the

stapler, be ready to grasp any vascular structures that may be bleeding. Once the spleen has been detached from its vascular and peritoneal attachments, the patient is placed into a deep Trendelenburg position and the Endocatch II bag is introduced. Then the patient is rotated into a reverse Trendelenburg position, allowing the spleen to fall into the open bag. The bag is closed after ensuring that no other structures have entered it, and the neck of the bag is exteriorized through the umbilical incision. The spleen is manually morcellated with sponge forceps and extracted in piecemeal fashion. During this part of the operation, it is very important to ensure that the bag is not perforated by overvigorous morcellation or extraction. It may take 10 to 20 minutes to accomplish splenic extraction. After removal of the bag and its contents, re-inspection of the area of dissection is performed to ensure that no evidence of complications is present. The incisions are then closed, and the patient is usually ready for discharge on the first or second postoperative day. Splenic diseases are also covered in Chapter 47.

## Cholecystectomy

Laparoscopic cholecystectomy is becoming a common operation for pediatric surgeons.<sup>31</sup> Sometimes the development of cholelithiasis is due to hemolytic

**Figure 50-14.** For laparoscopic cholecystectomy in infants and children, it is important to space the cannulas widely to create an adequate working space and not have the instruments inhibiting one another. **A**, A suggested diagram for location of the ports for an infant. **B**, The cannulas can be arranged as shown for a child between ages 3 and 10 years. **C**, Instruments can be positioned as they are for an adult.

disease, but often it is iatrogenic. Also, children presenting with biliary dyskinesia are being seen more frequently. Most pediatric patients undergoing laparoscopic cholecystectomy are in the adolescent age group. However, an occasional elementary school-age child will need this procedure, and, rarely, a preschool infant will be symptomatic from cholelithiasis.

When positioning the instruments and cannulas for the operation, it is important to space the cannulas widely for optimal working room (Fig. 50-14). This is especially true in the younger patient. The two right-sided instruments are usually for retracting purposes, with the most inferior instrument being used by the assistant and the most cephalad manipulated by the surgeon. These can often be inserted by using the stab incision technique (see Fig. 50-3). For the preschool patient a 5-mm umbilical port is placed, but for older patients a 10-mm port is usually necessary. The gallbladder will be extracted through this cannula or the umbilical fascial defect. For many pediatric patients, a 5-mm clip is used for ligation of the cystic duct and cystic artery, and therefore a 5-mm incision may be

placed in the patient's epigastric region. For smaller patients, this incision should be positioned more in the patient's left epigastrium to ensure adequate working space. However, in the teenager, this incision is located just to the right of the patient's midline.

Regardless of the patient's age, the operative steps are similar. Any omental or peritoneal attachments to the gallbladder are bluntly divided, and the tip of the gallbladder is rotated ventrally over the liver, which exposes the infundibulum and cystic duct. It is very important to retract the infundibulum laterally, which orients the cystic duct at a right angle to the common bile duct (Fig. 50-15). If the infundibulum is retracted cephalad, the cystic duct approaches a more vertical orientation and the cystic duct and common duct can be misidentified. This may lead either to injury or to ligation of the common duct. With the infundibulum retracted laterally, the cystic duct is well visualized and then easily skeletonized. Cholangiography often is not necessary. However, if the surgeon desires cholangiography, several techniques are available. In older children, a lateral incision in the cystic duct can be

**Figure 50-15.** When dissecting in the triangle of Calot, it is important to retract the infundibulum laterally which orients the cystic duct at a right angle to the common duct. **A**, The cystic duct is being retracted laterally and the cystic artery (*arrow*) has not been divided. **B**, The cystic artery has been divided. If the infundibulum is retracted cephalad rather than laterally, the cystic duct approaches a more vertical orientation and the cystic duct and common duct can be misidentified.

**Figure 50-16.** The cholangiography technique using the Kumar clamp is shown. **A**, An atraumatic clamp is placed across the gallbladder infundibulum. Through the side arm of the clamp, a sclerotherapy needle is introduced into the infundibulum and the dye is injected. **B**, The cholangiogram. Note the very small cystic duct entering a small common duct. The *black arrow* is oriented toward the atraumatic clamp, whereas the *white arrow* points to the sclerotherapy needle.

made, with insertion of a cholangiocatheter into the cystic duct, followed by cholangiography. In younger children, it is often easier to use the Kumar clamp technique, in which an atraumatic clamp is placed across the infundibulum and a sclerotherapy needle introduced through the side arm of the clamp into the infundibulum (Fig. 50-16).<sup>32,33</sup> After cholangiography, the sclerotherapy needle and cholangioclamp are removed. The advantage of this technique is that a lateral incision in a small cystic duct is technically very difficult, and this technique is much easier to accomplish in younger patients.

After cholangiography, if needed, the cystic duct is ligated and divided with endoscopic clips. Two clips are placed proximally near the junction of the cystic and common duct, and one clip is usually placed near the junction of the cystic duct and the infundibulum of the gallbladder. The cystic duct is then divided. In a similar fashion, the cystic artery is divided. The gallbladder is then dissected in a retrograde fashion from its attachments to the liver. A number of instruments can be used for this part of the operation, including the spatula cautery, the hook cautery, or the Maryland dissecting instrument attached to cautery. Regardless of the technique used, before complete detachment of the gallbladder, the area of dissection is carefully inspected again to ensure that hemostasis is adequate. Then the gallbladder is completely detached and extracted through the umbilical site. With a non-inflamed gallbladder, it can sometimes be removed through the umbilical cannula. However, it is often necessary to remove the cannula and extract the gallbladder through the fascial defect. After extraction, the area of dissection is again inspected and hemostasis assured. The ports/instruments are removed, and the incisions are closed. Most patients are ready for discharge the following day. An occasional teenage

patient may require an extra day of hospitalization. Gallbladder disease is also discussed in Chapter 44.

## Adrenalectomy

Patients with adrenal diseases are being more frequently seen by pediatric surgeons. Usually these diseases are benign, although pheochromocytoma may be seen with very severe physiologic alterations.

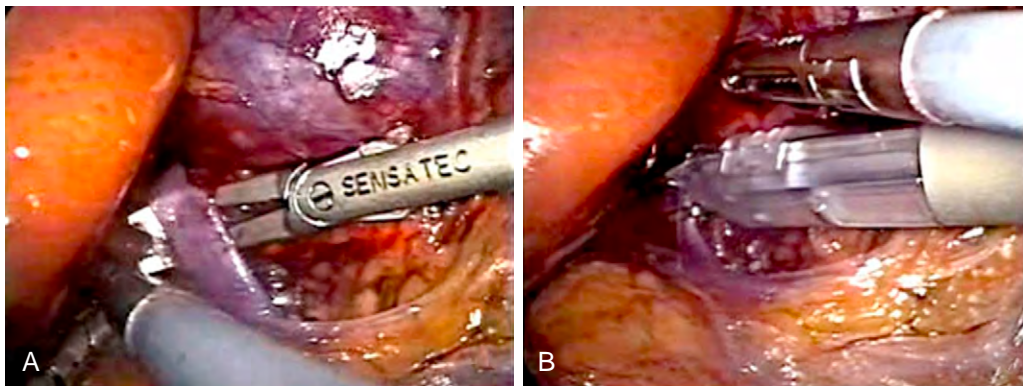

The patient should be placed in a lateral decubitus position with the operative side up (Fig. 50-17). For this operation, a 10-mm incision is made in the flank and extended down through the subcutaneous tissue and muscles into the peritoneal cavity. A 10-mm cannula is directly introduced into the peritoneal cavity, and insufflation is achieved. With a 10-mm cannula for this initial site, the dissection is easier and the specimen can usually be extracted either through the cannula or through the incision. After insufflation, accessory ports are then placed. Usually the accessory ports are 5 mm in size, although one or two can be 3 mm. Sometimes it is necessary to divide the peritoneal attachments to the colon first to place the most posterior cannula, because the operative approach is usually from a more posterior direction toward the adrenal gland.

For a left adrenalectomy, the adrenal vein is usually ligated with endoscopic clips early in the operation (Fig. 50-18). Next, the gland is carefully dissected free from the kidney on its inferior and lateral aspect and the diaphragmatic attachments superiorly. Medially, it is dissected from the midline structures. The ultrasonic scalpel can be useful in making this dissection relatively bloodless.

For a right adrenalectomy, the adrenal vein is ligated as one of the last parts of the operation, because the right adrenal vein is very short and directly enters the vena cava. Therefore, it is usually necessary to divide the

**Figure 50-17.** Patient positioning and sites of the incisions for laparoscopic adrenalectomy. **A**, The patient is usually positioned in a true lateral position. A roll is placed under the lumbar area, and the table is flexed. **B**, The incisions for a left laparoscopic adrenalectomy. The largest incision (*arrow*) is the site through which the intact specimen was removed in this patient. **C**, In a similar fashion, the incisions for a right laparoscopic adrenalectomy are visualized. Again, the intact specimen was removed through the largest incision (*arrow*), which was approximately 1.5 cm long.

**Figure 15-18.** Although in a right adrenalectomy the vein is ligated as a final step, ligation of the adrenal vein is usually one of the early steps in a left adrenalectomy. **A**, The left adrenal vein entering the left renal vein is identified. **B**, It is doubly clipped on each side and will be divided between the middle clips. (From Holcomb GW III: Laparoscopic adrenalectomy. In Holcomb GW, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 135-141.)

**Figure 15-19.** After identification and isolation of the right adrenal vein (*arrow*), it is doubly clipped on both the vena cava side and the adrenal gland side (**A**), and then divided between the middle two clips (**B**). The rest of the dissection can be completed easily with the ultrasonic scalpel. (From Holcomb GW III: Laparoscopic adrenalectomy. In Holcomb GW, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 135-141.)

right triangular ligament of the liver for access to the right adrenal gland. The right adrenal gland is circumscribed inferiorly, laterally, and superiorly by using the ultrasonic scalpel. With the right adrenal gland free on three sides, the right adrenal vein is carefully exposed medially. Endoscopic clips are placed on the adrenal

vein as it enters the vena cava, the right adrenal vein is divided, and the specimen removed (Fig. 50-19).

Most patients are ready for discharge the day after the operation, although patients with pheochromocytoma often need to be monitored the first postoperative night in an intensive care setting. Usually these

patients are ready for discharge on the second or third postoperative day.

Results of laparoscopic adrenalectomy in children have been favorable, with minimal morbidity and no mortality.<sup>34-38</sup>

## Small Bowel

### Duodenoduodenostomy

Laparoscopic repair of duodenal atresia and stenosis is becoming more frequently utilized.<sup>38-41</sup> In a recent report from my institution comparing 15 patients undergoing laparoscopic repair to 14 infants in a 3-year period having an open operation, the initiation of feedings and discharge was almost 7 days earlier for the laparoscopic group. There were no leaks in either group, but one patient in each group developed a symptomatic stenosis.<sup>41</sup>

Because the distal bowel is not distended, room exists within the infant's abdomen to perform the anastomosis. Familiarity with neonatal laparoscopic suturing is an important skill for surgeons performing this operation.

Four instruments are usually employed for repair of duodenal atresia/stenosis. A 5-mm port is introduced into the umbilicus and a 4- or 5-mm angled telescope is inserted for visualization. After the creation of a pneumoperitoneum, the two working ports for the surgeon are placed in the patient's right abdomen. An instrument utilized by the assistant is inserted in the patient's left abdomen. A suture can be placed around the falciform ligament to aid in retraction of the liver (Fig. 50-20). Usually, only one cannula is needed because the three instruments can be introduced through the stab incision technique in an infant with a very thin abdominal wall.

The operation is begun by identifying and mobilizing the dilated proximal duodenum. The distal duodenum is identified and mobilized on its antimesenteric side. If needed for better visualization of the proximal duodenum, a suture can be passed through the abdominal wall in the left upper quadrant, through the distal end of the proximal duodenal segment, and out

**Figure 50-20.** For a laparoscopic duodenal atresia/stenosis repair, a 5-mm port is placed in the umbilicus and secured with a suture to prevent its dislodgement. The two primary working ports for the surgeon are in the infant's right abdomen. The assistant's retracting port is in the left abdomen. In this photograph, a suture has been placed around the falciform ligament and tied over a bolster to help elevate the liver (*dotted arrow*). Also, a suture has been placed through the proximal duodenum to aid in its retraction for better visualization (*solid arrow*).

through the abdominal wall in the left upper quadrant (see Fig. 50-20). This suture is secured to a hemostat to allow mobilization of the proximal duodenal segment to aid in performing the anastomosis. A vertical incision is usually made with electrocautery or scissors in the distal duodenal segment, beginning at its blind end. An incision of similar length is made in the proximal duodenum at a right angle to the distal segment enterotomy. Tension on the traction suture on the proximal duodenal segment should be increased or decreased to line up the two duodenal enterotomies for the anastomosis. A diamond anastomosis is created in the traditional fashion. The anastomosis can be created using a continuous suture technique for both the anterior and posterior suture lines or an interrupted suture technique with silk, Vicryl, or U-clips (Fig. 50-21).<sup>41</sup> The anastomosis is begun in the

**Figure 50-21.** A, The duodenoduodenostomy can be performed using a continuous suture technique for both the anterior and posterior suture lines or an interrupted suture technique with silk, Vicryl, or U-clips. B, In the postoperative upper gastrointestinal study, the U-clips are well visualized (*arrow*). There was no evidence of a duodenal leak or stenosis on this study.

middle portion of the proximal duodenal enterotomy and the proximal end of the distal duodenal enterotomy. It is sometimes helpful to place stay sutures to hold the tissues of the proximal and distal duodenum in apposition for the anastomosis. If desired, the patency of the distal small bowel can be ascertained by using a saline injection technique. A 23-gauge needle is passed into the abdominal cavity attached to a 10-mL syringe. The distal bowel is grasped with a bowel grasper, and the needle is inserted through the abdominal wall and through the lumen of the distal bowel. Saline is injected and monitored visually. Two or three injections may be required more distally to follow the saline stream to the ileum.

The pneumoperitoneum is evacuated, and the instruments are removed. In neonates, even small fascial defects should be closed to prevent herniation of the omentum. The skin is approximated with sterile strips. Duodenal obstructions are discussed more fully in Chapter 31.

### Malrotation

Malrotation anomalies offer an excellent opportunity for laparoscopic visualization and repair if the patient does not have volvulus.<sup>42-45</sup> Laparoscopic exploration is useful both in the neonate and in the teenage patient with malrotation diagnosed by an upper gastrointestinal contrast study but with uncertainty about the intestinal attachments to the posterior abdominal wall.<sup>45</sup>

The patient is usually placed in the reverse Trendelenburg position to allow the small bowel and colon to fall away. The laparoscopic operation is begun by the insertion of four instruments. Because I utilize the umbilicus for exteriorization of the appendix for an appendectomy (rather than introduction of a stapler for an intracorporeal appendectomy), I usually place a 5-mm cannula at the umbilicus through which the telescope is introduced. The main working ports for the surgeon are on the patient's right abdomen. A fourth instrument is placed in the patient's left abdomen for use by the camera holder/assistant. Although it is possible to accomplish the operation using three instruments, a fourth instrument utilized by the camera holder can be very helpful in manipulating the intestinal segments.

The presence of malrotation is confirmed by identifying the pylorus and advancing distally along the duodenum. The next step is to find the cecum and carefully separate it from the duodenum by dividing Ladd's bands. Both of these techniques are necessary to ascertain fully the presence of malrotation. If the patient has a volvulus, an attempt at rotating the bowel in a counterclockwise direction is reasonable. However, it is often necessary to convert to an open operation. If necrotic bowel is found, it is usually best to open the patient for further evaluation and surgical correction if possible.

After division of the bands connecting the cecum to the duodenum, the mesentery can be separated widely. Adhesions in the folded mesentery of the small bowel

also should be released to allow a further broadening of the posterior mesenteric attachments. It is usually best to begin dividing the bands between the cecum and small bowel and then continue to divide these bands between the cecum, small bowel, and duodenum. The eventual goal of this dissection is to allow the cecum to fall freely into the left side of the peritoneal cavity and to release all subsequent adhesions in the small bowel mesentery. It is surprising that, even with very complex adhesions, an organized approach can unfold the adherent intestinal loops so that the proximal small bowel is retained in the right upper quadrant and the terminal ileum and colon naturally slide into the left side of the abdominal cavity.

An appendectomy is usually performed after the adhesions have been divided. The appendix is exteriorized through the umbilicus (Fig. 50-22) and an appendectomy performed per surgeon preference. Sometimes it is necessary to pull the cecum toward the right lower quadrant to return the appendiceal stump to the abdominal cavity.

The fascia of the incisions is then closed after the pneumoperitoneum has been evacuated. The patient is usually able to start feeding on the first or second postoperative day, unless a significant ischemic insult has occurred to the intestine.

Some pediatric surgeons have expressed concern that a laparoscopic Ladd procedure will not produce enough scarring of the colon and small bowel to prevent future volvulus. Volvulus following an open Ladd's procedure has been reported. I am unaware of midgut volvulus after a laparoscopic operation but this probably relates to the relatively small number of procedures performed. Malrotation is discussed in more detail in Chapter 32.

**Figure 50-22.** This young child is undergoing a laparoscopic Ladd procedure for malrotation. The appendix is being exteriorized through the umbilicus, and an extracorporeal appendectomy is performed. With this technique, 3-mm instruments can be utilized in small children and a large port is not needed for introduction of a stapler. Note two of the three instruments are seen inserted through the abdominal wall.

### Reduction of Intussusception

Intussusception is usually diagnosed and treated with a contrast enema and hydrostatic reduction. In approximately 10-20% of patients, surgical reduction is needed. Laparoscopy is an excellent method for the surgical reduction of most intussusceptions that are not amenable to correction by contrast enema or pneumatic reduction.<sup>46,47</sup> Occasionally the intussusception has spontaneously reduced during the interval between failure of the contrast enema and induction of the anesthetic. These patients certainly benefit from visualization of the reduced intussusception, as opposed to an incision to discover the same information. However, in most cases, the intussusception must be reduced by laparoscopic manipulation.

Three incisions are used for laparoscopic reduction of an intussusception. The configuration of these incisions is similar to that used for a laparoscopic appendectomy (Fig. 50-23). The endoscope is passed initially through the umbilicus and then rotated to the port in the left lower abdomen equidistant from the anterior superior iliac spine and the umbilicus. The other site is located in the suprapubic region. The patient is secured to the operating table, and the table is tilted to the left side to allow the small bowel to fall toward the left, so the cecum is well visualized. After visualization of the intussusception, steady traction is used to squeeze the edema out of the intussusception so that it can be reduced (Fig. 50-24). Although the classic teaching has been that one should not pull the two segments apart, laparoscopic surgeons have discovered that this dogma is inaccurate. Steady traction on the ileum with countertraction on the cecum, sometimes taking as long as 10 to 15 minutes, results in decrease of the edema in the intussusception so that the small bowel can be reduced from the colon (see Fig. 50-24). The operating surgeon must be very careful not to tear or injure the small bowel or colon during this process. A Babcock clamp, which can be used to grasp around the bowel onto the mesentery, or a long, small bowel clamp is best for pulling on the small bowel and for countertraction on the colon. After 10 to 15 minutes, if no reduction of the intussusception has occurred, the operation should be converted to an open procedure. Additionally, if it

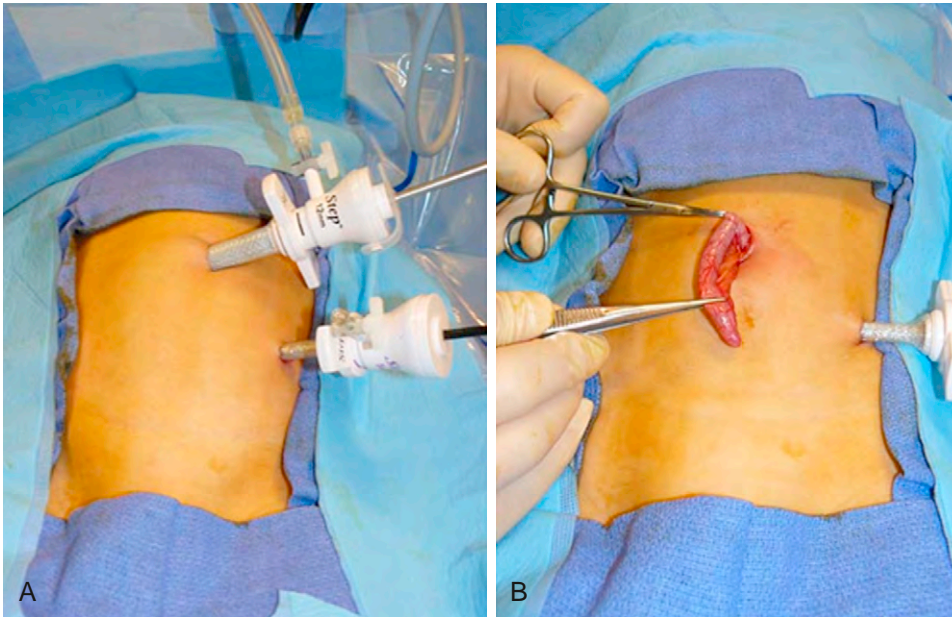

**Figure 50-23.** The incisions utilized for a laparoscopic reduction of an intussusception are similar to the configuration for a laparoscopic appendectomy. The 5-mm port in the umbilicus can be utilized for either a grasping forceps or the telescope and camera, depending on the surgeon's preference. The other two ports are the working ports through which the instruments are placed to help reduce the intussusception.

is apparent that the intussusception cannot be reduced because the bowel is gangrenous, a laparoscopic ileocolicectomy (described later) can be considered. In most cases, however, it is probably preferable to convert to an open procedure if reduction is not possible.

If the intussusception can be reduced laparoscopically, the pneumoperitoneum is evacuated. The fascia of the incisions should be closed to avoid herniation of the omentum.

**Figure 50-24.** A, Laparoscopic reduction of an intussusception entails gently pulling the small bowel out of the colon. B, The resulting small bowel intussusception can usually be easily reduced. (From Georgeson KE: Laparoscopic management of ileocolic intussusception. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy, Philadelphia, Elsevier, 2008, pp 71-73.)

**Figure 50-25.** In this young patient, an extracorporeal appendectomy was performed. **A**, Only two incisions were needed because of the mobile appendix. **B**, The appendix was exteriorized through the umbilical port site, and the appendectomy was performed.

Oral feeding is usually initiated the day after operation. The reported incidence of recurrence is the same for laparoscopic or open surgical reduction. Appendectomy is not usually performed in these patients. Further information about intussusception can be found in Chapter 39.

## Colon and Rectum

### Appendectomy

Laparoscopic appendectomy is becoming the standard of care for both nonruptured and ruptured appendicitis. Two primary approaches are used for laparoscopic appendectomy. The “in” technique (intracorporeal) uses three ports and is described in this section. The “out” technique (extracorporeal) is commonly used in Europe. With the “out” procedure, the appendix is mobilized without dividing the mesoappendix. The appendix is exteriorized through the single umbilical port site, and the appendectomy is performed in

a standard fashion externally through the umbilical incision (Fig. 50-25). The main problem with the “out” technique can be the bulbous size of the appendix, requiring enlargement of the umbilical port site. It also is sometimes difficult to mobilize the appendix and cecum adequately to pull the base of the appendix through the umbilicus. Some surgeons use a small right lower quadrant incision in these circumstances.

The technique most often used in the United States for laparoscopic appendectomy is performed within the peritoneal cavity by using three cannulas. The umbilical port is usually a 12-mm port. This large port is used anticipating that the bulbous, inflamed appendix will be removed through this cannula or the umbilical incision. Moreover, the stapler is inserted through this large port. The other two cannulas are positioned variably by laparoscopic surgeons. I prefer a left lower quadrant site for the endoscope and a suprapubic port site placement for the surgeon’s left-hand grasping forceps (Fig. 50-26). With the appendix retracted caudad, a window is created in the

**Figure 50-26.** **A**, The typical cannula placement for a laparoscopic appendectomy. Initially the 5-mm telescope and camera are introduced through the larger umbilical port. When the stapler is ready to be introduced, the telescope and camera are rotated to the left midabdominal port and the stapler is introduced through the 12-mm umbilical port. **B**, Postoperative appearance.

**Figure 50-27.** A, With the appendix retracted toward the pelvis, a window is created in the mesoappendix near the junction of the appendix and cecum. B, An endoscopic stapler is then inserted into the mesenteric window and the appendix is usually divided first, followed by ligation and division of the mesoappendix.

mesoappendix near the junction of the appendix and cecum (Fig. 50-27A). An endoscopic stapler is then inserted in this mesenteric window. I usually divide the appendix first followed by ligation and division of the mesoappendix (see Fig. 50-27B). The appendix is exteriorized through the 12-mm umbilical port. If it is too large, it is placed into a retrieval bag and exteriorized through the umbilical fascia and skin incision. Occasionally the fascia and skin of the umbilicus must be enlarged to allow removal of the appendix. This can be accomplished most easily by passing a grooved director both inferiorly and superiorly and by using electrocautery to increase the size of the opening in the umbilical skin and fascia. Once the appendix has been removed, the 12-mm cannula is replaced in the umbilical port site and then the abdomen and pelvis are thoroughly irrigated and aspirated. The ports are removed, and the pneumoperitoneum is evacuated. The umbilical fascia is closed, and the umbilical skin is approximated with absorbable suture.

A plethora of articles have addressed whether laparoscopic appendectomy is equivalent or superior to open appendectomy.<sup>48-55</sup> This controversy has been even more heated over the use of laparoscopic appendectomy for perforated appendicitis. Most of the early reports comparing laparoscopic with open appendectomy usually compared the learning curve for laparoscopic appendectomy with that for the open technique. However, as more large series have been reported, it is clear that the laparoscopic approach to appendectomy has some distinct advantages.<sup>53-55</sup> For my colleagues and I, the primary advantage for laparoscopic appendectomy for perforated and nonperforated appendicitis is a significantly lower wound infection rate. The incidence of intraperitoneal abscess formation seems to be about the same for both approaches. Cosmetic results appear to be better with the laparoscopic approach. For a more complete discussion on appendicitis, see Chapter 43.

### Crohn's Disease

Although the medical management of patients with Crohn's disease has improved over the past few years, it is not uncommon for these patients to have irreversible

obstruction of the terminal ileum, which can be an unremitting problem, even with appropriate medical management. Laparoscopic ileocelectomy can be performed using four port sites. These may be individualized per surgeon preference. I prefer a 12-mm cannula in the umbilicus and two 5-mm ports in the patient's left abdomen. Another 10- or 12-mm port is introduced in the right lower abdomen (Fig. 50-28). Bowel graspers are passed through the two left-side ports to help inspect the distal small bowel. A point is chosen to begin the resection. An endoscopic stapler with a vascular load is passed through the 12-mm umbilical cannula to divide the small bowel at the selected site. A second stapler is applied when needed. Either an ultrasonic scalpel or sequential vascular staple applications are used to divide the small bowel mesentery (Fig. 50-29). The appendix and cecum are mobilized by dividing the peritoneal attachments laterally. The entire cecum and part of the right colon are mobilized to make the subsequent ileocolic

**Figure 50-28.** The port sites for performing a laparoscopic ileocelectomy for Crohn's disease can be individualized according to the surgeon's preference. It is my preference to place a 12-mm cannula in the umbilicus and two 5-mm ports (arrows) in the patient's left lower abdomen. Another 10- or 12-mm port is introduced in the right lower abdomen. This is the site that the specimen is exteriorized and an extracorporeal anastomosis performed. (From Rothenberg SS: Laparoscopic ileocelectomy for Crohn's disease. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 65-69.)

**Figure 50-29.** Ligation and division of the mesentery can be performed with a variety of instruments. Often, more than one instrument is used. **A**, The endoscopic stapler is used to ligate and divide the mesentery. **B**, The Ligasure is used for the same purpose in a different patient. (From Rothenberg SS: Laparoscopic ileocelectomy for Crohn's disease. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 65-69.)

anastomosis easier. Dissection of the intestinal mesentery is continued to the mid-cecum. The specimen is exteriorized through the 12-mm right lower port, and an extracorporeal anastomosis is performed. An intracorporeal anastomosis can be performed as well.

The incisions are closed in standard fashion. Nasogastric drainage is not routinely necessary. Oral feeding may begin as soon as evidence of gastrointestinal function is seen.

Although ileocecal resection for Crohn's disease has been performed in relatively small numbers of children and adolescents,<sup>56-58</sup> the adult experience has shown that this is a safe technique with significant cosmetic advantages. Otherwise, length of stay and complications are similar to those with the open technique. Further discussion about Crohn's disease can be found in Chapter 42.

### Total Colectomy with J-Pouch Reconstruction

Approximately 20% of patients with ulcerative colitis have active symptoms before age 20 years (see Chapter 42). Some of these patients have unremitting symptoms that require urgent colectomy. Others have more chronic symptoms, such as persistent diarrhea, growth retardation, and delayed puberty. All of these patients are better managed with total colectomy with pouch reconstruction than with continued difficult medical management. Restorative proctocolectomy can be performed with a total laparoscopic technique or by laparoscopic colectomy with the proctectomy and J-pouch construction performed using a suprapubic incision. Moreover, because a proximal ileostomy is usually utilized to protect the pouch-anus anastomosis, the whole operative management can be in two or three stages.

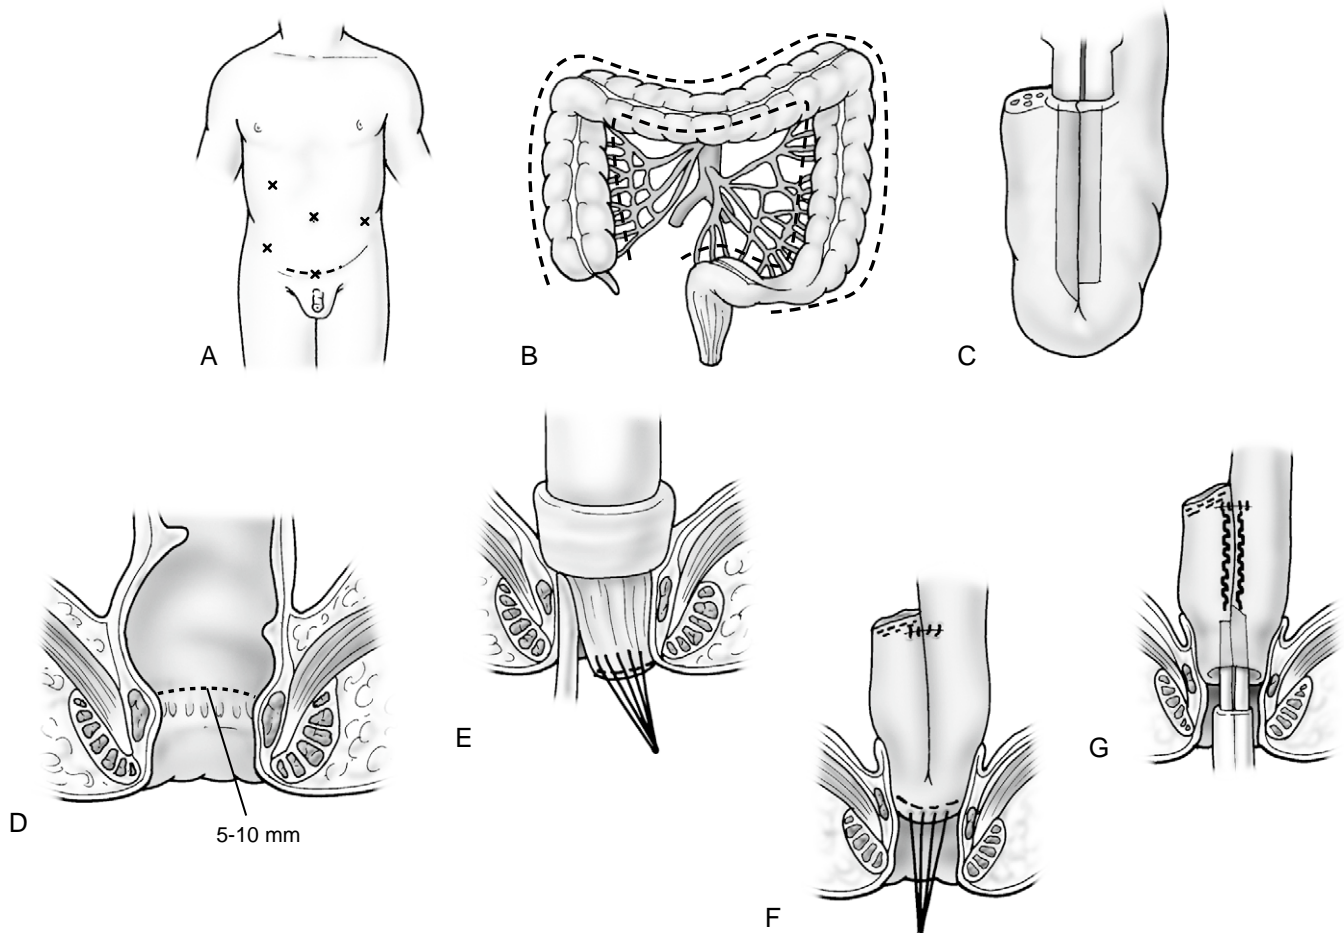

The laparoscopic-assisted colectomy is begun with the surgeon standing to the patient's right. Four or five cannula sites are used (Fig. 50-30). The distal sigmoid colon is lifted anteriorly, and the sigmoid mesocolon

is divided using an ultrasonic scalpel. The division of the mesocolon should be kept close to the colon to avoid bleeding. This dissection is carried cephalad to the descending colon. At this point, the lateral peritoneal attachments are divided up to the splenic flexure, followed by division of the descending mesocolon. The gastrocolic ligament is divided starting at the falciform ligament and extending toward the splenic flexure, followed by ligation and division of the lienocolic ligament. The transverse mesocolon is divided from the hepatic flexure toward the splenic flexure, where it joins the previous dissection of the descending mesocolon. At this point, the surgeon moves to a position between the patient's legs. The terminal ileum, appendix, cecum, and right colon are mobilized by dividing the lateral peritoneal attachments on the right side. The terminal ileum is divided with an endoscopic stapler. The mesocolon is divided close to the ascending colon, sparing the marginal artery, which is important for the future J-pouch. The surgeon divides the gastrocolic and hepatocolic ligaments on the right side of the abdomen, and the mesenteric division is completed. May be preferable to make a suprapubic incision for the proctectomy and pouch construction. After making the suprapubic incision, the rectosigmoid colon is divided with a gastrointestinal stapler, and the colon is removed. The remainder of the procedure is performed through an open approach.

Complication rates for total proctocolectomy and J-pouch pull-through are high (25%) for both the open and laparoscopic techniques. The most frequent complications are wound infection and small bowel obstruction.<sup>59,60</sup> The ileostomy is closed about 8 weeks after the initial operation.

### Pull-through Procedure for Hirschsprung's Disease

One of the most dramatic changes in pediatric surgical procedures over the past several decades has been the ascendance of single-stage techniques in the treatment

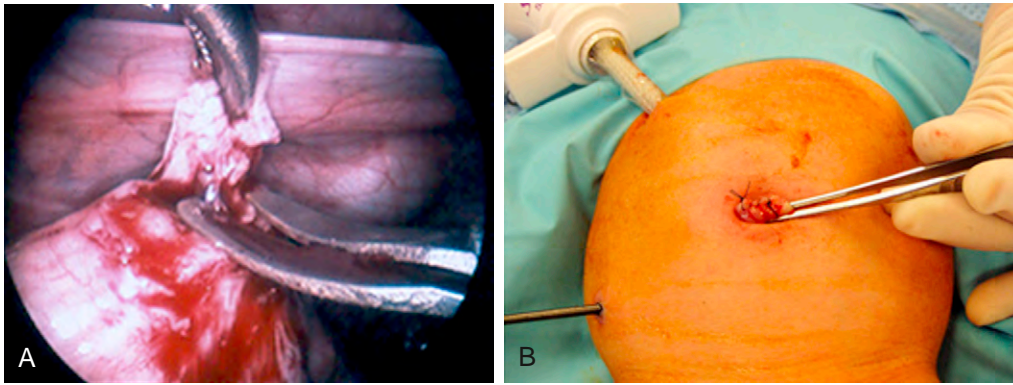

**Figure 50-30.** **A**, Four or five cannulas are placed as indicated for resection of the intra-abdominal colon. **B**, The intra-abdominal colon is separated from the lateral peritoneal attachments and its mesentery. **C**, An 8-cm J-pouch is formed with a stapler. **D**, The rectal mucosectomy is started near the top of the anorectal columns. **E**, Traction is applied to the mucosa, which is stripped away from the smooth muscle wall of the rectum. **F**, The J-pouch is passed through the muscular cuff without any twists. **G**, The lower portion of the J-pouch spur is divided at the time of closure of the ileostomy.

of Hirschsprung's disease. The primary pull-through procedure for Hirschsprung's disease was introduced in the early 1980s, but its popularity has increased since the late 1990s with the introduction of minimally invasive techniques.<sup>61-65</sup> The most popular technique now is the laparoscopic-assisted endorectal pull-through and its derivative, the transanal pull-through.<sup>64</sup> The laparoscopic technique offers several advantages over the pure transanal pull-through. Most significantly, the laparoscopic approach allows biopsy of the bowel above the apparent transition zone to confirm not only the presence of ganglion cells but also the absence of hypertrophic nerve fibers and the assessment of normally innervated smooth muscle above the transition zone. Because the mucosectomy is irreversible once completed, it is essential that confirmation of normal ganglion cells as well as the absence of hypertrophic nerve fibers be substantiated before initiating the rectal dissection.

A number of surgeons who have previously espoused the pure transanal pull-through now perform laparoscopy for biopsy. In one article, it was found that the transition zone defined by a barium

enema was 90% accurate when the colorectal specimens were studied for histologic evidence for ganglion cells.<sup>66</sup> However, this also implies that in up to 10% of cases, the radiographic transition zone will not be correct. Therefore, biopsy of the colon seems best to avoid the unusual case of an infant with total colon Hirschsprung's disease undergoing a transanal pull-through. In this scenario, the surgeon must be ready to perform either a straight ileoanal anastomosis or create an ileal pouch. The biopsy can be performed either totally laparoscopically or through a laparoscopic-assisted technique in which the portion of the colon for biopsy is exteriorized through the umbilicus and the biopsy performed in an extracorporeal manner (Fig. 50-31). The advantage of this technique is secure closure of the biopsy site in case a full-thickness biopsy was performed.

Transanal pull-through is easiest in patients younger than age 6 months. With increasing patient size, the ease of transanal pull-through diminishes. By performing even minimal laparoscopic dissection to the peritoneal reflection, the transanal dissection is made much easier and requires significantly less anal retraction.<sup>64</sup>

**Figure 50-31.** **A**, An intracorporeal biopsy is being performed on the sigmoid colon. A fine-tipped grasping forceps has been used to grasp the biopsy site, and Metzenbaum scissors are used to take the biopsy. **B**, An extracorporeal biopsy was performed through the umbilical incision in a different baby. One port and another instrument have been introduced through the infant's abdominal wall. A site on the colon for the biopsy was visualized and delivered just under the umbilical cannula. The umbilical cannula was removed, and this portion of the colon was grasped and exteriorized. An extracorporeal biopsy specimen was obtained and the biopsy site was closed. This is an alternative means for obtaining the biopsy specimen. (From Morowitz MJ, Georgeson KE: Laparoscopic-assisted pull-through for Hirschsprung's disease. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 102-108.)

Initially, a 5-mm umbilical port and a 5-mm right lower abdominal cannula are placed, followed by biopsy. If an appropriate transition zone is found, a right upper abdominal 5-mm port is inserted and the telescope rotated to this site. A 3-mm instrument is placed through a stab incision in the left upper abdomen for retraction by the assistant. The right lower abdomen site and the umbilical port become the primary working sites for the surgeon. A grasping instrument is inserted through the umbilical port and is manipulated by the surgeon's left hand. The endoscope is inserted through the right upper quadrant cannula, placed just below the liver in the anterior axillary line.

**Figure 50-32.** This operative photograph shows the view of the pelvis after most of the mesocolonic dissection. The sigmoid colon (*solid white arrow*) has been retracted toward the anterior abdominal wall. It is important to know the location of each ureter during this dissection. The left ureter is identified with a *white dotted arrow* and the right with a *black dotted arrow*. (From Morowitz MJ, Georgeson KE: Laparoscopic-assisted pull-through for Hirschsprung's disease. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 102-108.)

The surgeon's right hand manipulates instruments introduced through the port in the anterior axillary line in the right lower quadrant.

A hook cautery is used to devascularize the aganglionic segment of bowel. Sometimes, the ultrasonic scalpel is useful in children older than 1 year to divide the larger vessels. Care must be taken to ensure the ureters and vas deferens are not injured during this mobilization (Fig. 50-32). The legs are then elevated, and retraction sutures are placed circumferentially around the anus. A circumferential incision is made in the mucosa 5 mm above the dentate line. The endorectal dissection is done by using a cautery, scissors, and blunt dissection. As the endorectal dissection advances, the muscular cuff intussuscepts outward with traction on the mucosal sleeve. Dissection is continued to the level of the peritoneal reflection, where the muscular cuff is transected circumferentially. The colon is transected, and a watertight anastomosis is performed (Fig. 50-33).

The pneumoperitoneum is re-established, and the pull-through pedicle is inspected. A potential internal hernia space related to the vascular pedicle should be closed with interrupted sutures, preserving the vasculature to the colon. The pneumoperitoneum is evacuated, and the cannula sites are closed. The patients are usually fed on the first postoperative day and are often ready for discharge within 2 or 3 days. For further information about Hirschsprung's disease, see Chapter 35.

### *Pull-through Procedure for High Anorectal Malformations*

Historically, high anorectal malformations have been managed with a posterior sagittal anorectoplasty.<sup>67,68</sup> Although the operation is elegant to perform, the incidence of postoperative fecal incontinence remains high. The laparoscopic-assisted operation for imperforate anus was developed to avoid dividing the levator

**Figure 50-33.** A, The aganglionic colon is stripped of its mesentery close to the colon wall. When needed, a pedicle is developed, and the fusion fascia is divided laterally (*inset*). B, The mucosectomy is performed transanally, beginning about 3 to 5 mm above the dentate line. C, When the muscular sleeve of the rectum prolapses, the peritoneal cavity is entered posteriorly. D, The aganglionic bowel is removed through the anal opening, and the neorectum is secured to the anal mucosa at the dentate line.

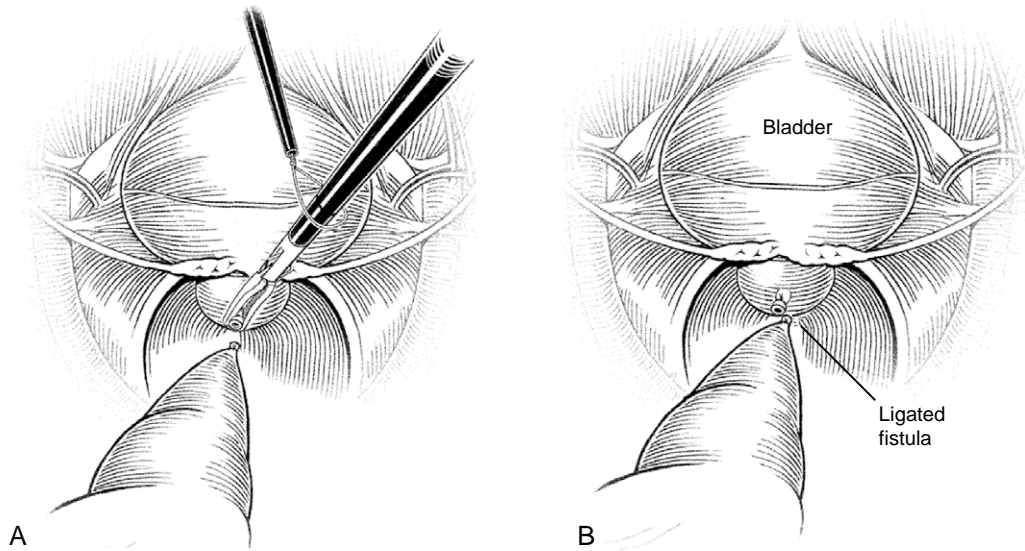

ani muscles and external sphincter muscles.<sup>69,70</sup> Conceptually, this operation approximates the operation for low anorectal malformations, in which the rectal fistula is redirected through the external sphincter complex.

A proximal sigmoid colostomy should be performed at birth. Several months later, the infant is positioned transversely across the operating table. Four cannula sites are used for the laparoscopic-assisted anorectal pull-through procedure. The position of these cannulas is identical to that used for the operation for Hirschsprung's disease. Dissection of the rectum is begun right at the level of the peritoneal reflection using the hook cautery. Injury to both ureters and to the vasculature of the rectosigmoid colon is assiduously avoided. The dissection is continued circumferentially around the rectum down to the rectourethral fistula. It is important to maintain the dissection precisely on the muscle of the rectum and fistula to avoid injury to other structures. The dissection is continued to the junction of the fistula and the urethra or bladder neck. As this point, the rectum begins to taper in size (Fig. 50-34). The fistula is divided 3 to 4 mm proximal to the urethra. A loop ligature is used to secure the urethral side of the fistula (Fig. 50-35). After division of the fistula, the pelvic floor can be clearly visualized (Fig. 50-36A).

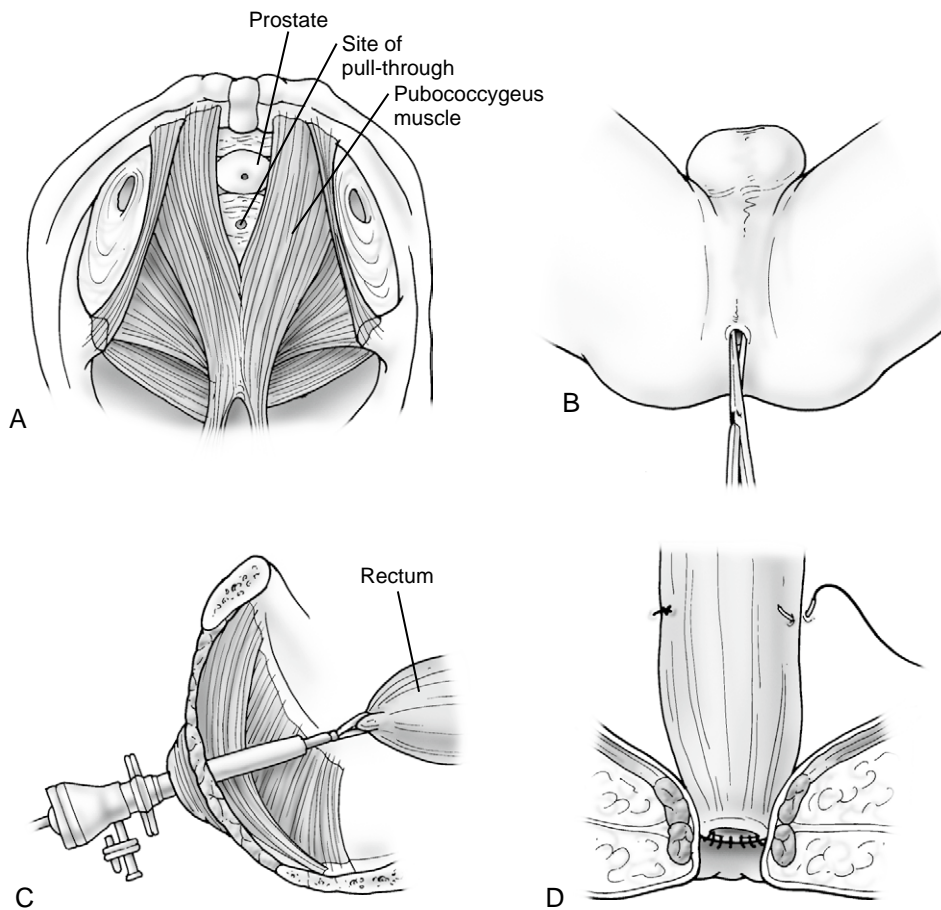

Electrical stimulation is used to map the location of the external sphincter complex. A 1-cm incision is made vertically in the gluteal cleft over the identified

**Figure 50-34.** The rectum (*asterisk*) is seen tapering in size to the rectourethral fistula (*arrow*) in the pelvis. (From Morowitz MJ, Georgeson KE: Laparoscopic-assisted pull-through for Hirschsprung's disease. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 102-108.)

**Figure 50-35.** After circumferential dissection of the rectum, the fistula has been divided and the rectal end ligated with a pretied ligature. **A**, The fistula on the urethral side is grasped with a Maryland clamp preloaded with a pretied loop ligature. **B**, The ligature is tightened around the urethral side of the fistula. (From Georgeson KE: Laparoscopic-assisted anorectal pull-through. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 115-119.)

**Figure 50-36.** **A**, The rectourethral fistula has been divided, allowing visualization of the pelvic floor. **B**, The external sphincters are identified with electrical stimulation, and the plane inside the sphincters is developed. **C**, A Veress needle covered by an expansile sleeve is passed through the sphincter complex by using laparoscopic visualization. **D**, The tract is radially dilated with a blunt trocar, and the rectal fistula pulled down to the anal skin. The fistula is attached to the anal skin, and the rectum is hitched to the presacral fascia to deepen the anal dimple and prevent prolapse of the rectal mucosa.

external sphincter complex. Blunt dissection is used to develop the elliptical plane inside the sphincter complex. A Veress needle covered by an expandable sleeve (US Surgical, Norwalk, CT) is passed through this incision and between the two limbs of the anterior portion of the levator ani complex (puborectalis muscle). This passage is performed under laparoscopic visualization. The Veress needle and associated expanding cannula sleeve are introduced into the pelvis directly in the midline. The Veress needle is removed, and the sleeve is expanded with 5-, 10-, and sometimes 12-mm cannulas. A grasper is passed through the cannula into the pelvic cavity. The fistulous tract is grasped and exteriorized through the passage in the levator ani complex. The fistula is secured to the anal skin with a single-layer anastomosis by using absorbable suture. The rectum is retracted upward and fixed to the presacral fascia with two sutures to invaginate the anal anastomosis and lengthen the skin-lined anal canal (see Fig. 50-36D). The neoanus is dilated beginning 3 to 4 weeks after the operation. The colostomy is closed when the fistulous tract has been dilated to an adequate size.

Although the early results of this operation have been encouraging, it is obvious that many of these patients lack the basic elements of continence, such as the internal anal sphincter or innervation to the muscles of continence. In a review of nonrandomized patients in which approximately half of the patients had been operated on by the laparoscopic-assisted

pull-through technique and the other half had been reconstructed using the posterior sagittal anorectoplasty operation, the laparoscopic-assisted group had a 90% incidence of a positive anorectal reflex, whereas in the posterior sagittal group, only 30% of the patients had an intact anorectal reflex.<sup>71</sup> Also noted in this study was that the rectum showed much better compliance in the laparoscopic group when compared with the posterior sagittal anorectoplasty group. The results of laparoscopic-assisted anorectoplasty will require years of follow-up studies to determine its role in the repair of high anorectal atresia. However, the early results are encouraging. Further information about management of anorectal anomalies is found in Chapter 36.

### SINGLE-SITE UMBILICAL LAPAROSCOPY SURGERY

Although the applicability of natural orifice transluminal endoscopic surgery (NOTES) appears limited in infants and children, another approach to reduce the number of abdominal incisions is single-site umbilical laparoscopic surgery (SSULS). With this approach, the operation is performed using the umbilicus as the single site for introduction of all instruments. There are a number of approaches for single-site umbilical surgery. Two techniques are shown in Figure 50-37. In one approach, a large (15-20 mm) umbilical incision is made

**Figure 50-37.** A number of techniques have been utilized for single-site laparoscopic surgery through the umbilicus. **A**, A laparoscopic appendectomy is being performed using a SILS Port placed through the umbilicus. With this technique, a 15- to 20-mm umbilical incision is necessary in order to insert the malleable port. There are three working channels in the port that can be utilized for inserting instruments. As seen, a 5-mm telescope, 5-mm grasper, and 12-mm stapler have all been introduced through this port for an intracorporeal laparoscopic appendectomy. On the right (**B**), an adolescent patient is also undergoing a laparoscopic appendectomy through a smaller umbilical incision. In this patient, a 5-mm port has been introduced in the umbilicus for the telescope and camera, and a 5-mm Maryland dissector has been inserted through a stab incision in the umbilical fascia just inferior to the cannula. The lateral peritoneal attachments to the appendix are bluntly lysed using the Maryland dissecting instrument until the appendix has been mobilized and can be brought through the umbilical incision for an extracorporeal appendectomy (see inset). In the inset, the proximal mesoappendix has been ligated with a vicryl suture and the mesoappendix distal to the ligature is being incised with the cautery. This extracorporeal technique is readily applicable for nonperforated appendicitis in which the appendix can be grasped and mobilized through the umbilicus.

through which a SILS Port (Covidien, Inc., Norwalk CT) is inserted. Instruments are then introduced down the three working channels. We have developed a technique using separate stab incisions around a single, umbilical port (see Fig. 50-37B). A 5-mm umbilical port for introduction of the telescope and camera is used. One, two, or three 3- or 5-mm instruments can be inserted through stab incisions adjacent to the 5-mm port. At the completion of the operation, the small stab incisions can be connected to the 5-mm incision, and a single fascial defect can be closed. This SSULS technique can be utilized for laparoscopic appendectomy relatively easily with a mobile appendix as the appendix can be grasped and delivered through the umbilicus, and an extracorporeal appendectomy can be performed. This

technique works well for non-perforated appendicitis but is more difficult for perforated appendicitis due to increased inflammation and adhesions encountered in the peritoneal cavity. Also, laparoscopic cholecystectomy can be performed using either of these two approaches as well. The main benefit of a single umbilical site appears to be cosmesis. Currently, prospective randomized trials comparing SSULS (as seen in Fig. 50-37B) with traditional three-port laparoscopic appendectomy for nonperforated appendicitis<sup>72</sup> and with four-port laparoscopic cholecystectomy for gallbladder disease<sup>73</sup> are currently under way at our institution. In the future, the use of single-site laparoscopy will likely be more applicable to infants and children than NOTES.

# INGUINAL HERNIAS AND HYDROCELES

Charles L. Snyder, MD

**I**nguinal hernia repairs are one of the most common operations performed by pediatric surgeons, and consultations for inguinal hernia are among the most frequent reasons for pediatric surgical referral. An inguinal hernia in a child usually refers to an indirect inguinal hernia but may include a femoral hernia and, rarely, a direct inguinal hernia. The diagnosis and management of inguinal hernias and hydroceles in infants and children and the attendant complications and controversies are discussed in this chapter.

## HISTORY

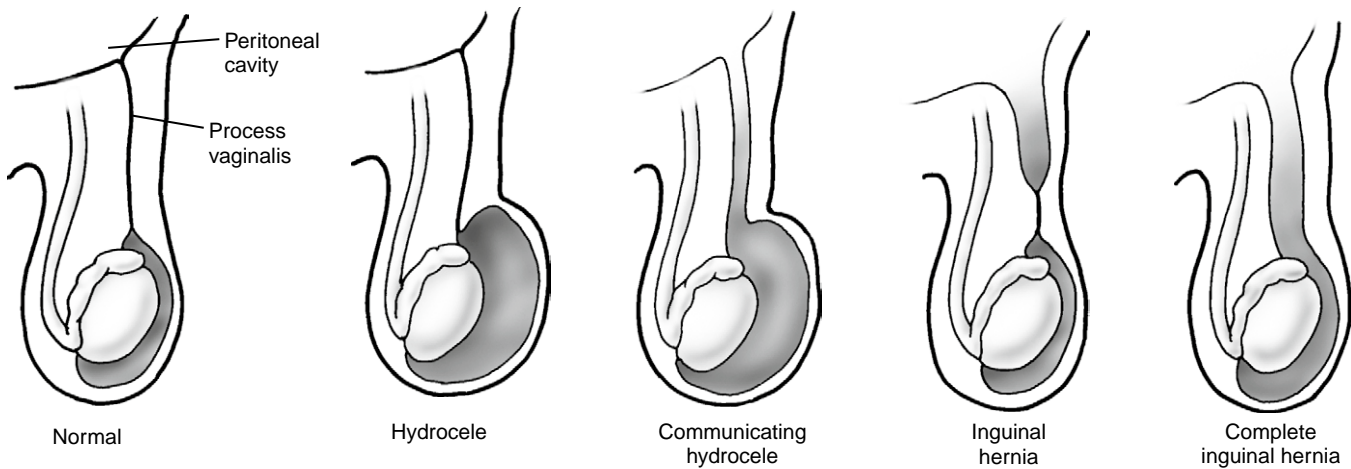

Inguinal hernias were first described in the Ebers Papyrus in 1550 BC.<sup>1</sup> Celsus is thought to have performed hernia repairs in AD 50.<sup>2</sup> Galen, in AD 150, described the processus vaginalis, defined hernias as a rupture of the peritoneum, and advised surgical repair.<sup>3</sup> Ambrose Paré advocated repair of inguinal hernias in childhood in the 16th century.<sup>1</sup> There was a flurry of progress in the 1800s, with Cooper's 1807 identification of the transversalis fascia and the ligament associated with his name and Cloquet's 1817 observation that the processus vaginalis is often patent at birth as well as his description of femoral hernias.<sup>4,5</sup> In 1877, von Czerny first described narrowing the inguinal canal and tightening the external inguinal ring,<sup>6,7</sup> followed by Bassini's description of internal inguinal ring tightening and reinforcement of the posterior canal in 1887.<sup>8,9</sup> Bassini's interest in the subject of inguinal anatomy was personal because he had sustained a groin wound with a cecal-cutaneous fistula in 1867.<sup>6</sup> Gross reported a 0.45% recurrence rate in a large series of hernia repairs (3874 children) in 1953.<sup>10</sup>

## EMBRYOLOGY AND ANATOMY

The processus vaginalis is a peritoneal diverticulum extending through the internal inguinal ring into the canal. It can be seen by 3 months of fetal life.<sup>11</sup> The somatic base of this diverticulum is the transversalis portion of the endoabdominal fascia. The gonads

form on the anteromedial nephrogenic ridges in the retroperitoneum during the 5th week of gestation. The gonads are attached to the scrotum by the gubernaculum in the male and to the labia via the round ligament in the female. Gonadal descent begins by 3 months' gestation, and the testis reaches the internal inguinal ring by about 7 months. Descent of the testis is initiated and directed by release of calcitonin gene-related peptide (CGRP) from the genitofemoral nerve (via fetal androgen release).<sup>12</sup> CGRP mediates closure of the patent processus vaginalis (PPV), although this process is not completely understood.<sup>11</sup> The testis begins to descend down the canal by the 7th month of fetal life preceded and guided by the processus vaginalis.<sup>11-13</sup> The processus, which is located anterior to the cord structures, gradually obliterates, and the scrotal portion forms the tunica vaginalis. The female anlage of the PPV is the canal of Nuck, a structure that leads to the labia majora. This also closes by about 7 months of fetal life, and ovarian descent is arrested in the pelvis.<sup>11</sup> The precise incidence of PPV in newborns is unknown and depends on gender and gestational age. The incidence has been estimated to be 40% to 60% but may be lower.<sup>14</sup> However, at autopsy, only 5% of adults have a PPV.<sup>11</sup> PPVs at birth can still close, but this becomes less likely with increasing age. It is failure of the PPV to close that results in an indirect inguinal hernia. As mentioned, the factors driving PPV closure are incompletely understood. Intra-abdominal pressure probably plays a role because disorders with increased abdominal pressure/fluid (e.g., ventriculoperitoneal shunts) are associated with an increased incidence of indirect inguinal hernia and with increased bilaterality.<sup>15</sup> Indirect inguinal hernias are more common on the right. The various clinical findings related to the processus vaginalis are illustrated in [Figure 51-1](#).

The layers of the abdominal wall contribute to the layers of the testis and spermatic cord as the gonad descends. The internal spermatic fascia is a continuation of the transversalis fascia, the cremaster muscle derives from the internal oblique, and the external spermatic fascia originates from the external oblique aponeurosis. The processus vaginalis envelops the testis as the visceral and parietal layers of the tunica vaginalis.

**Figure 51-1.** From left, configurations of hydrocele and hernia in relation to patency of the processus vaginalis.

## INCIDENCE AND ASSOCIATIONS

Approximately 0.8% to 4.4% of all children will develop an inguinal hernia, with a positive family history in about 11.5%.<sup>16</sup> In reviewing cases at our hospital over the past 4 years, there were 15,321 general surgical operations. Within this group, there were 1991 (13%) inguinal hernia repairs. Fifteen percent were performed in infants younger than 6 months of age, 54% of patients were between 6 months and 5 years of age, and 31% were 5 years of age or older. In another series of 6361 pediatric herniorrhaphies performed by a single surgeon, the male-to-female ratio was 5:1.<sup>17</sup> Right-sided hernias were twice as common as those on the left. The mean age in this series was 3.3 years.

The incidence of inguinal hernia varies directly with the degree of prematurity. The overall incidence of inguinal hernia in premature infants is estimated to be 10% to 30%, whereas term newborns have a rate of 3% to 5%.<sup>18-20</sup> Co-morbidities such as chronic lung disease associated with prematurity may play a substantial role in the development of an inguinal hernia in this population.

Other entities associated with an increased incidence of inguinal hernia (Table 51-1) include cryptorchidism, abdominal wall defects, connective tissue disorders (Ehlers-Danlos syndrome), mucopolysaccharidoses such as Hunter's or Hurler's syndrome,

cystic fibrosis, ascites, peritoneal dialysis, ventriculoperitoneal shunts, congenital hip dislocation, and meningomyelocele.

Patients with cystic fibrosis have an increased risk (eightfold in one report) of inguinal hernia,<sup>21</sup> with an incidence as high as 15%. This heightened risk may be due to elevated intra-abdominal pressure from respiratory problems, but developmental/embryologic factors may also play a role because the risk of hernia is increased in unaffected siblings and parents. Ventriculoperitoneal shunts are associated with an increased incidence of inguinal hernia as well as increased bilaterality, increased incarceration risk, and increased recurrence.<sup>15</sup> In a series of 430 children who underwent placement of a ventriculoperitoneal shunt, 15% developed hernias and hydroceles occurred in another 6%.<sup>22</sup> Injury to the shunt and shunt infection are other problems specific to these children.

## CLINICAL PRESENTATION

Most hernias are asymptomatic except for inguinal bulging with straining. They are often found by the parents or by the pediatrician on routine physical examination. The diagnosis is clinical and rests squarely on the history and physical examination. Maneuvers such as having the child raise the head while supine or "blowing up a balloon" with a thumb in the mouth may be helpful in small children. Standing the child upright may also help demonstrate the hernia. The differential diagnosis includes a retractile testis, lymphadenopathy, hydrocele, and prepubertal fat. In older children, neoplasia must be considered.

A common occurrence is a normal examination in combination with a suggestive history. Some surgeons have the child return for a second examination in 2 to 3 weeks, whereas others accept a good history as an indication for operation. Although subjective and dependent on the experience of the surgeon, our preference is for the latter course. False-negative explorations should be rare. In a series of 6361 hernia repairs by a single surgeon (definitive inguinal hernia on

**Table 51-1** Conditions Associated with an Increased Incidence of Inguinal Hernia

Prematurity
Cryptorchidism
Connective tissue disorders, mucopolysaccharidoses, congenital hip dislocation
Cystic fibrosis
Ascites, ventriculoperitoneal shunt, peritoneal dialysis
Abdominal wall defects
Meningomyelocele

examination was the indication for operation), there was only one false-negative exploration (0.02%).<sup>17</sup>

Ancillary findings such as a “silk glove sign” (feeling the thickened peritoneum of the patent processus as the cord is palpated) are of variable reliability.<sup>23,24</sup> Radiologic diagnostic aids are not generally necessary or helpful. Herniograms are of historic interest. Ultrasonography can be used to identify a PPV indirectly via widening of the internal inguinal ring (more than 4 to 5 mm is positive), but the technique is highly operator dependent and not in widespread use.<sup>25,26</sup> It is not generally necessary to restrict an asymptomatic child’s activities until repair is scheduled, but prompt repair may decrease interim incarceration.

Another question that has arisen in the laparoscopic era is what to do with an incidentally discovered PPV in a child undergoing operation for an unrelated problem. A common scenario is that of unilateral or bilateral PPV discovered during the course of a laparoscopic appendectomy. A hernia repair should not be performed concomitantly in that setting. The child and the family should be informed of the findings and instructed to watch for symptoms.

## OPERATIVE MANAGEMENT

### Anesthesia

There are no good data comparing regional to general anesthesia for pediatric inguinal hernia repair. A 2003 Cochrane meta-analysis of available data regarding this issue in premature infants concluded: “There is no reliable evidence from the trials reviewed concerning the effect of spinal as compared to general anaesthesia on the incidence of post-operative apnoea, bradycardia, or oxygen desaturation in ex-preterm infants undergoing herniorrhaphy.”<sup>27</sup>

Overnight stay is not necessary after inguinal hernia repair for healthy children or term infants. However, the risk of postoperative apnea and bradycardia is increased in premature infants and overnight

monitoring is necessary. The postconceptual age (gestational age + chronologic age) is commonly used to decide which infants require admission. Several studies have addressed this issue.<sup>28,29</sup> Sixty weeks postconceptual age is used at our hospital, because a less than 1% risk of postoperative apnea was found in former premature infants of more than 56 weeks’ postconceptual age in a comprehensive analysis of eight prospective studies.<sup>30</sup>

### Timing

Because premature infants have an increased incidence of inguinal hernia, this is a common diagnosis in the neonatal intensive care unit. The incidence of bowel incarceration in premature infants is significantly increased (threefold in one large series).<sup>17</sup> Many institutions use 2 kg as a lower limit for repair in asymptomatic and otherwise relatively healthy newborns. We usually repair the hernia before discharge to avoid the need for readmission to repair the hernia and to decrease the risk of incarceration.<sup>31-33</sup> However, this decision is surgeon-dependent and often depends on other co-morbidities.

### Operative Technique

Pediatric indirect inguinal hernias are usually repaired through an inguinal crease incision by splitting the external oblique aponeurosis up to the level of the internal inguinal ring. After the ilioinguinal nerve is identified, the anterior hernia sac is grasped and the vas and vessels (in the usual male hernia) are pushed away from the sac (Fig. 51-2A). The sac is clamped and divided (see Fig. 51-2B). A high ligation is performed after the sac is opened and inspected. If contralateral laparoscopic evaluation is performed, a small cannula can be gently advanced through the opened sac (see Fig. 51-2C). A 70-degree, 2.7-mm laparoscope allows examination of the contralateral side (Figs. 51-3 and 51-4).

There is an uncommon but disturbing incidence of late inguinal abscess formation related to the use of

**Figure 51-2.** A, After a right inguinal incision in an infant boy, the sac has been separated from the vas and vessels by grasping the sac and “teasing” the cord structures away. The hernia sac, located anteromedial to the cord, has been carefully separated from the vas and vessels (vessel loop) and is clamped in preparation for division of the sac. B, In preparation for diagnostic laparoscopy to evaluate the contralateral internal ring, the sac is opened. A vessel loop is around the cord structures. C, A cannula has been introduced into the opened hernia sac and the sac has been tied (solid arrow) to keep the abdomen insufflated. The cord structures (dotted arrow) are retracted with the vessel loop.

**Figure 51-3.** Laparoscopic evaluation of the contralateral inguinal region is used by many pediatric surgeons. **A**, A view of the left internal ring shows the inverted “V” of the laterally located gonadal vessels and the medial vas. At the apex of the “V,” the left internal inguinal ring is completely closed. **B**, A right-patent process vaginalis is seen in a 7-year-old with a known left inguinal hernia.

silk suture material.<sup>34,35</sup> Therefore, absorbable suture material is now preferred. The sac may be twisted before ligation, but too much twisting may draw the vas and cord structures up into the base of the sac, where they risk being inadvertently ligated. It is not necessary to remove the distal sac. Removing the distal sac may increase the risk of injury to the cord structures and the testis. Distal hydroceles should be opened widely and drained. It is important to ensure that the testis is in the scrotum at the conclusion of the procedure to avoid iatrogenic cryptorchidism.

Sliding hernias are uncommon but are more frequent in females, with an incidence as high as 20% to 40%. A fallopian tube or ovary may be involved. The bladder may constitute the medial wall of the sac in infants.<sup>36</sup> The appendix (Amyand’s hernia) may form a sliding component on the right. Distal ligation of the sac with proximal purse-string inversion is our preferred management of sliding inguinal hernias.<sup>37</sup>

Laparoscopic hernia repair has been used in children in both Europe and the United States.<sup>38,39</sup> In one recent series of 712 inguinal hernia repairs in 542 children (median age, 1.6 yr), operative times were similar to those for open procedures. A 5-mm umbilical port was inserted and two 2-mm cannulas

were used for suturing. The recurrence rate was 4.1%, with a median follow-up of just over 3 years. This rate dropped to 2% in the latter part of the study. Hydroceles occurred in 0.7%.<sup>40</sup>

Mesh or prosthetic materials are almost never required in children. One exception may be recurrent hernias in children with connective tissue disorders or mucopolysaccharidoses.

### Contralateral Hernias

Contralateral exploration for unilateral inguinal hernia in children has a long and controversial history. Meta-analyses, cost analyses, and decision-tree analyses have all been performed.<sup>41-44</sup> The results are discussed in more detail later, but a succinct summary of the conclusions is that routine contralateral exploration is not justified.

Surveys of pediatric surgeons have demonstrated a decrease in the practice of routine contralateral exploration over time, but laparoscopic evaluation of the contralateral side via the hernia sac has grown in popularity.<sup>45,46</sup> In the more recent survey, nearly half of the respondents said they would routinely explore the contralateral side in boys younger than 2 years old and

**Figure 51-4.** **A**, In a small percentage of cases, a veil of peritoneum will cover the contralateral internal ring and obscure the laparoscopic findings such that the surgeon is not completely certain whether a contralateral patent processus vaginalis (CPPV) is present. In this situation, a technique has been reported to retract the veil of tissue. **B**, A silver probe is introduced in the contralateral lower abdomen/flank and used to retract the veil medially so that the 70-degree telescope can then look down the possible CPPV. **C**, In this patient, a significant CPPV was visualized once the veil of peritoneum was retracted medially. (Adapted from Geiger JD: Selective laparoscopic probing for a contralateral patent processus vaginalis reduces the need for a contralateral exploration in inconclusive cases. *J Pediatr Surg* 35:1151-1154, 2000.)

in girls younger than 4 years old. Contralateral exploration was more likely in females. Approximately one third of surgeons performed laparoscopic evaluation of the contralateral side.

Many reports have addressed the incidence of a contralateral clinical hernia after unilateral repair.<sup>47</sup> A prospective study of 548 patients followed for a mean of 2 years found that 8.8% developed a contralateral hernia, with an average interval of 6 months. The incidence was higher in younger infants, premature infants, and females.<sup>48</sup> Another series of infants younger than 1 year of age who underwent unilateral inguinal hernia repair reported that only 7.7% developed a contralateral hernia during follow-up ranging from 5 to 10 years. Median time to occurrence was 18 months.<sup>49</sup> Another similar study of patients younger than 1 year of age found a 9% incidence of contralateral hernia, also after a mean of 18 months.<sup>50</sup> A meta-analysis of 15,310 patients in combined studies found a 7% incidence of a metachronous hernia.<sup>43</sup>

Although dated, a meta-analysis by Sparkman in 1962 showed 57% of children with a contralateral patent processus vaginalis at the time of unilateral hernia repair.<sup>51</sup> Also, perhaps the best study in terms of a controlled cohort was by MacGregor, who performed 148 unilateral inguinal hernia repairs in children younger than age 10 years over a 32-year period. Ninety-six percent of those were followed for a mean of 20 years of age. Over this length of time, he found that 28% returned with a symptomatic contralateral inguinal hernia.<sup>52</sup>

Left-sided initial hernia repairs may be associated with an increased risk of contralateral disease. Younger patient age and prematurity are also, albeit less frequently, identified as markers for a metachronous hernia. Although female gender carries a lower risk of contralateral exploration, and possibly a higher risk of PPV or clinical hernia, a study of 300 girls followed after unilateral herniorrhaphy found a metachronous hernia developed in only 8%.<sup>53</sup> Younger age, female gender, and a left-sided unilateral hernia have been used as selection criteria for diagnostic contralateral laparoscopy as well as open exploration.

The advent of laparoscopy has not clarified the situation but has added additional information. Theoretical benefits of diagnostic contralateral laparoscopy in children with unilateral hernia include identification of a contralateral PPV (and potential future hernia) without the attendant risks of contralateral open exploration. The mean additional operating time in one analysis was 6 minutes. There is some economic justification for this approach as well.<sup>42,44</sup>

One critical decision point is the incidence of PPV in children with a unilateral hernia. Probably the most accurate assessment is via diagnostic contralateral laparoscopy (See Figs. 51-3 and 51-4), with the caveat that (1) many of these PPVs will not develop clinically symptomatic hernias and (2) it may be difficult to distinguish a peritoneal fold from a true PPV. This technique was initially described in the early 1990s by Lobe and Holcomb.<sup>54,55</sup> The only significant change is that these original reports described umbilical laparoscopy

rather than repair through the ipsilateral inguinal hernia sac.

Contralateral laparoscopic evaluation cannot be performed in 4% to 5% of children because of a small or thin sac or poor visualization.<sup>23</sup> Large combined laparoscopic series document a 30% to 40% overall incidence of contralateral PPV.<sup>23,42</sup> However, it remains unclear how many will develop a symptomatic contralateral hernia throughout their lifetime.

## Pain Management

A randomized prospective trial of local instillation of long-acting analgesics (e.g., bupivacaine) versus caudal block for postoperative pain control after pediatric inguinal hernia repair demonstrated no significant difference in pain control.<sup>56</sup> Instillation of local anesthetics into the wound ("splash technique") is effective as well.

## COMPLICATIONS

### Incarceration

The incidence of incarceration is variable and ranges from 12% to 17%.<sup>17,57,58</sup> Younger age and prematurity are risk factors for incarceration.<sup>59</sup> The mean age of patients with incarceration is significantly lower than that of those who have elective repair.<sup>17,60</sup>

Symptoms of incarceration are manifested as a fussy or inconsolable infant with intermittent abdominal pain and vomiting. A tender and sometimes erythematous irreducible mass is noted in the groin. Abdominal distention is a late sign, as are bloody stools. Peritoneal signs indicate strangulation. Incarceration may be the presenting sign of the hernia. It can be difficult to distinguish a hydrocele of the cord from an incarcerated hernia. A happy infant with no tenderness suggests the former diagnosis, but if several examiners have vigorously attempted to "reduce" the hydrocele, the distinction can be difficult and ultrasonography may be helpful.

It is sometimes stated that gangrenous bowel cannot be reduced, but exceptions make this a dangerous "rule" to rely on. The presence of peritonitis or septic shock is an absolute contraindication to attempted reduction. Symptoms of bowel obstruction are a relative contraindication. Monitored conscious sedation is used after intravenous access and rehydration. Firm and continuous pressure is applied around the incarceration. Successful reduction is usually confirmed by a sudden "pop" of the contents back into the peritoneal cavity. Questionable or incomplete reductions should be explored. Once an incarcerated hernia is reduced, a delay of 24 to 48 hours to allow resolution of edema is recommended. Reliability of the family as well as clinical (very difficult reduction) and geographic considerations dictate the need for admission and observation before definitive repair. Overall, 90% to 95% of incarcerated hernias can be successfully reduced.<sup>61</sup> Only 8% required emergency operation in one report

of 743 incarcerated hernias, and two children required bowel resection.<sup>17</sup>

Urgent operation is necessary if nonoperative management fails. The hernia may reduce with induction of general anesthesia. If so, the hernia sac must be opened and inspected. The presence of enteric contents or bloody fluid mandates either open exploration (separate incision or La Roque maneuver) or laparoscopic evaluation. It may be necessary to open the internal inguinal ring laterally to reduce the bowel. Some surgeons approach an incarcerated hernia via a transumbilical laparoscopy to both reduce the hernia and evaluate the bowel.<sup>40,62,63</sup> Intestinal injury requiring treatment is rare (1% to 2%), even with incarceration.<sup>57</sup> The hernia sac is often quite edematous and friable, and repair of the hernia can be quite difficult. The risk of recurrence is increased. We do not routinely perform laparoscopy on the contralateral side in patients with incarceration because of these concerns.

Within a true incarcerated hernia, the testis on the affected side is often edematous and somewhat cyanotic. Unless the gonad is frankly necrotic, it should be preserved. The parents of any boy with an incarcerated hernia should be counseled about the possibility of testicular loss or atrophy, but in most cases this will not occur. The incidence of testicular atrophy is 2% to 3%.<sup>33,61</sup> Incarceration of an ovary may not always impair its blood supply, but most pediatric surgeons would promptly (but not emergently) repair the hernia in a girl with an asymptomatic nontender ovarian incarceration.<sup>62</sup>

## Recurrence

The risk of recurrence in an elective inguinal hernia repair is less than 1% in several large series.<sup>17,63</sup> It is higher in premature infants, in children with incarcerated hernias, and in children with associated diseases (e.g., connective tissue disorder, ventriculoperitoneal shunt).<sup>15,64</sup> Recurrence rates are as high as 50% in children with connective tissue disorders and mucopolysaccharidoses. A recurrent hernia even can be the presenting symptom in these diseases.<sup>65</sup> Recurrence rates may also be increased in teenagers.<sup>17</sup>

## Injury to Cord/Testis

Injury to the cord/testis is a rare occurrence in elective hernia repairs, with an incidence of approximately 1 in 1000 in large surgical series.<sup>17</sup> The true incidence may be underestimated because, in animal models, instrument manipulation or simply touching/pinching the cord can cause microscopic injury and scarring. A recognized injury to the vas should be managed by immediate repair with fine (8-0) suture, and the family should be informed of the event. In institutions in which hernia sacs are routinely examined by a pathologist, mesonephric rests or adrenal rests are occasionally seen but do not indicate injury to the vas. However, a review of 7314 male pediatric hernia specimens over a 14-year period at a major children's hospital found either vas deferens or epididymis in 0.53% of specimens.<sup>66</sup>

## Other Complications

Infection occurs in 1% to 3% of cases, and postoperative hematoma has a similarly low incidence. Persistent hydrocele can occur, particularly if a very large hydrocele was present preoperatively. It is important to instruct the family about this possibility before repair. Most postoperative hydroceles are simply observed for 6 to 12 months. If they do not resolve, aspiration may be tried once or twice. In our experience, aspiration is not usually permanently successful. Persistent nonresolving hydroceles usually require transumbilical diagnostic laparoscopy to exclude a recurrent hernia. In the absence of recurrence, a transscrotal exploration and obliteration of the hydrocele sac is performed.

Loss of domain due to a huge hernia in a tiny infant can occur and may even require staged repair. Death directly related to inguinal hernia or its repair is exceedingly rare.

## SPECIAL ISSUES

### Hydroceles

A frequent issue is whether the presence of a hydrocele in an asymptomatic infant indicates an inguinal hernia. If the hydrocele was not present at birth, or dramatically changes in size (communicating hydrocele), a PPV is present. Massive hydroceles and those extending along the length of the inguinal canal may also require operation. Static hydroceles that fail to reabsorb also indicate a PPV. Our practice is to observe these hydroceles until the child is 1 year of age.

Excision of the hydrocele sac is not necessary. The fluid is evacuated, and the distal sac is opened widely. Large or thick sacs may be everted behind the cord (Bottle procedure) if necessary.<sup>67</sup>

### Direct Inguinal Hernias

Direct inguinal hernias are rare in children, even older teenagers. Some recurrences after indirect inguinal hernia repair (or negative contralateral exploration) are direct inguinal hernias. Pediatric direct inguinal hernias are managed with standard "adult" inguinal hernia repairs. Our preference is for a McVay repair (approximation of the transversalis aponeurotic arch and internal oblique aponeurosis to the anterior ileopubic tract and shelving edge of the inguinal ligament).

### Femoral Hernias

Femoral hernias are relatively equally distributed by gender<sup>68,69</sup> but much less common than indirect inguinal hernias. In two combined series of over 10,000 patients, 0.2% of hernias were femoral.<sup>70,71</sup> Most (two thirds) are not suspected before operation (Fig. 51-5).<sup>69,71</sup> A mass below the inguinal ligament should alert the clinician to this possibility. Ten to 20 percent of femoral hernias are bilateral. Recurrence

**Figure 51-5.** This young girl presented with symptoms suggestive, but not conclusive, of a left femoral hernia. Therefore, diagnostic laparoscopy was performed through the umbilicus to confirm the diagnosis prior to an inguinal approach and a McVay repair. **A**, The internal opening to the femoral hernia is seen. **B**, After the McVay repair, the femoral defect is closed.

is increased after femoral hernia repair compared with indirect inguinal herniorrhaphy.<sup>68</sup>

### Absent or Atrophic Vas

Occasionally, a small or absent vas is found during inguinal hernia repair. This should prompt a workup for cystic fibrosis. Renal ultrasonography is also necessary because ipsilateral renal agenesis is associated.<sup>72,73</sup> Congenital absence (bilateral or unilateral) of the vas is a heterogeneous disorder, largely due to mutations in the cystic fibrosis gene. Differing genotypes are noted with congenital absence of the vas as an isolated entity versus congenital absence of the vas in association with renal anomalies.<sup>74</sup>

### Intersex

The finding of a testis during repair of a female hernia should raise the question of congenital androgen insensitivity syndrome (CAIS) or true hermaphroditism. Some authors have reported that as many as

1.6% of female infants with inguinal hernias will have CAIS.<sup>31</sup> Bilateral hernias in girls are not associated with a higher risk of CAIS than is a unilateral hernia. Conversely, as many as 75% of CAIS patients present with a hernia.<sup>75</sup>

Laparoscopy may allow evaluation of the fallopian tube, ovary, and uterus. The gonad should be sampled. Some advocate rectal examination to attempt to palpate the uterus. Vaginostomy is an option. In the presence of CAIS, an absent cervix will be found. Karyotyping and pelvic ultrasonography should be performed. Eventual gonadectomy will be necessary, although the timing is controversial. Further discussion is found in Chapter 63.

### Other Disorders

Incidentally discovered yellow nodules along the spermatic cord or testis are due to adrenal rests and may be safely removed. Splenogonadal fusion is a very rare entity that may masquerade as a testicular neoplasm. Frozen section confirmation allows gonadal preservation.

# UNDESCENDED TESTES AND TESTICULAR TUMORS

Hillary L. Copp, MD • Linda D. Shortliffe, MD

Numerous factors interact to affect normal testicular descent (Fig. 52-1). Any abnormality in this process can result in an undescended testis (UDT). Also known as cryptorchidism, a UDT carries fertility and malignancy implications.

## EMBRYOLOGY

Testicular development and descent depend on a complex interaction among endocrine, paracrine, growth, and mechanical factors. Bipotential gonadal tissue located on the embryo's genital ridge begins differentiation into a testis during weeks 6 and 7 under the effects of the testis-determining *SRY* gene. Sertoli cells begin to produce müllerian inhibitory factor (MIF) soon thereafter, causing regression of müllerian duct structures. By week 9, Leydig cells produce testosterone and stimulate development of wolffian structures, including the epididymis and vas deferens. The testis resides in the abdomen near the internal ring until descent through the inguinal canal occurs at the beginning of the third trimester.

An important player in testicular descent is the gubernaculum testis. The gubernaculum is a mucofibrous structure with its apex at the testis and epididymis and its base in the scrotum. It undergoes two developmental phases: outgrowth and regression.<sup>1-3</sup> A crucial mediator of gubernacular development is the testis-secreted hormone insulin-like factor 3. Outgrowth refers to a rapid swelling of the gubernaculum. This process dilates the inguinal canal and creates a pathway for testicular descent. Mice with homozygous mutant insulin-like factor 3 have been found to have poorly developed gubernacula and intra-abdominal testes.<sup>4</sup> Furthermore, if a competitive inhibitor of insulin-like factor 3 is given during pregnancy, cryptorchidism is induced in the offspring.<sup>5</sup>

During the second phase (regression), the gubernaculum undergoes cellular remodeling and becomes a fibrous structure rich in collagen and elastic fibers.

Moreover, it is depleted in both smooth and striated muscle cells.<sup>6</sup> Mechanical and anatomic factors, including intra-abdominal pressure and a patent processus vaginalis, are required for normal testicular descent. According to this hypothesis, intra-abdominal pressure causes protrusion of the processus vaginalis through the internal inguinal ring, transmitting abdominal pressure to the gubernaculum and initiating descent. It should be noted that the gubernaculum does not provide traction on the testis to cause descent. It is not

**Figure 52-1.** Testicular descent in males: (1) 90-mm crown-rump length (CRL) (12-24 weeks of gestational age); (2) 125-mm CRL (15-17 weeks); (3) 230-mm CRL (24-26 weeks); (4) 280-mm CRL (28-30 weeks); (5) at term. The convoluted structure is the epididymis. (Adapted from Hadziselimovic F: Embryology of testicular descent and maldescent. In Hadziselimovic F [ed]: Cryptorchidism: Management and Implications. New York, Springer-Verlag, 1983, p 23.)

anchored to the scrotum, and it does not insert onto the testis.

Androgens have also been shown to contribute to testicular descent. In humans, the frequency of UDT is increased in boys with diseases that affect androgen secretion or function.<sup>7,8</sup> When anti-androgens are given to pregnant rats, the rate of UDT in male offspring is 50%.<sup>9-12</sup> Experimentally, estradiol plays an inhibitory role in testicular descent through downregulation of insulin-like factor 3. Furthermore, maternal exposure to estrogen, such as diethylstilbestrol (DES), is associated with cryptorchidism.<sup>13,14</sup> In addition, growth factors such as epidermal growth factor play an active role at the level of the placenta to enhance gonadotropin release, which stimulates the fetal testis to secrete factors involved in descent such as descenin, an androgen-independent growth factor involved in gubernacular development.<sup>1</sup>

Other mediators of descent include MIF and calcitonin gene-related peptide (CGRP). The role of MIF is probably limited to causing resorption of müllerian structures, which may produce an anatomic obstruction to descent.<sup>2,3</sup> Research in animal models has shown that CGRP is excreted by the genitofemoral nerve under androgen stimulation. It causes contraction of cremasteric muscle fibers and subsequent descent of the gubernaculum, followed by the testis.<sup>15-18</sup> The cremaster muscle is the chief component of the gubernaculum of rats, but it is entirely distinct from the gubernaculum in humans. Therefore, the role of CGRP in human testicular descent remains controversial.<sup>19-21</sup>

The role of the epididymis in testicular descent also has been considered. The gubernaculum inserts into the epididymis, which precedes the testis into the scrotum. Some investigators postulate that under androgen stimulation the gubernaculum facilitates epididymal descent, indirectly guiding the testis into the scrotum.<sup>22</sup> Others believe that an abnormality of the paracrine function of testosterone is responsible for epididymal anomalies and UDT but that epididymal abnormalities do not cause UDT.<sup>20</sup> Epididymal anomalies are found in up to 50% of men with UDT.<sup>23,24</sup>

## CLASSIFICATION

Variability in nomenclature relating to UDT has led to ambiguity in the literature and difficulty in comparing treatment results. The clearest classification divides UDT into palpable and nonpalpable.<sup>25</sup> A true UDT has had its descent halted somewhere along the path of normal descent. The ectopic UDT has deviated from the path of normal descent and can be found in the inguinal region, perineum, femoral canal, penopubic area, or even the contralateral hemiscrotum. A retractile testis is a normally descended testis that retracts into the inguinal canal as a result of cremaster muscle contraction. It can be manipulated down into the scrotum on examination without tension and will remain in place. Acquired UDT refers to a

testis that was previously descended on examination and can no longer be brought down into the scrotum. An association between retractile testis and secondary testicular ascent has been identified.<sup>26,27</sup> Acquired UDT may also be due to iatrogenic causes. A previously descended testis may become trapped in scar tissue cephalic to the scrotum after inguinal surgery.

Testes may be nonpalpable secondary to an intra-abdominal location. Nonpalpable intra-abdominal testes are further classified as closed-ring and open-ring variants, depending on the status of the internal ring. The distinction between palpable and nonpalpable can be blurred by the fact that the palpable testis associated with an open ring may become nonpalpable when it falls into the abdomen through the open internal ring.

A nonpalpable testis may also be absent or vanishing due to intrauterine or perinatal torsion. This condition is known as monorchia, or anorchia if both testes are absent. Biopsy of tissue at the blind-ending gonadal vessels may reveal hemosiderin and calcification as a remnant of the previously torsed testis.

## INCIDENCE

UDT occurs in 3% of term male infants and in up to 33% of premature male infants. The majority of testes descend within the first 9 to 12 months. At age 1 year, the incidence of UDT is 1%, and testicular descent after 1 year is unlikely.<sup>28</sup> However, 2% to 3% of boys undergo orchiopexy for UDT. An explanation for this discrepancy between higher orchiopexy rates compared with the actual incidence of the disease is the acquired undescended testis rate. In a recent retrospective review of 172 patients with 274 retractile testes, the incidence of secondary ascent was 6.9%.<sup>27</sup> The overall rate of secondary testicular ascent has been reported between 2% to 45%.<sup>29</sup>

Series documenting the location of a UDT find that two thirds to three fourths of cases are palpable, with most being palpable within the inguinal canal or distal to the external ring.<sup>30,31</sup> Anomalies associated with UDT include a patent processus vaginalis, epididymal abnormalities, and, uncommonly, hypospadias, posterior urethral valves, prune belly syndrome, and anomalies of the upper urinary tract.

Controversy exists as to whether the incidence of cryptorchidism may be increasing. One study found the incidence of UDT higher in Denmark versus its neighboring country of Finland.<sup>32</sup> Moreover, the incidence in Denmark had increased over time. The authors postulated that environmental and lifestyle exposures may predispose to cryptorchidism and contribute to this increase in incidence. However, these claims were contested by another study that showed the incidence of UDT was stable in Denmark and similar to previous reports from the 1950s.<sup>33</sup> It suggested that differences in the incidence between these studies were most likely due to varying definitions of what constitutes a UDT.

## DIAGNOSIS

A careful history and physical examination should enable one to make a distinction between a retractile testis and a low UDT. Because the cremasteric reflex is weak or absent for the first 2 years of life, the diagnosis of a retractile testis is suggested in a boy with documentation of a scrotal testes at birth who is seen later with a suspected UDT.

The diagnosis and location of a UDT are determined by thorough physical examination performed in a warm room. The patient should be examined in both a supine and a frog-legged sitting position. In the sitting position, the boy can lean back on his hands with his knees bent outward and the soles of the feet touching or the lower legs gently crossed. The scrotum is observed for hypoplasia and examined for the presence of either testis. In cases of monorchia, the solitary testis may be hypertrophied. The first maneuver to locate the testis is to walk the fingers gently down the inguinal canal from the internal ring toward the scrotum, trying to push subcutaneous structures toward the scrotum. Lubricating gel may aid in reducing friction. Examining the patient in a squatting position may help identify the testis. Gentle pressure on the mid abdomen may help push the testis into the inguinal canal.

On physical examination, both the retractile testis and the low UDT may be manipulated into the scrotum. The retractile testis should remain in the dependent portion of the scrotum temporarily without traction, whereas the low UDT does not remain in the scrotum. With a retractile testis the ipsilateral hemiscrotum is fully developed, whereas in the other forms of UDT the hemiscrotum may be underdeveloped. Although the long-term implications of human chorionic gonadotropin (hCG) stimulation are not entirely known, hCG injections may be helpful in distinguishing the low UDT from the retractile testis.<sup>34</sup> In response to a total of 10,000 international units (IU) of hCG administered intramuscularly over a 1- to 3-week period, a retractile testis should descend but a low UDT will not.

If neither testis is palpable, anorchia must be differentiated from bilateral UDT. This can be determined by the hCG stimulation test. Baseline testosterone, follicle-stimulating hormone (FSH), and luteinizing hormone (LH) levels are measured before administration of 2000 IU of hCG daily for 3 days, with a testosterone level determined on day 6.<sup>35</sup> If the baseline FSH level is elevated (3 SD above the mean) in a boy younger than 9 years, anorchia is likely and no further evaluation is recommended. If baseline LH and FSH levels are normal and hCG stimulation results in an appropriate elevation of testosterone, testicular tissue is likely present and the patient should undergo exploration. If the testosterone level does not increase in response to hCG stimulation, testicular tissue may still be present and exploration should be performed. The hCG stimulation test does not indicate whether testes or functioning testicular remnants are present.<sup>35</sup>

Radiographic imaging is rarely helpful in locating a UDT. Multiple studies have shown that the experienced surgeon examiner has a higher sensitivity in locating the UDT than does ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI).<sup>36,37</sup> Of the options, MRI is favored, and it may be useful in obese children.<sup>37-39</sup> The addition of gadolinium in magnetic resonance angiography (MRA) can further improve sensitivity and specificity, because testicular tissue is particularly bright on MRA.<sup>40</sup> For the clinically impalpable testis, laparoscopy has a 95% or higher sensitivity for locating a testis or proving it absent.<sup>37,41,42</sup>

## FERTILITY

A UDT and, to a lesser degree, its contralateral mate have been demonstrated to be histologically abnormal by investigators who perform bilateral testis biopsies at the time of orchiopexy. Others have found that the epididymis is often malformed.<sup>43-45</sup> A blunted normal testosterone surge at 60 to 90 days may result in a lack of Leydig cell proliferation and delay in transformation of gonocytes to adult dark spermatogonia. Histopathologic changes include a decrease in the ratio of spermatogonia per tubule and Leydig cell atrophy. An experimental rat model has demonstrated preservation of germ cell number and spermatogenesis in rats undergoing early orchiopexy versus hypospermatogenesis with germ cell apoptosis in rats not undergoing operation for undescended testes.<sup>46</sup> Furthermore, delayed orchiopexy at 3 years versus 9 months of age resulted in impaired testicular catch-up growth.<sup>47</sup> Clinically, patients with a history of UDT exhibit subnormal semen analyses. Despite these findings, the paternity rate of men with a history of unilateral UDT is equivalent to that of the normal population. However, bilateral UDT results in impaired fertility, with paternity rates of 50% to 65%, even if corrected early.<sup>48-51</sup>

## RISK OF MALIGNANCY

The risk of developing testicular cancer is 5 to 60 times greater for men with cryptorchidism.<sup>28,52</sup> The risk of malignancy arising from a UDT varies with location and is 1% with inguinal and 5% with abdominal testes.<sup>53-55</sup> There are two competing theories for why this increased risk exists. The first theory rests on the carcinogenic potential of the altered environment of the undescended testis. If this theory is correct, the timing of correction could potentially influence the development of malignancy. In other words, the longer the exposure to the altered surroundings, the greater the cancer risk. This theory has been supported by a recent epidemiologic study examining 16,983 men who underwent surgical correction for UDT.<sup>56</sup> The relative risk of testicular cancer in patients who had orchiopexy before age 13 years was 2.23 versus 5.40 for those having surgery at 13 years or older. An additional meta-analysis showed that orchiopexy after

10 years compared with the operation before 10 years of age was associated with six times the risk of malignancy.<sup>57</sup> The association of orchiopexy with a decrease in cancer risk has not, however, been demonstrated prospectively. Nevertheless, orchiopexy facilitates testicular examination and cancer detection. In addition, indirect evidence supports a decreased cancer risk with early surgical intervention.

The alternate theory is that the malignancy risk may be due to an underlying genetic or hormonal etiology that causes both cryptorchidism and testicular cancer. Support for this theory is demonstrated by the fact that in those patients with a UDT, 15% to 20% of testicular tumors arise in the normally descended contralateral testis.<sup>58</sup> In addition, the incidence of carcinoma in situ (CIS), a premalignant lesion, is 2% to 4% in men with cryptorchidism compared with less than 1% in normal men. In the postpubertal male, CIS progresses to invasive germ cell tumors in 50% of cases within 5 years.<sup>59</sup> The natural history of CIS diagnosed in a young child at the time of orchiopexy, however, is less clear. It has been recommended that these patients undergo repeated testis biopsy after puberty.<sup>60</sup>

The risk of malignancy is highest in testes originally located abdominally. Cancers arising in uncorrected abdominal testes are most frequently seminomas. In contrast, malignancies arising after successful orchiopexy, regardless of original location, are most frequently nonseminomatous germ cell tumors.<sup>61-63</sup>

## TREATMENT

### Indications and Timing

In addition to the evidence that early scrotal placement may affect the risk of malignancy and infertility, treatment of a UDT also reduces the risk of torsion, facilitates examination of the testis, improves the endocrine function of the testis, and creates a normal-appearing scrotum (see Fig. 52-1).

The UDT is unlikely to descend after age 9 to 12 months. The recommended age for a child to undergo orchiopexy is at or near age 1 year.<sup>64</sup> Repair may be undertaken earlier if a symptomatic hernia is present. The risk associated with undergoing general anesthesia after 6 months is low in hospitals with dedicated pediatric anesthesiologists.

For the unilateral UDT that presents after the onset of puberty, orchiopexy or orchiectomy is recommended. The unilateral, palpable UDT in postpubertal males should be brought down surgically if the testis appears normal and orchiopexy can be easily achieved. If orchiopexy is difficult and a normal contralateral testis is present, or if the UDT is abnormally soft and small, then the UDT should be removed. Orchiectomy is the treatment of choice for management of the postpubertal, unilateral intra-abdominal UDT because of increased cancer risk. In addition, the cord length is often too short for orchiopexy. Laparoscopic orchiectomy is ideal in this setting.<sup>65</sup>

### Hormonal Treatment

The value of hormonal therapy in the treatment of UDT is controversial. Buserelin, an LH-releasing hormone agonist or GnRH agonist, is frequently used to treat UDT in Europe. The highest success rates have been observed in cases in which the testis is at or distal to the external ring.<sup>66-69</sup> Trials combining buserelin and hCG have yielded success rates in the range of 60%, but the testis may not remain in the scrotum after therapy and surgical repair is required in 40% of patients.<sup>22,69-71</sup>

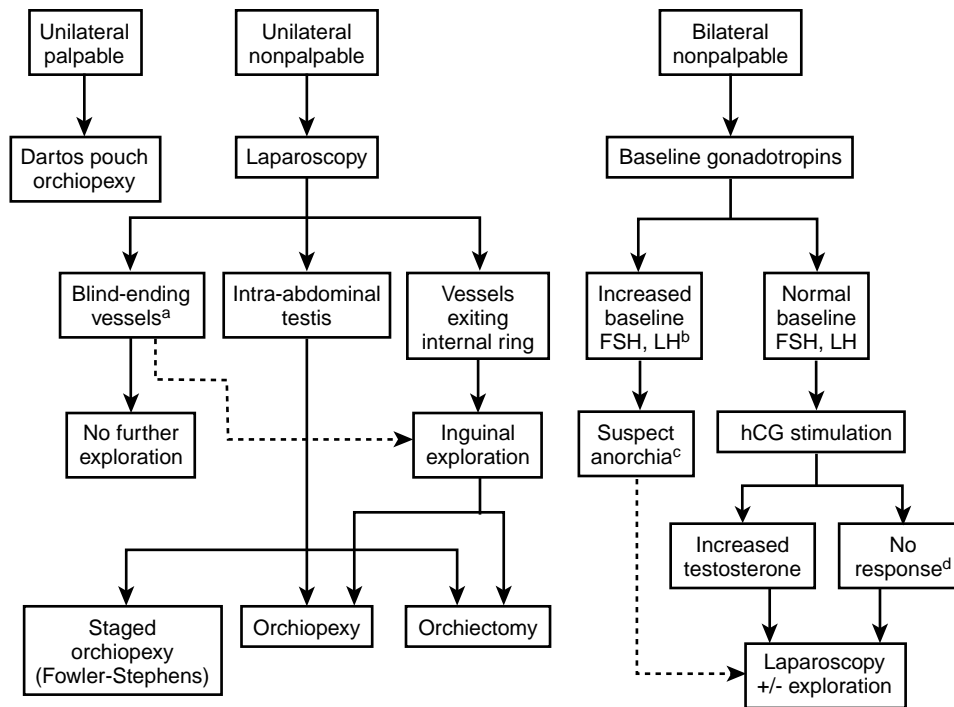

Some authors recommend low-dose hCG therapy, regardless of surgical plans, to restore a normal endocrine milieu and to enhance germ cell maturation.<sup>72</sup> hCG may cause virilization, although lower doses do not produce this side effect. Combined hormonal therapy is demanding and requires daily nasal administration of the LH-releasing hormone agonist for 4 weeks and several intramuscular injections. Buserelin, the LH-releasing hormone agonist, has never been approved by the U.S. Food and Drug Administration for this use.

### Surgical Intervention

The surgical approach for UDT depends on whether the testis is palpable (Fig. 52-2). Unilateral and bilateral palpable UDT are treated the same way. It is important to re-examine the patient after induction of anesthesia because up to 18% of nonpalpable testes may become palpable on examination under anesthesia.<sup>73</sup> For unilateral and bilateral nonpalpable UDT, definitive management may be determined through a combination of inguinal exploration and diagnostic laparoscopy. We prefer to approach the nonpalpable testis first through diagnostic laparoscopy and then proceed to inguinal exploration as needed. In one retrospective review of 215 nonpalpable testes, only 34% were located distal to the internal ring. Therefore, an initial standard inguinal incision for the remaining 66% of the nonpalpable testes would have been unnecessary or would have provided suboptimal exposure. The initial implementation of diagnostic laparoscopy eliminates extensive exploration for the 10% of the cases that are intra-abdominal, vanishing testes.<sup>73</sup> However, some surgeons still prefer to first explore the groin and then perform laparoscopy. They argue that the only time laparoscopy is definitive is when an intra-abdominal testis is encountered. Because this occurs only 30% of the time, they believe that laparoscopy is usually an additional, unnecessary step.<sup>74</sup>

### Palpable Undescended Testes

The mainstay of therapy for the palpable UDT is surgical orchiopexy with creation of a subdartos pouch. This may be performed through a standard, two-incision, inguinal approach or a single-incision, high scrotal approach.<sup>75-79</sup> With the standard inguinal approach the success rate, defined as a testis that remains in the scrotum and does not atrophy, is 95%.<sup>80</sup> Similar

**Figure 52-2.** Management algorithm for undescended testis. FSH, follicle-stimulating hormone; LH, luteinizing hormone; hCG, human chorionic gonadotropin.

<sup>a</sup>If blind-ending vessels are unequivocally identified, then there is no need for further exploration.

<sup>b</sup>Baseline FSH and LH levels are elevated if values are 3 SD above the mean.

<sup>c</sup>Increased suspicion of anorchia with elevated baseline FSH and LH levels; however, exploration is still warranted.

<sup>d</sup>Testicular remnant tissue may be present despite a negative hCG stimulation test; therefore, exploration for testicular remnant tissue should still be performed.

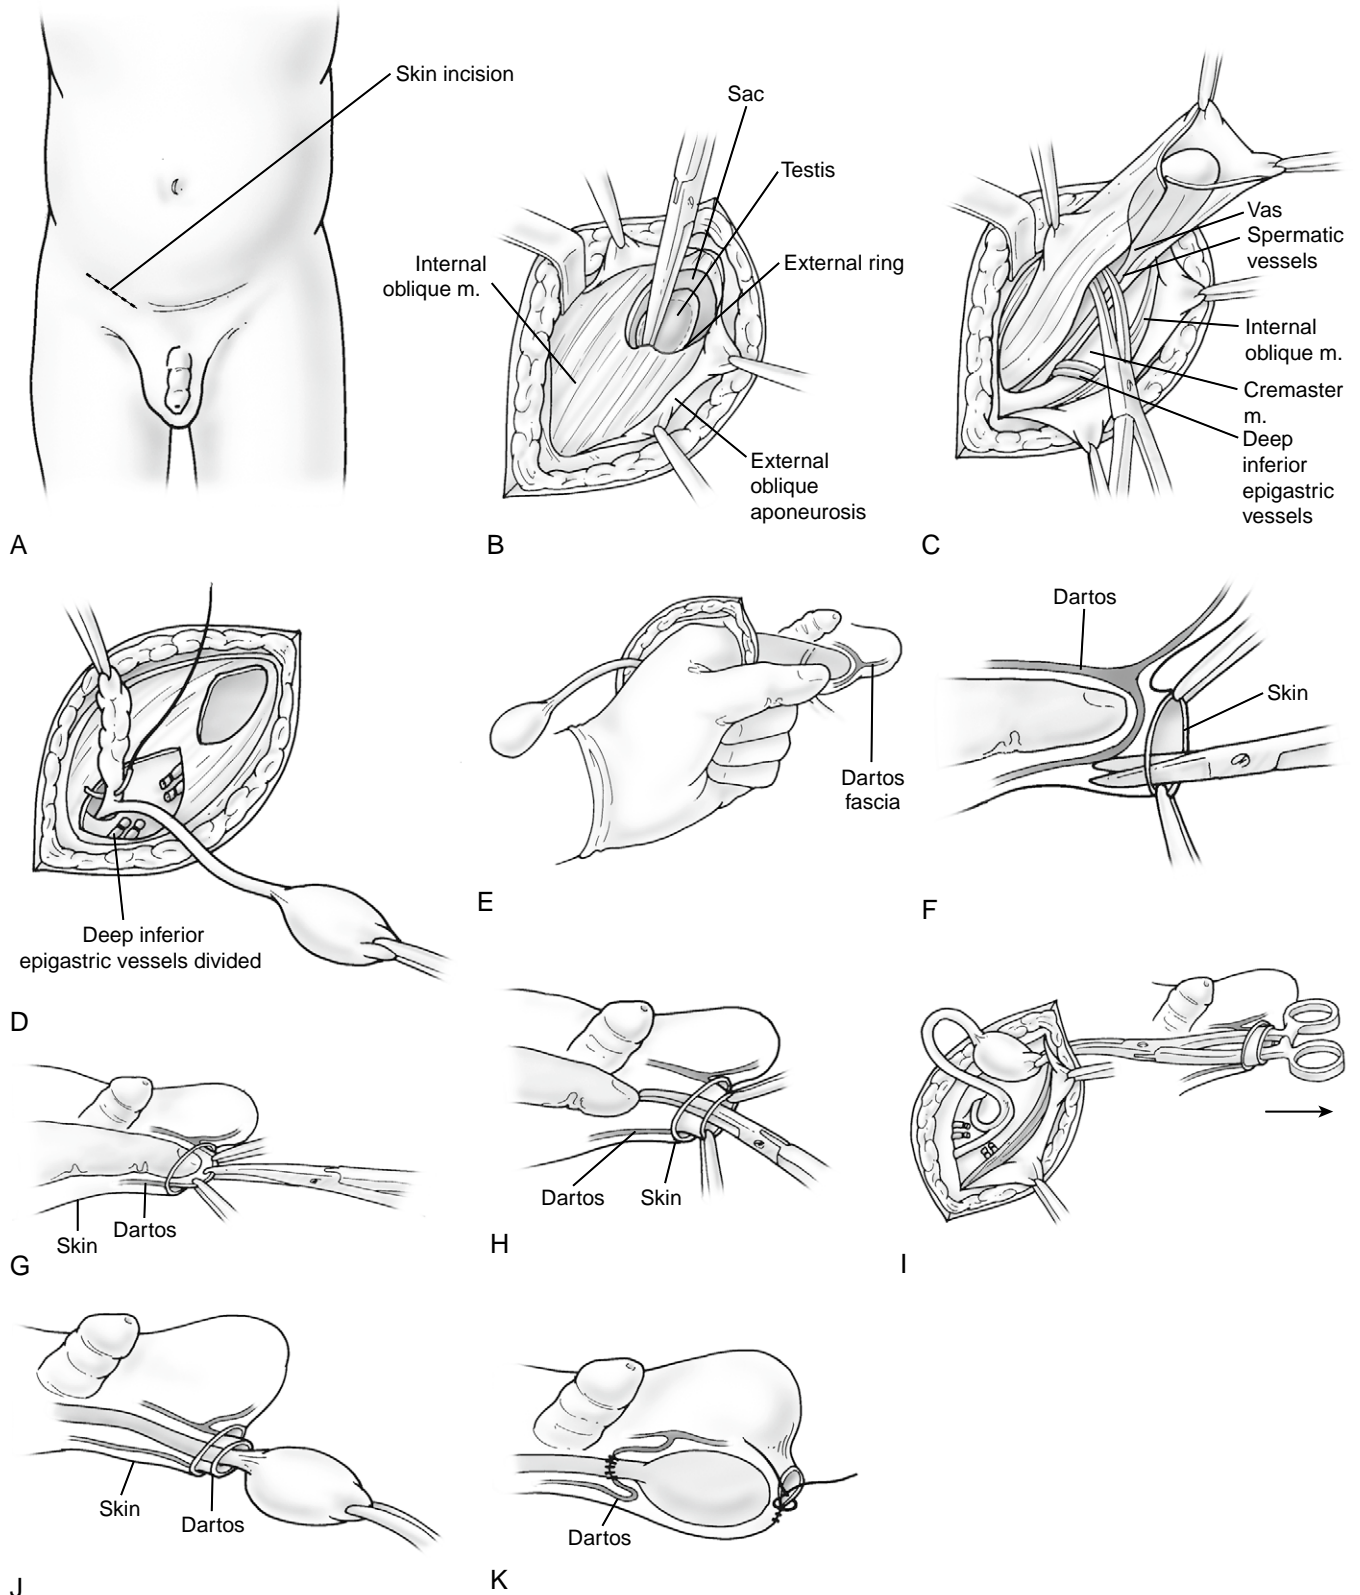

success rates have been reported for the high scrotal approach.<sup>78,79</sup> With both techniques, scrotal fixation is achieved by scarring of the everted tunica vaginalis to the surrounding tissues.<sup>81</sup> Eversion of the tunica vaginalis also decreases the risk of torsion.<sup>82</sup> The placement of sutures in the tunica albuginea for scrotal fixation is generally discouraged because it causes significant testicular inflammation, increases infertility risk, and may damage intratesticular vessels, especially those in the lower pole of the testis.<sup>83,84</sup> Routine biopsy of the testis at the time of surgery is controversial but may provide prognostic information regarding fertility.<sup>85,86</sup>

A standard inguinal approach to orchiopexy with a subdartos pouch is depicted in [Figure 52-3](#).<sup>75-77</sup> The operation is usually performed as an outpatient procedure under general anesthesia. The patient is supine. Intraoperative administration of an ilioinguinal nerve block with bupivacaine provides excellent postoperative analgesia. The incision should be made along one of Langer's lines, over the internal ring. The external oblique aponeurosis is incised laterally from the external ring in the direction of its fibers, avoiding injury to the ilioinguinal nerve. Once located, the testis and spermatic cord are freed. The testis and hernia sac are dissected from the canal. The tunica vaginalis is then dissected away from the vas deferens and the vessels before its division. The proximal sac is

twisted, doubly suture ligated, and amputated. Retroperitoneal dissection through the internal ring may provide additional cord length for the testis to reach the scrotum.

A tunnel is created from the inguinal canal into the scrotum by using a finger or a large surgical clamp. The scrotum is bluntly enlarged. A subdartos pouch is created by placing the finger through the tunnel and stretching the skin in a dependent portion of the scrotum. A 1- to 2-cm incision is made in the skin over the finger, and a hemostat is inserted just under the skin and spread both superiorly and inferiorly to create the pouch. A clamp is then placed on the surgeon's finger in this scrotal incision, and its tip is guided into the inguinal canal by withdrawing the finger. The clamp is then used to grasp the adventitial tissue around the testis. The clamp is then pulled back to guide the testis into the pouch. One should avoid grasping the testis or vas deferens directly, because this may cause scarring. Alternatively, a testicular transfixation suture may be used to deliver the testis to the dartos pouch.

Once the testis is in the dartos pouch, a suture is used to narrow the neck of the pouch to prevent testicular retraction. This suture also may be attached to the cut edge of the tunica. Testis measurements and biopsy may be performed at this time. The scrotal skin incision is closed. The external oblique aponeurosis is

**Figure 52-3.** Standard inguinal orchiopexy approach. **A**, Transverse skin incision. **B**, External oblique aponeurosis is opened in the directions of its fibers, with care taken to avoid the ilioinguinal nerve. **C**, The testis is delivered, and the patent processus vaginalis is opened distally near the testis. **D**, The processus vaginalis (or indirect hernia sac) is separated from the cord structures and ligated at the internal ring. Adequate cord length is usually obtained by retroperitoneal dissection of the cord contents. If additional length is required, the inferior epigastric vessels may be ligated (Prentiss maneuver), permitting medialization of the cord. **E**, A finger is passed inferiorly into the scrotum to aid in creation of the dartos pouch. **F** to **H**, Dartos pouch creation and passage of a clamp through the scrotum into the inguinal canal. **I**, Adventitial tissue of the testis is grasped with the clamp. **J**, The testis is brought into the dartos pouch. **K**, Dartos fascia and skin are closed. (From Ellis DG: Undescended testes. In Ashcraft KW [ed]: *Pediatric Urology*. Philadelphia, WB Saunders, 1990, p 423.)

reapproximated with absorbable suture. The skin and subcuticular tissue are closed with interrupted subcuticular stitches. A flexible collodion or topical tissue adhesive dressing is useful in diapered boys.

The patient is seen in the outpatient clinic after a few weeks for a wound check and again several months later for testicular examination. Final position and condition of the testis should be noted. Although rare, complications include atrophy and retraction.

A single scrotal incision technique has also been applied to orchiopexy. While some authors using the scrotal incision orchiopexy technique have shown shorter operative times with similar success and complication rates to the standard inguinal approach, one group demonstrated a 3% risk of postoperative hernia when the scrotal incision method was applied.<sup>78,87</sup>

### Unilateral Nonpalpable Undescended Testis

Depending on surgeon preference, the nonpalpable UDT may be approached through inguinal exploration or diagnostic laparoscopy. If the surgeon decides to first approach it through inguinal exploration and no testis or remnant is identified, then diagnostic laparoscopy or laparotomy may be needed to ensure the testis is not in an intra-abdominal location. If the vessels appear atretic or “blind ending” as they exit the abdomen, some surgeons have recommended no further exploration, but this is controversial.

The surgeon may also begin with diagnostic laparoscopy through an umbilical port (Fig. 52-4).<sup>31,41</sup> If the testicular vessels are seen exiting the internal ring, an inguinal incision is used to locate the testis or testicular remnant (Fig. 52-5). Orchiopexy is performed if a viable testis is found. If the vessels end blindly in the inguinal canal (vanishing testis), the tip of the vessels may be sent for pathologic examination. Remnants of testicular tissue or hemosiderin and calcifications are indicative of probable perinatal torsion and testicular resorption.

If diagnostic laparoscopy reveals an intra-abdominal testis, several options are available. The Fowler-Stephens

**Figure 52-4.** After diagnostic laparoscopy through a 5-mm umbilical cannula, if ligation and division of the testicular vessels are required, two accessory 3-mm instruments are introduced into the abdominal cavity using the stab incision technique. The surgeon should stand on the side opposite the nonpalpable testis. (From Holcomb GW III: Laparoscopic orchiopexy. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 144-148.)

orchiopexy involves ligation of the spermatic vessels, which makes the testis dependent on the vasal and cremasteric arteries for viability.<sup>88,89</sup> For this reason, the Fowler-Stephens approach is not a good option after prior inguinal exploration because the vascular supply to the testis may have been compromised. After ligation of the testicular vessels, which can be done laparoscopically or by laparotomy, a delay of about 6 months is recommended before orchiopexy to allow development of collateral circulation (Fig. 52-6). The success rate of this procedure in modern single-center

**Figure 52-5.** **A**, The vas deferens and testicular vessels in this patient end blindly in the retroperitoneum. The internal ring is closed. In this very unusual situation, inguinal exploration is not necessary. **B**, In the more common scenario, the testicular vessels and vas deferens are seen to enter the inguinal canal. There is no evidence for a patent processus vaginalis. The vessels and vas deferens appear to be of relatively normal caliber. In this situation, inguinal exploration is necessary. (From Holcomb GW III: Laparoscopic orchiopexy. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 144-148.)

**Figure 52-6.** **A**, After intra-abdominal mobilization of the testis, the gubernaculum has been grasped with forceps inserted through a 10-mm cannula that has been introduced through the scrotal incision, over the pubic tubercle and into the abdomen. The testis is then withdrawn into the cannula. Often, it is not possible to place the testis entirely into the 10-mm port. **B**, The testis is delivered over the pubic tubercle and into the right hemiscrotum. (From Holcomb GW III: Laparoscopic orchiopey. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 144-148.)

case series when defined as lack of atrophy and normal scrotal position is greater than 90%.<sup>90-93</sup> These success rates were maintained in studies that had a long-term mean follow-up of more than 3 years. Furthermore, a multi-institutional analysis revealed a similar 90% success rate for the two-stage laparoscopic Fowler-Stephens orchiopey.<sup>94</sup> However, a higher failure rate was observed when the single-stage Fowler-Stephens orchiopey was performed, and therefore caution is advised with this approach.

Other options for surgical management of intra-abdominal testes include microvascular orchiopey (autotransplantation) and orchietomy. In the hands of skilled laparoscopists, results from the two-stage laparoscopic orchiopey compare favorably with those of open surgery.<sup>95</sup> Others have found that a one-stage laparoscopic orchiopey without ligation is often possible, especially when the testis lies below the iliac vessels. Magnification and wide mobilization with laparoscopy can afford greater cord length and perhaps better preservation of collateral vascular supply.<sup>96,97</sup>

### Bilateral Nonpalpable Undescended Testes

Diagnostic laparoscopy or laparotomy may be performed to determine surgical therapy in the same manner as for unilateral, nonpalpable UDT.

### Secondary Undescended Testis

Secondary UDT is an uncommon complication of inguinal hernia repair, orchiopey, or hydrocelectomy. When it is found, surgical dissection is different from that of primary repair because scarring from the previous procedure makes dissection difficult. The surgical technique that we have found successful for reoperative orchiopey minimizes the risk to the spermatic

cord contents (especially the vas deferens) by mobilizing the entire cord and scar en bloc along with a strip of external oblique aponeurosis.<sup>98</sup> The incision is made through the previous scar, and the testis, which is usually palpable near the pubic tubercle, is exposed. A traction suture is placed through the tunica albuginea in the mid-testis. Parallel incisions in the external oblique aponeurosis allow the testis/cord/aponeurosis complex to be lifted from the canal so that a plane is developed between the spermatic cord and the inguinal floor. This dissection is carried superiorly to the internal ring, where the external oblique aponeurosis is cut to allow full mobilization of the cord and testis. Dissection continues above the scar, into the retroperitoneum, to produce sufficient length to permit placement of the testis into a dartos pouch. If more length is necessary, division of the inferior epigastric vessels allows the cord to be displaced medially.

## TESTICULAR CANCER

The peak incidence of pediatric testicular tumors occurs between ages 12 to 18 months, followed by a small peak during puberty. Testicular cancer is uncommon in children, accounting for 1% to 2% of all pediatric solid tumors. In contrast to the rising incidence of testicular cancer observed in adult men, the incidence of pediatric testicular germ cell tumors in U.S. children was stable from 1973 to 2000.<sup>99</sup> However, comparable to adults, race influenced the incidence of testicular germ cell tumors with an increased risk seen in Asian/Pacific Islanders versus whites.<sup>100</sup>

Germ cell tumors comprise 65% to 85% of pediatric testicular tumors. Children have a much larger percentage of benign testicular lesions than adults. Recently, the prevalence of the various histologic subtypes of testicular tumors was reviewed and found that an even higher percentage of pediatric testicular

tumors may be benign. Tumor registries have reported that greater than 60% of tumors were yolk sac and approximately 20% were teratoma.<sup>54,99</sup> In contrast, pooled data on 98 patients from four academic medical centers found that teratomas accounted for 48% of testicular tumors, whereas yolk sac tumors (YSTs) were responsible for **only 15% of testicular tumors**.<sup>101</sup> The other main tumor types included epidermoid cysts and gonadal stromal tumors. The authors proposed that tumor registries are more prone to reporting bias because benign lesions are likely underreported compared with malignant lesions.

## Presentation and Diagnosis

A testicular tumor typically presents as a painless scrotal mass. A history of trauma is often given and may be the inciting event that brings attention to the scrotal mass. Differential diagnoses include hydrocele, hernia, and tumor. Malignancy typically is nontender, does not transilluminate, and is not accompanied by an abnormal urinalysis. A hydrocele may impede adequate testicular examination. Also, a tumor arising in a UDT may undergo torsion and be seen as acute abdominal pain. Hormonally active tumors may occur with precocious puberty with or without a palpable lesion.

As part of the initial evaluation for a testicular mass, testicular ultrasonography and serum levels of tumor

markers should be obtained. Ultrasonography is highly sensitive and can detect even small tumors masked by a hydrocele. Ultrasound findings of internal calcifications and a heterogeneous mass suggest teratoma. These findings may be useful in preoperative planning for testis-sparing surgery.

Serum tumor marker levels are valuable not only in the diagnosis but also in the follow-up of testicular malignancy.  $\alpha$ -Fetoprotein (AFP) is a glycoprotein produced by the fetal yolk sac, liver, and gastrointestinal tract. It is elevated in a variety of benign and malignant diseases, including YSTs of the testis. The normal AFP value declines significantly in the months after birth.<sup>102</sup> The half-life of AFP is approximately 5.5 days, and the normal adult level of less than 10 ng/mL is not achieved until around 10 months of age (Fig. 52-7).<sup>103,104</sup> The  $\beta$  subunit of hCG ( $\beta$ -hCG) is a glycoprotein produced by embryonal carcinomas and mixed teratomas. Its half-life is 24 hours, and it is normally not detected in significant amount in boys (<5 IU/L).

Once the diagnosis of high-risk testicular cancer is made histologically, CT can be used to evaluate metastatic disease. CT has largely supplanted retroperitoneal lymph node dissection (RPLND) for the purpose of staging; however, it carries a 15% to 20% false-negative rate.<sup>105</sup> MRI also has been used to detect Leydig cell tumors, testicular epidermoid cysts, and Sertoli

**Figure 52-7.** This graph displays the normal ranges of serum  $\alpha$ -fetoprotein (AFP) in early infancy. The AFP levels in nanograms per milliliter are on the y-axis and age in days is on the x-axis. The normal range for AFP may be estimated by the middle regression line. The two flanking lines represent the 95% confidence interval. (From Ohama K, Nagase H, Ogino K, et al: Alpha-fetoprotein (AFP) levels in normal children. *Eur J Pediatr Surg* 7:267-269, 1997.)

cell tumors.<sup>106-108</sup> Information obtained can similarly guide the surgical approach, but the cost-effectiveness of MRI is unclear.

## Carcinoma in Situ

CIS of the testis is a premalignant lesion. Testicular cancer is reported to develop in at least 50% of testes known to harbor CIS.<sup>59</sup> CIS is seen in patients with UDT and intersex disorders, conditions that are known to carry a higher risk of testicular cancer than that in the general population.<sup>109</sup> In addition, CIS often co-exists in the testis that harbors a known cancer.

CIS growth is stimulated by endocrinologic changes during puberty. However, the natural history of CIS in prepubertal testes is less clear.<sup>110,111</sup> Testicular biopsy at the time of orchiopexy is not performed routinely. However, when it is done, CIS is seen in 0.36% to 0.45%.<sup>85,86</sup> If biopsy of a cryptorchid testis reveals CIS, it has been recommended that the patient undergo repeated postpubertal biopsy. The prevalence of CIS in adult men with a history of UDT is 2% to 4%.<sup>59,112,113</sup> If CIS is identified in the prepubertal testis, it is typically managed with annual testicular examinations and testicular ultrasonography despite the reputed 50% incidence of conversion to carcinoma in adult men. In postpubertal patients, some clinicians recommend that these patients undergo biopsy of the contralateral testis and unilateral orchiectomy. If biopsy of the remaining testis also reveals CIS, they recommend 18 to 20 Gy of radiation treatment. The same investigators advocate routine postpubertal testicular biopsy in all cases of UDT. This practice has not been routine in the United States, however, and remains controversial.<sup>114</sup>

## Germ Cell Tumors

YSTs are also known as endodermal sinus tumors, embryonal adenocarcinomas, orchidoblastomas, or Teilmum's tumors.<sup>115</sup> Most occur within the first 2 years of life. Grossly, YSTs are firm and yellow/white. Microscopically, they are characterized by Schiller-Duval bodies and stain for AFP.<sup>54,55,116</sup>

Metastasis of YSTs to the retroperitoneum is uncommon in children (4% to 6%).<sup>55</sup> Approximately 95% of YSTs are confined to the testis. The lungs are the most common site of distant metastasis, which occurs in 20% of patients. The 5-year survival rate for YST approaches 99%.

The standard diagnostic and therapeutic procedure for all testicular tumors is radical inguinal orchiectomy. To minimize the risk of metastases during manipulation, the spermatic cord is clamped or ligated immediately on entry into the inguinal canal. The role of RPLND in children with YST is controversial. Currently, most YSTs are treated with radical orchiectomy and patients are observed for recurrence by measuring AFP levels. If the AFP level was elevated at the time of orchiectomy and subsequently returns to normal, RPLND is not performed.

Staging of YSTs requires abdominal and pelvic CT and chest radiography, pathologic examination of the radical orchiectomy specimen, and determination of serum levels of tumor markers (Table 52-1).<sup>117</sup> Stage I tumors are limited to the testis. They are completely resected by radical inguinal orchiectomy, after which tumor marker levels normalize. Patients with unknown or normal markers at diagnosis must have a negative ipsilateral RPLND for the disease to be stage I. Tumor marker levels are measured monthly and chest radiographs obtained every 2 months for the first 2 years. Chest and abdominal CT scans are obtained every 3 months for the first year and every 6 months for the second year. After 2 years without recurrence, follow-up may be extended to every 6 months or yearly.<sup>55</sup>

Stage II disease includes those tumors with microscopic node involvement discovered by RPLND. Tumors diagnosed and treated with transscrotal orchiectomy or sampled also should be considered stage II, because resection via a transscrotal incision alters the normal lymphatic drainage of the tumor. Lymphatic drainage of the testis is to the retroperitoneal nodes, whereas the scrotum drains to the inguinal nodes. If a testicular tumor is diagnosed through a scrotal incision, ipsilateral hemiscrotectomy should be considered.<sup>110</sup> All patients with stage II disease should receive combination chemotherapy with cisplatin, etoposide, and bleomycin (PEB). Five-year survival rates with the PEB regimen approach 100% in this patient population.<sup>55,118</sup> Patients with a persistent mass or elevated AFP after chemotherapy should undergo RPLND.

Stage III disease includes retroperitoneal spread seen on imaging studies and occult metastases manifest by persistent elevation of tumor markers after orchiectomy. Metastasis beyond the retroperitoneum or to any viscera defines stage IV disease. For both stage III and stage IV disease, chemotherapy follows the same protocols as described for stage II disease. RPLND is performed after chemotherapy. The overall survival approaches 100%.

Histologically, teratomas are composed of all three layers of embryonic tissue: ectoderm, endoderm, and mesoderm. Grossly, they may contain differentiated tissue such as cartilage, muscle, bone, and fat; a cystic component also may be present. Before puberty, they follow a benign course and can be managed with testis-sparing surgery.<sup>54,55,119</sup> Long-term follow-up at a mean of 7 years has demonstrated no tumor recurrence in the ipsilateral or contralateral gonad with a testis-sparing approach.<sup>120</sup> However, when a child is initially seen at or after puberty, radical inguinal orchiectomy with high ligation of the spermatic cord is indicated, because teratoma can follow a malignant postpubertal course. When immature elements are seen on frozen sections, radical orchiectomy should be performed. Overall disease-free survival after orchiectomy is excellent.<sup>121</sup>

Teratocarcinoma, or mixed germ cell tumor, accounts for 20% of pediatric germ cell tumors. Teratocarcinoma is more commonly seen in a previously undescended

**Table 52-1** TNM Classification of Pediatric Testis Tumors

<b>Primary Tumor (T)</b>	
TX	Primary tumor cannot be assessed (in the absence of radical orchiectomy)
T0	Histologic scar, no evidence of primary tumor
Tis	Intratubular tumor (in situ tumor), preinvasive cancer
T1	Tumor limited to testis, including rete testis
T2	Tumor invades beyond tunica albuginea or into epididymis
T3	Tumor invades spermatic cord
T4	Tumor invades scrotum
<b>Regional Lymph Nodes (N)</b>	
NX	Regional nodes not assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node, ≤ 2 cm in greatest dimension
N2	Metastasis in a single lymph node, > 2 cm but ≤ 5 cm in greatest dimension, or multiple lymph nodes none > 5 cm in greatest dimension
N3	Metastasis in a lymph node > 5 cm in greatest dimension
<b>Distant Metastasis (M)</b>	
MX	Presence of metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
<b>Serum Tumor Markers (S)</b>	
SX	Marker studies not available or not performed
S0	Marker levels within normal limits
S1	LDH < 1.5 × normal <i>and</i> hCG < 5000 (mIU/mL) <i>and</i> AFP < 1000 (ng/mL)
S2	LDH 1.5-10 × normal <i>or</i> hCG 5,000-50,000 (mIU/mL) <i>or</i> AFP 1,000-10,000 (ng/mL)
S3	LDH > 10 × normal <i>or</i> hCG > 50,000 (mIU/mL) <i>or</i> AFP > 10,000 (ng/mL)

Normal is the upper limit of normal for the LDH assay.  
LDH, lactate dehydrogenase; hCG, human chorionic gonadotropin; AFP, alpha-fetoprotein.  
From AJCC Manual for Staging of Cancer, 5th ed. Philadelphia, Lippincott-Raven, 1997.

testis that has been brought down into the scrotum and may contain any mixture of YST, embryonal carcinoma, choriocarcinoma, and seminoma.<sup>117,122</sup> Eighty percent of teratocarcinomas are confined to the testis at presentation. Foci of choriocarcinoma confer a poorer prognosis. RPLND is usually performed even

for stage I disease, and higher-stage disease is treated with chemotherapeutic protocols similar to those used for adults.

Seminoma is rare in children. This tumor is treated with radical orchiectomy and retroperitoneal radiation.<sup>123</sup> It is the most common tumor found in an uncorrected abdominal UDT.

## Non-Germ Cell Tumors (Gonadal Stromal Tumors)

Leydig cell tumor is one of the most common non-germ cell tumors (NGCTs). The peak incidence in boys occurs from ages 5 to 9 years.<sup>54,124</sup> The clinical triad includes a unilateral testicular mass (90% to 93%), precocious puberty, and elevated 17-ketosteroid levels.<sup>125</sup> Because these tumors produce testosterone and occasionally other androgens, roughly 20% of patients may have endocrinologic signs of precocious puberty and gynecomastia.<sup>117</sup> Alternative explanations for precocious puberty include pituitary lesions and congenital adrenal hyperplasia. To eliminate these diagnoses, the pituitary/adrenal axis must be evaluated by assaying 17-ketosteroids and performing a dexamethasone suppression test. Reinke's crystals identified on histologic sections or on fine-needle aspirates are pathognomonic for this tumor and can be found in 35% to 40% of all patients.<sup>126,127</sup> However, they are rarely seen in children.<sup>55</sup> When the diagnosis is made preoperatively, testis-sparing enucleation through a transscrotal approach may be considered because these tumors tend to follow a benign course in boys.<sup>128</sup>

The granulosa cell tumor also has a benign course and may be approached with testis-sparing surgery. This tumor should be suspected in neonates with normal age-adjusted AFP levels with a complex, multiseptated, hypoechoic mass on testicular ultrasonography.<sup>129</sup>

The Sertoli cell tumor is a very rare form of NGCT and also is seen as a painless testicular mass. A small percentage of patients have gynecomastia. Although nonspecific, ultrasonography can show testicular microlithiasis.<sup>130</sup> The clinical course is usually benign, and tumors can be managed with testis-sparing surgery.

Gonadoblastoma is a form of NGCT usually seen in association with intersex disorders. The patients are typically 46XY phenotypic females with intra-abdominal testes who are seen with virilization after puberty. Up to one third of patients have bilateral gonadal lesions. Whereas the clinical course is usually benign, the germ cell component of these tumors carries a 10% risk of malignant degeneration. Early gonadectomy is recommended, especially if the patient is raised as a female.<sup>131,132</sup>

# THE ACUTE SCROTUM

Charles M. Leys, MD, MSCI • John M. Gatti, MD

The term *acute scrotum* refers to acute scrotal pain with or without swelling and erythema. This presentation should always be treated as an emergency because of the possibility of testicular torsion and permanent ischemic damage to the testis. Table 53-1 lists the differential diagnoses for the acute scrotum. The etiology is generally age dependent. Most conditions are nonemergent, but prompt differentiation between testicular torsion and other causes is critical. Torsion of the appendix testis/epididymis is most common in prepubertal boys, whereas testicular torsion most commonly presents in neonates and adolescents.<sup>1,2</sup>

## TESTICULAR TORSION

Torsion of the testis results from twisting of the spermatic cord, which leads to a compromised testicular blood supply and subsequent testicular infarction. The consequent ischemic damage affects long-term testicular morphology and sperm formation. However, there is generally a 4- to 8-hour window before significant damage occurs.<sup>3</sup> Table 53-2 shows that the probability of testicular salvage declines significantly beyond 6 hours. Emergent surgical treatment is indicated even beyond that window, however, because testicular viability is difficult to predict and spontaneous detorsion can occur first.<sup>4</sup>

Torsion may be classified as intravaginal or extravaginal. Intravaginal torsion is more common and occurs when the spermatic cord twists within the tunica vaginalis. This is predisposed by abnormal fixation of the testis and epididymis within the tunica vaginalis. Normally, the tunica will invest the epididymis and posterior surface of the testis, fixing it to the scrotum with a vertical lie. Abnormal fixation occurs when the tunica vaginalis attaches more proximally on the spermatic cord, creating a long mesorchium on which the testis can twist. The testis will then lie horizontally. In this situation, the pendulous testis is predisposed to twisting with leg movement or cremasteric contraction (Fig. 53-1). This anatomic variant is classically described as the “bell-clapper” deformity and has an incidence as high as 12% in cadaveric studies. Often, it is found in the contralateral scrotum as well.<sup>5</sup>

Extravaginal torsion is a perinatal event that occurs when the spermatic cord twists proximal to the tunica vaginalis. During testicular descent into the scrotum the tunica vaginalis is not firmly fixed to the scrotum, allowing the tunic and testis to spin on the vascular pedicle.

Testicular torsion typically occurs before age 3 years and after puberty. It is rare in prepubertal boys and after age 25 years. The clinical presentation of torsion classically involves the sudden onset of severe, unilateral pain in the testis, lower thigh, or lower abdomen. It is often associated with nausea and vomiting. Episodes of intermittent testicular pain may precede the acute presentation, suggesting prior incomplete torsion and spontaneous detorsion. Physical examination may reveal the involved testis retracted up toward the inguinal region with a transverse orientation and an anteriorly located epididymis. The torsed testis is usually enlarged and tender throughout. In contrast, focal tenderness at the superior pole or caput epididymis may occur with a torsed appendix testis or epididymitis. Depending on the duration of torsion, the involved hemiscrotum will show varying degrees of swelling and erythema, which may obliterate landmarks and make the examination more difficult. The cremasteric reflex is often absent with testicular torsion. However, the presence of this reflex does not reliably exclude torsion.<sup>6-8</sup>

Often the diagnosis of torsion is clinically apparent and is managed by immediate scrotal exploration. If

Data from Smith-Harrison L, Koontz WW Jr: Torsion of the testis: Changing concepts. In Ball TP Jr, Novicki DE, Barrett DM, et al (eds): AUA Update Series. Vol. 9 (lesson 32). Houston, American Urological Association Office of Education, 1990.

the diagnosis is uncertain, adjunctive diagnostic studies may aid in determining the etiology of the acute scrotum. A urinalysis revealing pyuria and bacteriuria is more indicative of infectious epididymitis/orchitis but can be found with torsion. Testicular blood flow can be examined using either high-resolution ultrasonography with color flow Doppler or radionuclide imaging. These imaging studies are most useful to help confirm the presence of testicular blood flow when a diagnosis other than torsion is suspected. Ultrasonography has become the more popular study at most institutions because it allows determination of blood flow, is less time consuming, is more readily available, and does not expose the patient to ionizing radiation.<sup>9,10</sup> In experienced hands, color flow Doppler ultrasound imaging has a sensitivity of 89.9%, a specificity of 98.8%, and a false-positive rate of 1%.<sup>11</sup> Doppler ultrasonography may detect coiling of the spermatic cord, indicating torsion, even with normal blood flow within the testis.<sup>12</sup> It is important that ultrasonography is used only when the diagnosis is equivocal. If torsion is strongly suspected clinically, further studies will only delay emergent surgical exploration.

If testicular torsion is suspected but a delay to the operating room is unavoidable, manual detorsion can

**Figure 53-1.** Bell-clapper deformity. The tunica vaginalis inserts very high on the spermatic cord, which predisposes to testicular torsion.

be attempted. Detorsion should be performed in a medial to lateral, “open book” rotation, because this will be the correct direction in two thirds of patients.<sup>13</sup> If successful, the testis will typically drop lower in the scrotum and the patient will report sudden relief of pain. If the initial attempt is not successful, an attempt in the reverse direction may be performed.<sup>14</sup> Although these maneuvers may decrease the degree of ischemia, prompt surgical exploration and fixation remains mandatory because the detorsion may not be complete and recurrent torsion can occur.

Exploration is typically performed using a median raphe incision in the scrotum. The symptomatic hemiscrotum is entered first and the testis delivered, detorsed, and placed in warm, moist sponges while the contralateral hemiscrotum is explored. The unaffected testis must be fixed to the scrotal wall with non-absorbable suture in at least three points, excluding the tunica vaginalis by excising a portion or tucking it back in the scrotum. Excluding the tunica vaginalis allows better fixation of the testis to the scrotum, as with dartos pouch fixation used in newborn scrotal fixation.<sup>15,16</sup> Attention is then turned back to the affected testis. If the testis appears clearly nonviable, it should be removed to avoid potential damage to the contralateral testis. Animal studies have demonstrated contralateral testicular damage mediated by antisperm antibodies formed in response to testicular damage in the torsed gonad.<sup>17,18</sup> As a result, some surgeons suggest removal of all testes that have experienced significant ischemic injury. However, it is questionable whether such antibody formation is physiologically significant in humans. Therefore, our practice is to remove the testis only if it appears nonviable. If the torsed testis becomes reperfused or bleeding is noted from a cut surface, it should be fixed in the same fashion as the contralateral testis. Although bilateral fixation reduces the probability of torsion in the future, this procedure does not absolutely guarantee against this possibility, because cases of torsion after fixation have been reported.<sup>19</sup> Therefore, any patient with a presentation suggestive of testicular torsion should be evaluated and treated with the same diligence, regardless of whether previous fixation has been performed.

### Intermittent Testicular Pain

A number of boys who present with testicular torsion will describe prior episodes of acute testicular pain that spontaneously resolved. Although intermittent testicular pain is not an unusual complaint in adolescent males, these episodes may represent intermittent torsion with spontaneous resolution.<sup>20</sup> This diagnosis should be strongly considered in adolescent males who report significant testicular pain that has resolved, especially with multiple episodes. This suspicion is reinforced if the testis has a transverse orientation or excess mobility. Ideally, the diagnosis could be proved with Doppler ultrasound imaging while symptomatic, although this may be difficult to obtain in a timely fashion. If clinical concern remains, even

with a normal physical examination, elective scrotal exploration looking for a “bell-clapper” deformity may be warranted. Scrotal ultrasonography before elective exploration is useful to evaluate for an occult testicular lesion.

### Perinatal Testicular Torsion

The term *perinatal torsion* is applied to both prenatal and postnatal events, with most (75%) occurring prenatally.<sup>21</sup> It may be difficult to distinguish between the two types of perinatal torsions, but the difference is important because it may affect the timing of operative management. Prenatal torsion classically presents as a hard, nontender scrotal mass noted at birth, usually with underlying dark discoloration of the skin and fixation of the skin to the mass. These findings suggest infarction of the testis secondary to a prior torsion. Postnatal torsion presents as a more classic, acutely inflamed scrotum with erythema and tenderness. The scrotum may be reported as normal at delivery, suggesting an acute postnatal event. This diagnosis requires emergent exploration with detorsion and bilateral fixation. If the timing of the torsion is in question, prompt exploration is the best course unless other medical conditions make general anesthesia exceptionally risky. Doppler ultrasonography may be helpful in uncertain cases.

The timing of exploration for prenatal torsion has been controversial. The classic teaching has been that surgical exploration is not indicated because of negligible salvage rates and increased neonatal anesthetic risks.<sup>22</sup> However, this has been challenged by reports of asynchronous torsion with devastating loss of the remaining contralateral testis.<sup>23-25</sup> Furthermore, if the torsion were to happen at or just prior to delivery, salvage may be possible. One series of 30 neonatal torsions explored within 6 hours of birth found two testes that could be salvaged and demonstrated normal growth 1 year later.<sup>26</sup> Therefore, many surgeons have become more aggressive with earlier exploration of these infarcted testes to fix the contralateral side and prevent potential bilateral torsion.

Unless other medical conditions preclude general anesthesia, our practice has been early exploration. This has the added benefit of ensuring the correct diagnosis because a testicular teratoma or a hernia sac filled with meconium or blood can mimic prenatal torsion. Postnatal torsion clearly mandates emergent exploration because salvage rates have been reported as high as 40% to 50%, which is similar to torsion later in life.<sup>27</sup> Surgical exploration is performed through an inguinal incision because a testicular tumor may be encountered in rare instances. In such a situation, a scrotal incision could lead to inguinal nodal spread.<sup>28,29</sup> Contralateral exploration is accomplished through a transverse scrotal incision, with placement of the testis in a dartos pouch between the external spermatic fascia of the scrotum and the dartos fascia. This technique is less traumatic to the small, delicate neonatal gonad and probably provides better fixation than sutures.<sup>15,16</sup>

## CONDITIONS MIMICKING TESTICULAR TORSION

### Torsion of Testicular Appendages

Torsion of the appendix testis or appendix epididymis is the most common cause of an acute scrotum and is frequently misdiagnosed as acute epididymitis or epididymo-orchitis. Morgagni is credited with the first description of an appendix testis in Padua, Italy, in 1761.<sup>30</sup> Torsion of the appendage was first reported by Colt in 1922 in Scotland.<sup>31</sup> The testicular appendage represents a vestigial remnant of the müllerian duct, and the epididymal appendage is of wolffian duct origin. Torsion of these appendages occurs most commonly between ages 7 and 10 years. It is thought that a prepubertal hormonal boost stimulates these structures, producing an increase in size and making them susceptible to twisting.<sup>32</sup>

Torsion of testicular appendages can mimic testicular torsion, with sudden onset of pain, and can be associated with nausea and vomiting. Results of urinalysis are normal. Early in the course, the appendage can be palpated and is exquisitely and focally tender. The examiner may be able to elicit differential tenderness between the upper and lower poles of the affected testis. Classically called the “blue dot” sign, the inflamed and ischemic appendage may be seen through the scrotal skin as a subtle blue-colored mass (Fig. 53-2).<sup>33</sup> As inflammation increases, however, the epididymis, testis, and scrotal tissues become edematous and erythematous and the diagnosis becomes more difficult. Ultrasonography can be diagnostic early in the presentation and demonstrates a discrete appendage. However, later, it may only show increased blood flow to the adjacent epididymis and testis or, possibly, a reactive hydrocele, resulting in the misdiagnosis of acute epididymitis or epididymo-orchitis.<sup>34</sup>

Torsion of these appendages is self-limited and is best treated with nonsteroidal anti-inflammatory medications and comfort measures such as restricted activity and warm compresses. The pain resolves as the appendage infarcts and necroses. It may then become a calcified free body within the tunica vaginalis. The syndrome can recur because there are

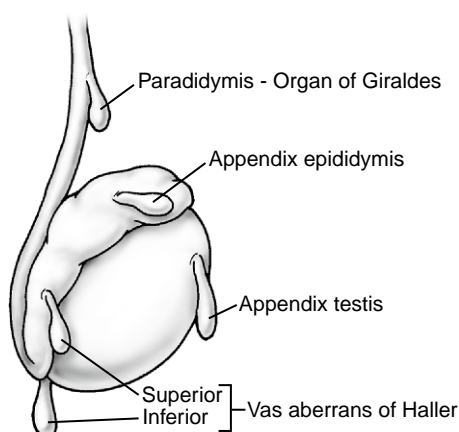

**Figure 53-2.** A torsed and gangrenous appendix testis is shown. This is the cause of the “blue dot” sign.

potentially five anatomic sites of appendages that can undergo torsion (appendix testis, appendix epididymis, paradidymis/organ of Giraldes, and superior and inferior vas aberrans of Haller) (Fig. 53-3).<sup>35-37</sup> Surgical exploration is indicated when the diagnosis of testicular torsion cannot be reliably excluded or when the symptoms are prolonged and fail to resolve spontaneously. The torsed appendage can be easily excised through a small scrotal incision with immediate symptom relief.

## Epididymitis

True bacterial epididymitis is quite rare in children, accounting for 10% to 15% of patients with an acute scrotum. It is commonly employed as an inaccurate, generalized diagnosis in a patient with scrotal pain without evidence of testicular torsion. Bacterial infection extends from the bladder and urethra to the epididymis in a retrograde direction via the ejaculatory ducts and may be associated with a clinical urinary tract infection or urethritis. The scrotal pain and swelling typically have a slow onset, worsening over days rather than hours. Examination reveals induration, swelling, and tenderness of the hemiscrotum. The edema will make palpation of the testis itself very difficult. A positive urinalysis and culture, or urethral swab in sexually active adolescents, suggests the diagnosis. *Neisseria gonorrhoeae* and *Chlamydia* are classically found in sexually active boys, but common urinary pathogens, including coliforms and *Mycoplasma* species, are more likely in younger children. When studies suggest a bacterial infection, appropriate antibiotic therapy is initiated and adjusted according to culture results. If acute epididymitis is found on scrotal exploration, cultures should be obtained, but the contralateral side should not be opened to avoid spreading the infection. As with any urinary tract infection in a boy, a renal bladder sonogram and voiding cystourethrogram should be obtained after the infection has resolved. Vesicoureteric reflux is the most common finding, but other abnormalities such as an ectopic

**Figure 53-3.** Testicular appendages. (From Rolnick D, Kawanoue S, Szanto P, et al: Anatomic incidence of testicular appendages. *J Urol* 100:755-756, 1968.)

ureter (to the vas, ejaculatory duct, or seminal vesicle), ejaculatory duct obstruction, or urethral valves can also be found.

Viral infections are believed to be a common cause for acute epididymitis but are usually diagnosed presumptively. Mumps orchitis occurs in approximately one third of postpubertal boys affected by the virus and fortunately is rare in the modern era of immunization.<sup>38</sup> Adenovirus, enterovirus, influenza, and parainfluenza virus infections have also been found. Management is supportive, antibiotics are not indicated, and the pain is generally self-limited. Aggressive testing is usually not warranted, but viral cultures and serologic studies may be useful in clustered familial or community cases.<sup>39</sup>

## Idiopathic Scrotal Edema

Scrotal swelling of unknown etiology is termed *idiopathic scrotal edema* and usually affects boys between the ages of 5 to 9 years. The syndrome is characterized by the insidious onset of swelling and erythema that typically begins in the perineum or inguinal region and spreads to the hemiscrotum. The condition may be associated with pruritus but is usually not painful. The testis is not tender on examination. Ultrasonography will show normal testicular blood flow and is not usually helpful. Many cases due to contact dermatitis, insect bites, and minor trauma are undoubtedly given this diagnosis. Evaluation should seek to exclude cellulitis from an adjacent infection (inguinal, perirectal, or urethral). The patient is managed with comfort measures, with antihistamines or topical corticosteroids possibly providing relief. If cellulitis is a concern, oral antibiotics can be administered.<sup>40</sup>

## Voiding Dysfunction

Voiding dysfunction is a common cause of scrotal pain, especially when it is bilateral, and is not commonly recognized unless the diagnosis is sought. The pain is the result of bladder instability causing high pressure voiding against a voluntarily closed external sphincter. Dilatation of the posterior urethra ("spinning-top urethra") is commonly seen on a voiding cystourethrogram in patients with voiding dysfunction. Urine may be forced up the ejaculatory duct, resulting in local inflammation and a "chemical" epididymitis or epididymo-orchitis.<sup>41</sup> A renal bladder sonogram may show a thickened bladder wall and is also useful to evaluate for ureteral ectopia to the ejaculatory duct or vas deferens as a potential cause in recurrent cases. There is no pathognomonic test for voiding dysfunction. However, a thorough history will often reveal urinary urgency, incontinence, a staccato urinary stream indicative of inappropriate sphincter activity, and occult constipation. Effective treatment strategies include timed voiding regimens, dietary modification, an aggressive bowel regimen to control constipation, and anticholinergic or  $\alpha$ -antagonist medication when appropriate.

## Henoch-Schönlein Purpura

Henoch-Schönlein purpura is a vasculitic syndrome that can involve the skin, joints, and gastrointestinal and genitourinary systems. Up to one third of patients may develop pain, erythema, and swelling of the scrotum and spermatic cord, most commonly in boys younger than 7 years of age. Although this condition may mimic testicular torsion, a Doppler ultrasound study will reveal normal blood flow to the testis. A thorough history and physical examination may reveal other systemic symptoms, such as skin purpura, joint pain, and hematuria. Supportive measures are typically adequate, although systemic corticosteroids may be helpful.<sup>42,43</sup> Despite the rarity of coincident diagnoses, cases of concurrent Henoch-Schönlein purpura and testicular torsion have been reported.<sup>44</sup>

## TESTICULAR TRAUMA

Testicular trauma in children is rare. The diagnosis can be made by taking a complete history, with careful attention to factors that may indicate sexual abuse. Examination of an injured testis will reveal swelling and

marked tenderness, associated with swelling and bruising of the scrotum. The most common injury is a hematoma of the testis. Ultrasonography should be obtained to evaluate for rupture of the tunica albuginea, which is an indication for operative repair. Repair is particularly important in postpubertal boys because of the potential for autoimmune injury to the opposing testis. A large hematoma in the space between the tunica vaginalis and the tunica albuginea should be evacuated to avoid pressure necrosis of the testis. Epididymal injuries can occur, including disruption of the epididymis from the testis, with a poor outcome likely after repair.

## OTHER CONDITIONS

Other causes of the acute scrotum include an incarcerated inguinal hernia, hydrocele, and neoplasia. Testicular tumors may occur in the neonatal period and early childhood, although they are usually not associated with pain or scrotal wall changes. They are usually firm on examination and should be further evaluated with ultrasonography. Management is tailored to the diagnosis. See Chapter 52 for more information about testicular tumors.

# DEVELOPMENTAL AND POSITIONAL ANOMALIES OF THE KIDNEYS

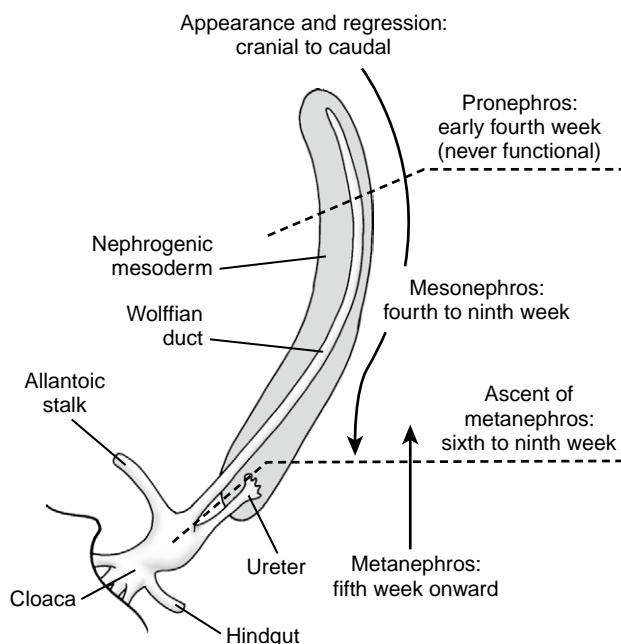

Hsi-Yang Wu, MD • Howard M. Snyder III, MD

Anomalies of renal formation and position result in interesting radiographs, but their clinical importance lies in their associated conditions. For example, the multicystic dysplastic kidney often involutes, yet the initial evaluation aims to determine that the contralateral kidney is not at risk from vesicoureteral reflux (VUR) or ureteropelvic junction (UPJ) obstruction. Whereas no therapy is needed for unilateral renal agenesis, the link between a solitary kidney and the VACTERL (vertebral, anal, cardiac, tracheoesophageal fistula, renal, limb) and Mayer-Rokitansky (vaginal agenesis) syndromes is the main reason for further evaluation. Hydronephrosis is often seen in abnormalities of position and rotation but does not necessarily mean that obstruction is present. Therefore, anomalies of renal formation and position often pose more of a diagnostic problem than a surgical one.

## RENAL EMBRYOLOGY

The pronephros, which has no adult function, induces the mesonephros to differentiate into the mesonephric duct during the 4th to 8th weeks of fetal life. The mesonephric duct is the basis of the wolffian system, which develops into the seminal vesicles, vas deferens, epididymis, and efferent ductules of the testis in boys and into the epoöphoron and paroöphoron (vestigial remnants between the fallopian tube and ovary) in girls. The ureteral bud branches off the mesonephric duct, contacts the metanephric blastema bud between weeks 9 and 12 of fetal life, and induces the entire collecting system of ureter, renal pelvis, calyx, and collecting tubules. The kidney develops via induction of the metanephric blastema by the ureteral bud into Bowman's capsule, the convoluted tubules, and the loop of Henle.<sup>1</sup> Figure 54-1 illustrates the progression of development from pronephros, mesonephros, to metanephros.

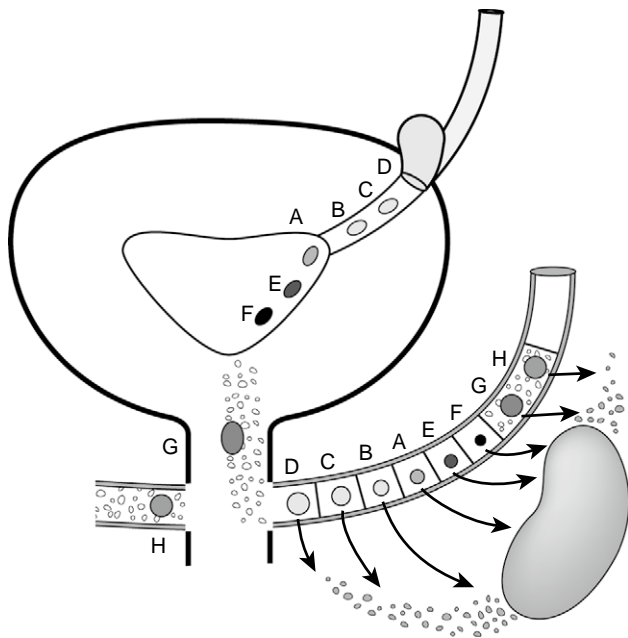

The kidneys begin at the upper sacral level with the renal pelvis facing anteriorly. The kidneys ascend either because the lumbar and sacral regions grow faster than the cervical and thoracic regions between 4 to 8 weeks or because there is active migration. As the kidneys ascend, the renal pelvis rotates medially by 90 degrees, leading to the normal configuration of the renal pelvis lying medial to the parenchyma. During this time, the blood supply shifts from the inferior branches of the aorta to more cephalad branches, with the final renal artery being located at about L2. Failure of normal ascent leads to the persistence of a low-lying blood supply.<sup>1</sup>

**Figure 54-1.** Development of the kidney. (Redrawn from Gray SW, Skandalakis JE: Embryology for Surgeons. Philadelphia, WB Saunders, 1972, p 444.)

## RENAL DYSPLASIA AND HYPOPLASIA

Because the development of the kidney depends on proper interaction between the ureteral bud and the metanephric blastema, it should not be surprising that an abnormality in the location of the ureteral orifice is associated with abnormally induced renal tissue.<sup>2</sup> Examination of the thickness of the renal parenchyma and number of glomeruli associated with normal and ectopic ureters in fetal specimens suggests that it is the initial interaction between bud and blastema that determines whether normal renal tissue will develop,

**Figure 54-2.** Relation of ureteral orifice location and associated metanephric tissue. (Redrawn from Mackie GG, Stephens FD: Duplex kidneys: A correlation of renal dysplasia with position of the ureteral orifice. *J Urol* 114:274-280, 1975.)

rather than subsequent obstruction or VUR.<sup>2</sup> Figure 54-2 shows how a ureter that arises in the proper trigonal location (see Fig. 54-2A, E, F) is associated with normal renal parenchyma, whereas a ureter arising from a more cranial location (see Fig. 54-2B-D) or caudal location (see Fig. 54-2G, H) is associated with progressively less normal renal parenchyma.

Renal dysplasia and hypoplasia can be considered errors in renal induction. Figure 54-3 shows varying changes, progressing from agenesis, dysplasia, and perhaps hypoplasia of the kidney. Although *dysplasia* is technically a histologic term, it refers to kidneys that contain primitive tubules either focally or diffusely. These ducts are lined by epithelium and surrounded by swaths of primitive collagen. No treatment is necessary for the dysplastic kidney, but there is a 14% risk of reflux in the contralateral kidney.<sup>3</sup> Hypoplastic kidneys are small, normal kidneys with a decreased number of nephrons. Dysplasia can also occur in hypoplastic kidneys. Whereas secondary hypoplasia can occur due to infection or obstruction, two types of hypoplastic kidneys are clinically important: the oligomeganephronic type and the Ask-Upmark kidney. In oligomeganephronia, there is a decrease in the number of nephrons with an associated hypertrophy of the ones that are present. Patients present with polyuria and failure to concentrate their urine but no hypertension. Imaging with ultrasound reveals small kidneys. Medical management with protein restriction and high fluid and salt intake is undertaken. Once the glomerular filtration rate drops significantly, dialysis is required.<sup>4</sup> The Ask-Upmark kidney was initially believed to be a developmental problem but is now believed to represent reflux nephropathy. The key finding is a small kidney with segmental hypoplasia, probably secondary to ascending pyelonephritis. VUR and hypertension are usually present. Most patients are older than 10 years of age with a 2:1 female-to-male ratio. If the disease is unilateral, nephrectomy may cure the hypertension. Bilateral disease is managed medically.<sup>5</sup>

**Figure 54-3.** Renal agenesis (A), dysplasia (B), and hypoplasia (C). (Redrawn from Gray SW, Skandalakis JE: *Embryology for Surgeons*. Philadelphia, WB Saunders, 1972, p 455.)

## RENAL AGENESIS

Absence of a kidney may be due to abnormal induction of the metanephric blastema or involution of a multicystic dysplastic kidney. The presence or absence of the ureter is helpful in suggesting the cause of renal agenesis. Absence of a hemitrigone implies that the ureteral bud failed to form properly. A normal trigone with some evidence of a ureter leading to a nubbin suggests involution of a multicystic dysplastic kidney.

Unilateral renal agenesis occurs in 1:1000 live births with a 2:1 male predominance.<sup>6,7</sup> Unilateral renal agenesis can result in compensatory hypertrophy of the contralateral kidney. The left kidney is more likely to be affected in unilateral renal agenesis.<sup>8</sup> Because unilateral renal agenesis is asymptomatic and eventual renal function is normal, the diagnosis is usually made on prenatal ultrasonography or it is incidentally found during imaging for other abdominal symptoms. Sometimes it can be suspected on plain abdominal films if the colon is medially deviated at the splenic or hepatic flexure.<sup>9</sup> These patients should consider obtaining a medical alert bracelet so that in case of traumatic injury, the solitary kidney is not inadvertently removed.

In a neonate with the prenatal diagnosis of unilateral renal agenesis, physical examination at the time of birth should be focused on detecting the anomalies present in the VACTERL association.<sup>10</sup> A voiding cystourethrogram (VCUG) should also be obtained because approximately 30% of patients with unilateral renal agenesis will have VUR in the contralateral kidney.<sup>10</sup>

Males with unilateral renal agenesis are at risk for abnormal wolffian structures. The vas and seminal vesicle may be absent, or the seminal vesicle may be present as a cyst while the ipsilateral testis will be normal. Because the seminal vesicle develops as a separate bud from the wolffian duct at 12 weeks, it can be present in cases of unilateral renal agenesis due to regression of a multicystic dysplastic kidney. Seminal vesicle cysts that are causing symptomatic obstruction are usually removed via a transvesical approach. Conversely, if a vas is found to be abnormal or absent during a hernia repair or orchiopexy, the kidneys should be evaluated postoperatively with ultrasonography.

Females with unilateral renal agenesis should have their genital anatomy evaluated because up to 30% will have an abnormality of the müllerian duct due to the Mayer-Rokitansky syndrome (müllerian, uterine, upper vaginal duplications with or without obstruction, or vaginal agenesis).<sup>11,12</sup> The abnormal induction of the mesonephric duct is believed to cause partial or complete nonunion of the paired müllerian ducts.<sup>13</sup> Conversely, 40% of patients with abnormalities of the müllerian organs will have unilateral renal agenesis or ectopia.<sup>14</sup> In patients with duplicated vaginas and unilateral vaginal agenesis, the side without a vagina is also the side without a kidney.<sup>13</sup>

If the diagnosis of Mayer-Rokitansky syndrome is not made prenatally, the patients can present either as infants with hydrocolpos or as adolescents with lower abdominal pain after the onset of menses due to an obstructed vagina or uterus (with or without

duplication). Magnetic resonance imaging (MRI) is useful in delineating the pelvic anatomy in these cases. In vaginal agenesis, the vagina is only present as a shallow pouch. There is a wide variety of abnormalities of the vagina, uterus, and fallopian tubes (Fig. 54-4), but the ovaries are embryologically normal.

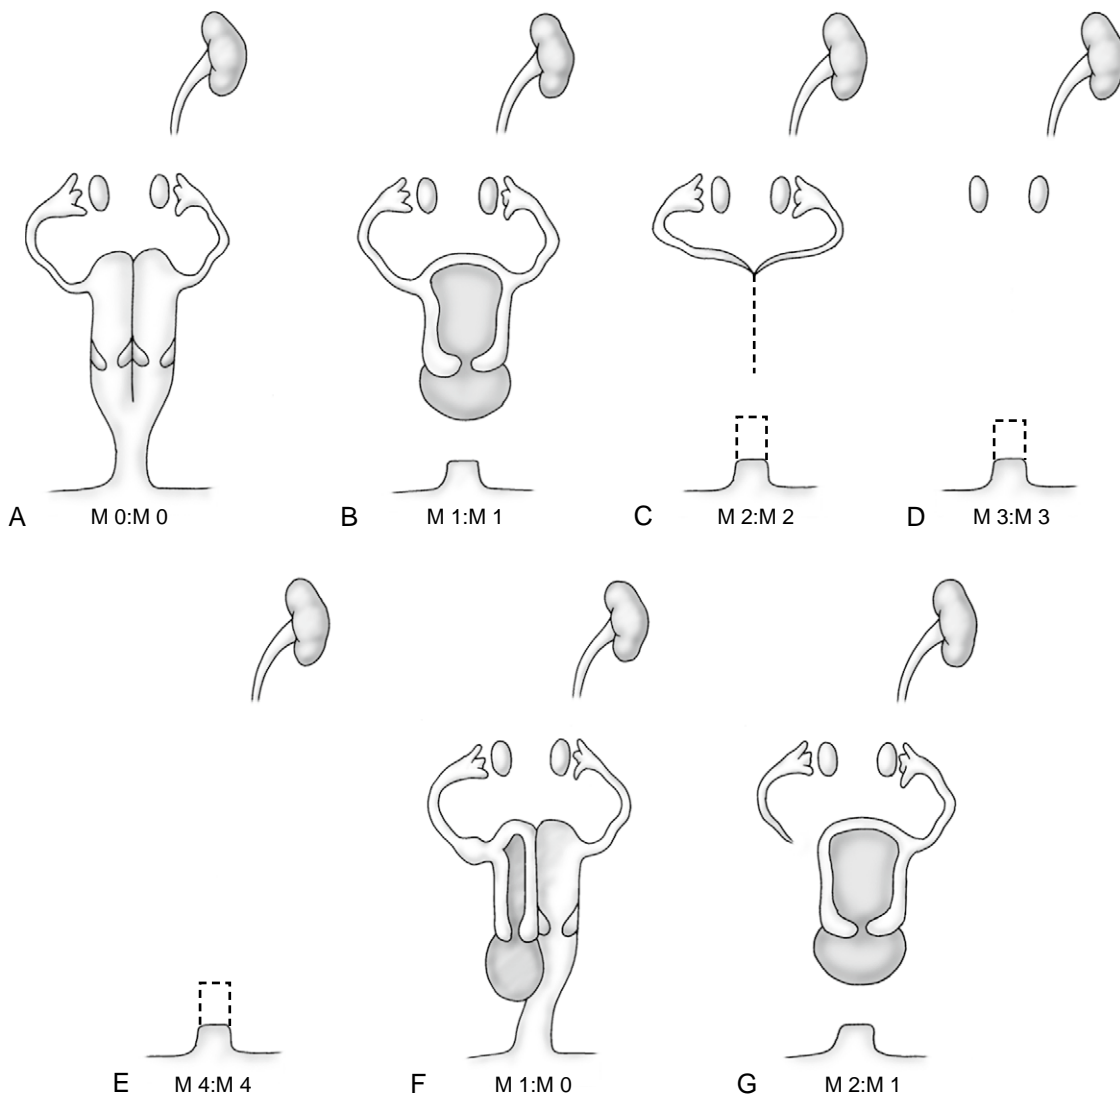

Bilateral renal agenesis occurs in 1:4800 live births and has a 3:1 male predominance.<sup>15</sup> Infants affected with bilateral renal agenesis present with oligohydramnios, pulmonary hypoplasia, Potter's facies (low-set ears, broad flat nose, a prominent skin fold beginning over the eye and running to the cheek), and the great majority die soon after birth of their pulmonary hypoplasia. The renal arteries and ureters are usually absent and the bladder is underdeveloped. The vas is usually present, but female genital structures are usually abnormal.<sup>16,17</sup> The adrenals are usually present but appear round, instead of flattened, owing to the lack of compression by the kidneys.<sup>15</sup> Prenatal diagnosis is useful in determining that heroic efforts at extracorporeal membrane oxygenation or hemodialysis are not indicated after delivery.

## SUPERNUMERARY KIDNEY

This is a rare condition in which a completely separate kidney is found in addition to two normally positioned kidneys. The additional kidney has its own blood supply and parenchyma and usually is found caudad to the normal kidney. It is usually smaller than the normally positioned kidney. This additional kidney represents abnormal induction of metanephric blastema by an abnormally directed ureteral bud, either as a separate ureteral bud from the mesonephric duct or as part of a "Y" duplication. If the supernumerary kidney is located cranial to the normal kidney, the ureter is usually completely separate and may enter the bladder ectopically. Presumably this is a result of a completely separate ureteral bud inducing the metanephric blastema and migrating very low on the mesonephric duct, separate from the normally positioned kidney.<sup>18,19</sup> If the ureter ends ectopically, it may present as incontinence in a girl or as infection in a poorly functioning renal unit. The diagnosis can be difficult to make.<sup>20</sup> Stone disease and hydronephrosis can be found in up to 50% of patients. Treatment should be reserved for these problems, because the presence of a supernumerary kidney itself is not worrisome.<sup>19</sup> Like other ectopic kidneys, these kidneys may be more subject to trauma, so a medical alert bracelet may be important.

## RENAL ECTOPIA

Failure of rotation, while not strictly ectopia, usually results in a kidney in which the renal pelvis is anteriorly directed. In the unusual situation in which hyper-rotation occurs, the renal pelvis can actually point posteriorly. The renal vessels are normally positioned. The renal pelvis and calyces will often appear abnormal due to their unusual orientation, which

**Figure 54-4.** Variations in müllerian anatomy in Mayer-Rokitansky syndrome. M0, Right or left vagina and uterus, or duplex vagina and uterus with partial or complex septum. M1, Partial or complete absence of vagina. M2, Absence of vagina and uterus. M3, Absence of vagina, uterus, and fallopian tube. M4, Absence of vagina, uterus, fallopian tube, and ovary. (Redrawn from Tarry WR, Duckett JW, Stephens FD: The Mayer-Rokitansky syndrome: Pathogenesis, classification and management. *J Urol* 136:648-652, 1986.)

results in an interesting intravenous urogram. With oblique views the anatomy can be established and does not usually require repair, even in poorly functioning units. The best method to localize even poorly functioning ectopic renal tissue is with a nuclear medicine study. There are two technical factors to be considered in interpreting renal scans in ectopic kidneys. First, the radionuclide in the bladder can overlap a pelvic kidney so a catheter may need to be inserted for the study. Second, the pelvic kidney is located farther anterior than orthotopic kidneys and the function may be artificially lowered by the distance of the kidney from the camera. Placing the patient prone may result in a more accurate assessment.

Simple ectopia results in a kidney that is located anywhere from the pelvis to the diaphragm. The incidence is 1:1000 live births with a 3:2 male predominance.<sup>21</sup> The contralateral kidney often also has an abnormality of rotation or ectopia. The development

of the ipsilateral adrenal is unaffected. A “thoracic kidney” is actually subdiaphragmatic, although it may lie in the chest through a focal eventration of the diaphragm. It is not associated with a true congenital diaphragmatic hernia.<sup>22</sup> An ectopic “abdominal kidney” is above the iliac crest, the “lumbar kidney” is anterior to the iliac vessels at the sacral promontory, and the “pelvic kidney” is below the aortic bifurcation and opposite the sacrum. All of these ectopic kidneys are more susceptible to trauma because they are not as well protected by the lower rib cage and are anterior in position. It may be advisable for these patients to avoid contact sports in which there is a risk of abdominal trauma.

Most ectopic kidneys are asymptomatic and are detected either on prenatal ultrasonography or incidentally on other imaging studies. Ectopic kidneys are at higher risk for UPJ obstruction, VUR, and stone formation. The anatomy can include an extrarenal pelvis and infundibulum and a high insertion of the

ureter into the pelvis. This anatomic arrangement can mimic a UPJ obstruction, so careful evaluation is necessary to avoid unnecessary surgery.<sup>23</sup> More than half will have a dilated renal pelvis. Of these, 50% are due to obstruction, 25% are due to reflux, and 25% are merely dilated without UPJ obstruction.<sup>24</sup> For repair of UPJ obstruction with a high insertion of the ureter, a side-to-side ureteropyelostomy or ureterocalycostomy to a dilated lower pole calyx is sometimes required to obtain dependent drainage.

Although endoscopic techniques for treatment of UPJ obstruction have been used in children,<sup>25</sup> the presence of anomalous vessels suggests that either an open or laparoscopic approach would be safer than endoscopic incision of a UPJ obstruction in an ectopic kidney. The advent of computed tomography (CT) angiography and magnetic resonance urography (MRU) has made the assessment of anomalous vessels in ectopic or horseshoe kidneys easier and more noninvasive.

## FUSION DEFECTS

### Horseshoe Kidney

A horseshoe kidney is found in 1:400 live births and has a 2:1 male predominance.<sup>26</sup> The kidney is usually lower than normal, since the lower poles fuse in the midline and drape anteriorly over the spine. The isthmus can be fibrotic or contain parenchyma. This anomaly is believed to occur at between 4 to 6 weeks of life, because the orientation of the renal pelvis is anterior. It is proposed that as the kidneys “hurdle” the iliac vessels during ascent they come into contact at the lower pole and fuse (Fig. 54-5). Other variations of upper pole and mid-pole contact are possible but much less common than the usual lower pole fusion. The kidney is usually low owing to its inability to ascend past the inferior mesenteric artery. Each renal moiety retains its ureter, which is draped over the isthmus. The renal pelvis is usually anterior. The arterial supply varies from the normal single vessel to each moiety to vessels arising from any conceivable nearby blood supply. Horseshoe kidneys are more commonly found in patients with sacral agenesis, high cloacae, and Turner’s syndrome (45,XO gonadal dysgenesis).<sup>27</sup> They are associated with a higher risk of renal cell carcinoma and Wilms’ tumor.<sup>28-30</sup> In one study the presence of a horseshoe kidney in the setting of a Wilms’ tumor was not suspected preoperatively in 13 of 41 patients despite imaging studies.<sup>30</sup>

One third of patients with a horseshoe kidney have no symptoms. The patients with symptoms often complain of vague abdominal or back pain. Ten percent have ureteral duplication, 50% have VUR, and 33% have UPJ obstruction.<sup>27,31,32</sup> Repair of UPJ obstruction in a horseshoe kidney requires placement of the anastomosis to avoid a secondary kinking at the UPJ. Division of the isthmus is not required. Treatment of kidney stones in horseshoe kidneys can be accomplished by extracorporeal shock wave lithotripsy, ureteroscopy, or percutaneous nephrolithotomy. Percutaneous approaches are

**Figure 54-5.** Variations of horseshoe kidney. (Redrawn from Benjamin JA, Schullian DM: Observations of kidneys with horseshoe configuration: The contribution of Leonardo Botallo. *J Hist Med Allied Sci* 5:315, 1950, after Gutierrez, 1931.)

sometimes difficult because the kidneys do not reside next to the body wall, making access to the collecting system difficult. However, percutaneous approaches result in a higher stone-free rate than ureteroscopy or shock wave lithotripsy.<sup>33,34</sup> Although there is no increase

in the rate of metabolic abnormalities in patients with horseshoe kidneys and kidney stones, suggesting that stasis in an extrarenal pelvis contributes to the formation of kidney stones,<sup>35</sup> patients with a horseshoe kidney and kidney stones are more likely to have hypocitraturia than other patients with kidney stones.<sup>36</sup>

### Cross-Fused Renal Ectopia

This anomaly is more common than crossed, nonfused renal ectopia and is more common in boys. The lower pole of one kidney crosses the midline to fuse with an orthotopically placed contralateral kidney. Usually the left kidney crosses the midline. Presumably during ascent, the left kidney encounters a roadblock, rotates, and fuses with the lower pole of the right kidney. The ureters insert in the normal position in the bladder. This has been described as an “S” or “L” shaped kidney. Diagnosis can be made using intravenous pyelography (IVP), CT, or MRU. Solitary crossed ectopia (unilateral renal agenesis, contralateral kidney crossed to opposite side) is a rare finding. Multicystic dysplasia, obstruction, and VUR can be found in the ectopic kidney.

## CYSTIC RENAL DISEASE AND CYSTIC TUMORS

### Autosomal Recessive Polycystic Kidney Disease

Autosomal recessive polycystic kidney disease (ARPKD) was formerly called infantile polycystic kidney disease, which is inaccurate because it can present in older patients. Although it occurs in 1:40,000 live births, many patients die soon afterward. The kidneys are

bilaterally enlarged, with very small cysts radially oriented throughout the parenchyma (Fig. 54-6). The cysts represent dilated collecting tubules. Periportal hepatic fibrosis also occurs in varying degrees and can lead to portal hypertension. The hepatic involvement appears to be inversely proportional to the renal involvement. The disease has been classified into four forms.<sup>37</sup> The severe perinatal form (>90% renal involvement) leads to death by 6 weeks from pulmonary hypoplasia. The neonatal form (60% renal involvement) is usually lethal by 1 year. The infantile form (25% renal involvement) results in hepatosplenomegaly, with survival up to 10 years. The juvenile form (<10% renal involvement) has severe periportal fibrosis. Some patients survive up to 15 years, but the development of portal hypertension is usually lethal. Because this is an autosomal recessive disease, screening of the family should be undertaken to determine which siblings are carriers.

A prenatal ultrasound evaluation showing bilaterally enlarged, echogenic kidneys suggests ARPKD. The IVP or CT shows a classic striated “sunburst” pattern. Unfortunately, the prognosis is poor for the perinatal or neonatal forms of ARPKD. The patients who survive the neonatal period seem to do well with some degree of renal insufficiency. Eventually, dialysis is usually required. In older patients, the kidneys become smaller as renal failure develops. The overall treatment for ARPKD is supportive, with renal transplantation being the ultimate therapy.

### Autosomal Dominant Polycystic Kidney Disease

Although autosomal dominant polycystic kidney disease (ADPKD) tends to clinically present in the third to fifth decades, it has been diagnosed in the ultrasound

**Figure 54-6.** Gross pathology of autosomal recessive polycystic kidney disease.

era in asymptomatic children as well. The cysts in ADPKD are different in configuration, being few and scattered in distinction to those seen in ARPKD. This condition occurs in 1:500 patients.<sup>38</sup> Patients usually present with flank pain, hematuria, hypertension, and possibly renal failure, if there are extensive bilateral cysts. Neonates can present with renal enlargement, although children from affected families who are screened usually only have a few cysts. Failure to see cysts on screening ultrasonography in a child at risk for ARPKD does not exclude the disease because the cysts can develop later in life. Linkage analysis of the loci on chromosome 4 and 16 is more sensitive.<sup>39</sup> The cysts are located throughout the cortex and medulla, although the fetal form seems to affect the glomeruli predominantly. Hepatic involvement is limited to biliary cysts. Associated findings include cysts in the spleen, pancreas, and lungs; mitral valve prolapse; colon diverticula; and berry aneurysms of the circle of Willis.

Hypertension is commonly found in these children and may be part of the presentation. Renal failure in childhood is very rare. Periodic evaluation of blood pressure and proteinuria during childhood is recommended.<sup>40,41</sup> Unlike ARPKD, there is no increased risk of renal cell carcinoma. Renal transplant candidates can obtain organs from family members who have been screened for the disease.

### Multicystic Dysplastic Kidney

The multicystic dysplastic kidney (MCDK) is believed to be caused by severe early ureteral obstruction or a failure in ureteral bud/metanephric blastema induction.<sup>42,43</sup> The main differential diagnosis is severe hydronephrosis due to UPJ obstruction. Radiographically, this occurs when the peripheral cysts surround a dominant central cyst mimicking the renal pelvis ("hydronephrotic" form of MCDK). The classic ultrasound appearance shows cysts randomly distributed throughout the kidney without a dominant medial cyst or evidence of communication between cysts. The parenchyma, if present, has abnormal echogenicity and is seen between the cysts, instead of being arranged on their periphery. A renal scan will show no function in an MCDK. The affected area may be the upper pole of a duplicated collecting system or one half of a horseshoe kidney.

The MCDK is the most common renal cystic mass in the newborn. Currently, most are detected on prenatal ultrasonography. Bilateral forms are not compatible with life. Postnatal evaluation consists of a VUG to look for VUR in the contralateral kidney, which occurs 30% of the time.<sup>44</sup> If there is significant hydronephrosis (caliectasis) in the contralateral kidney (this occurs 12% of the time), then a diuretic renal scan may be necessary. Contralateral UPJ obstruction or VUR is more likely with a smaller MCDK or a lower ureteral atresia ipsilateral to the MCDK.<sup>45,46</sup> There are reports of malignancy arising from an MCDK, although it is unclear whether the affected kidneys were truly MCDK.<sup>47</sup> Hypertension has also been reported in association with MCDK, although

**Figure 54-7.** Resected multicystic dysplastic kidney.

resection is not always curative and the rate does not appear to be any higher than in the general population.<sup>48</sup> An MCDK usually involutes, but it can occasionally grow.<sup>48</sup> The follow-up is repeat imaging with ultrasonography every 6 months for the first 2 years of life. It is not usually feasible to monitor a patient indefinitely for an MCDK. We have taken an operative approach at 18 to 24 months of life if the MCDK is not involuting or if parenchyma remains visible on the sonogram. Although the indications are controversial, the kidney can be removed at that age via a small incision as an outpatient procedure (Fig. 54-7). Occasionally, the MCDK can involute prenatally, leaving a ureter with a small nubbin of tissue in the renal fossa. These were previously called "aplastic" kidneys but are now believed to represent the remnants of an MCDK.

### Cystic Nephroma

Formerly called a "multilocular cyst," this is a well-demarcated tumor of cysts with an overall round configuration, lined with epithelium and septa that contain tubules.<sup>49</sup> It is considered to be the benign end of a spectrum progressing from cystic Wilms' tumor, cystic partially differentiated nephroblastoma, to cystic nephroma. It usually is found in boys younger than age 4 (male-to-female ratio 2:1) or women older than 30 (female-to-male ratio 8:1). It is rarely bilateral and is cured by partial nephrectomy, shelling out the tumor by following the plane of the pseudocapsule. There is a risk of sarcomatous degeneration in adults if it is not removed.<sup>50</sup>

## Cystic Partially Differentiated Nephroblastoma

This lesion was formerly called a multilocular cystic nephroma. It is radiologically identical to the cystic nephroma and can only be diagnosed pathologically. The majority of patients are boys younger than 2 years old or women in their third to fourth decades. A classic (but not diagnostic) radiologic finding is herniation of a parenchymal mass into the renal pelvis.<sup>22</sup> The tumor is usually well circumscribed. Hemorrhage and calcification are usually absent. Pathologically, it differs from the cystic nephroma in that there is blastema found in the septations.

Patients usually present with an asymptomatic flank mass and, occasionally, hematuria. Surgical treatment consists of partial nephrectomy as for cystic nephroma, since the tumors rarely recur and are not multifocal. No chemotherapy is required for stage I (limited to capsule, fully resected) tumors. Although experience is limited, stage II (outside renal capsule but fully resected) tumors are usually treated with vincristine, dactinomycin, and doxorubicin. Four-year survival for both stages is 100%.<sup>51,52</sup>

## Simple Cysts and Calyceal Diverticula

The simple renal cyst on ultrasonography has the following characteristics: distinct wall, no internal echoes, and posterior enhancement. If these criteria are not met, a CT scan is obtained to confirm that the fluid does not enhance. The differential diagnosis is a calyceal diverticulum or hydrocalyx, both

of which communicate with the collecting system and in which the fluid should enhance on either IVP or CT. Ultrasonography is able to detect milk of calcium layering within a diverticulum. Calyceal diverticula require treatment when they harbor stones or infection. In the IVP era, 40% of calyceal diverticula were believed to be symptomatic.<sup>53</sup> In the ultrasound era, with its greater number of incidental findings, it is not clear how often calyceal diverticula require treatment. Minimally invasive approaches such as percutaneous, laparoscopic, and ureteroscopic ablation appear to be equally successful.<sup>54</sup>

Simple cysts reside in the cortex and are lined by simple columnar epithelium. They can grow, resorb, or remain the same size. They are usually asymptomatic and are found incidentally. Once they are found, we usually follow the patient with ultrasonography at 3- to 6-month intervals to determine if the cyst is growing. The underlying concern is whether this cyst is the first sign of ADPKD. A family history of renal cystic disease, renal failure, or death in the neonatal period from unknown causes should be sought. Biopsy to rule out tumor, followed by drainage, or unroofing should be undertaken only if the cyst characteristics are other than those listed for a simple cyst or if the cyst becomes symptomatic due to obstruction of an infundibulum or the UPJ. Minimally invasive approaches such as percutaneous puncture with instillation of sclerosing agents (absolute alcohol, bismuth, povidone-iodine<sup>55</sup>) or laparoscopic decortication<sup>56</sup> may shift the threshold for treatment of large asymptomatic simple cysts.

# URETERAL OBSTRUCTION AND MALFORMATIONS

Tyler Christensen, MD • Douglas E. Coplen, MD

**H**ydroureter and ureteral malformations are among the most common abnormalities of the urinary tract in children. Historically, these anomalies were first identified during evaluation of urinary tract infections, abdominal pain, or incontinence. However, with the increasing use of fetal and neonatal ultrasonography, they are now often detected before symptoms develop. Urinary tract dilation is present in 1 in 100 fetuses, but significant uropathy is found in only 1 in 500.<sup>1</sup> Thus, the surgeon must critically evaluate these findings to determine their clinical significance and whether intervention is required.

## URETEROPELVIC JUNCTION OBSTRUCTION IN CHILDREN

With ureteropelvic junction (UPJ) obstruction, there is inadequate drainage of urine from the renal pelvis into the ureter, resulting in hydrostatic distention of the renal pelvis and intrarenal calyces. The combination of increased intrapelvic pressure and stasis of urine in the collecting ducts results in progressive damage to the kidney.

Historically, the incidence of UPJ obstruction has been estimated at 1 in 5000 live births. However, with the advent of antenatal ultrasonography, the prevalence of dilation has been found to be much higher. Recent retrospective reviews have shown that although the incidence of detected dilation has increased, the actual number of operations for UPJ obstruction has been relatively constant at 1:1250 births.<sup>2,3</sup> UPJ obstruction is more common in boys (2:1), and two thirds occur on the left side. Bilateral UPJ obstruction occurs in 5% to 10% of patients and is much more frequently seen in younger children.<sup>4,5</sup>

### Etiology

During development of the upper ureter, the lumen of the ureteral bud solidifies with ureteral lengthening and later recanalization.<sup>6</sup> Failure to recanalize adequately is

thought to be the cause of most intrinsic UPJ obstructions. Other causes of intrinsic UPJ obstruction include ureteral valves, polyps, and leiomyomas.<sup>7</sup>

At operation, the most common observation is ureteral narrowing of a variable length that joins the renal pelvis above the expected dependent position.<sup>8</sup> This “high insertion” of the ureter causes an angulation with respect to the renal pelvis. At low-volume states, peristaltic waves of urine cross the UPJ. However, as the flow increases beyond a threshold, the renal pelvis dilates.<sup>9</sup> The dilated pelvis may functionally kink the ureter further, increasing the pelvic pressure.<sup>10</sup> In 20% to 30% of patients, the ureter is draped over a lower-pole vessel, producing an extrinsic UPJ obstruction. This aberrancy may be secondary to incomplete renal rotation that is associated with a normal segmental vessel.<sup>11,12</sup>

Histologic evaluation reveals a decrease or complete absence of smooth muscle fibers at the UPJ.<sup>8,13</sup> Electron microscopy may show an increase in collagen deposition between the muscle fibers that is, most likely, a response to the obstruction as opposed to the cause.<sup>14</sup> Fibrosis and interruption of the smooth muscle continuity block transmission of the peristaltic wave while defective innervation also may play a role.<sup>15,16</sup> UPJ obstruction can be acquired. It has been observed in late follow-up of high-grade vesicoureteral reflux (VUR), after cutaneous ureterostomy, and after decompression of the dilated urinary tract. In these cases, the obstruction is caused by extrinsic scarring and adhesions that cause fixed deformation and distortion of the UPJ. VUR is present in 14% of patients with UPJ obstruction.<sup>17,18</sup>

### Clinical Presentation

Most renal dilation and obstruction is now detected prenatally (Fig. 55-1). Less frequently, it is detected because of an abdominal mass, urinary tract infection, association with other anomalies (i.e., VACTERL syndrome), or abnormalities seen during contrast or

**Figure 55-1.** These neonatal ultrasound images were performed in infants noted to have renal pelvic dilation found on prenatal ultrasonography. **A**, The findings here are essentially normal. There is a dark renal pyramid and no renal pelvic dilation. **B**, This image shows renal pelvic dilation with minimal caliectasis. **C**, Note diffuse caliectasis and mild cortical thinning. **D**, Severe hydronephrosis with cortical thinning is evident.

radionuclide radiography. In older children, vague, poorly localized, cyclic, or acute abdominal pain associated with nausea is common. Some of these children are initially seen by gastroenterologists. The cause for the intermittent obstruction is unclear, but renal function is almost always preserved. Hematuria after minor trauma or vigorous exercise may be a presenting feature, most likely secondary to rupture of mucosal vessels in the dilated collecting system.<sup>4</sup> Episodic flank pain associated with diuresis is a common presenting feature in young adults but is uncommon in children.

## Diagnosis

When the antenatal diagnosis of UPJ obstruction is made, the initial postpartum evaluation should be performed at 10 to 14 days of life to avoid false-negative studies resulting from neonatal dehydration. Bilateral UPJ obstruction is rarely associated with significant enough obstruction to cause oligohydramnios and warrant antenatal intervention. The neonate is placed on preventive amoxicillin (10 mg/kg once a day), pending the results of the studies. Ultrasonography confirms the presence of pelvic and calyceal dilation, with variable thinning of the renal parenchyma (see Fig. 55-1). The presence of corticomedullary junctions is indicative of preserved function.<sup>19</sup> Ultrasound is used to evaluate the contralateral kidney, the bladder, and the distal ipsilateral ureter to avoid confusion with a ureterovesical junction (UVJ) obstruction, but it will not provide functional information.

A voiding cystourethrogram (VCUG) was previously indicated in all patients being evaluated for UPJ obstruction. VUR increases the chance that infection will occur, even in a partially obstructed system. However, with a larger percentage of dilation now being seen with prenatal ultrasonography, it is clear that a VCUG is not required in all children with dilation because only 5% to 30% will have reflux and the majority will spontaneously resolve without infectious complications.<sup>20</sup> Children with isolated pyelectasis and no ureteral dilation have a very low incidence of reflux and may not require a screening VCUG. VUR that leads to kinking of the UPJ may be the primary disease process in some cases (Fig. 55-2).

The diuretic isotopic renogram is the most useful technique in the evaluation of hydronephrosis, differential renal function, and drainage of the kidneys. In this study, the transit of an injected radioisotope through the urinary tract is monitored by a gamma camera. The early uptake of the tracer indicates the split renal function, while the washout, augmented by the administration of a diuretic, is evaluated and plotted by a computer to demonstrate drainage.<sup>21,22</sup> The study is obtained with either technetium-99m-labeled diethylenetriamine pentaacetic acid (<sup>99m</sup>Tc-DTPA), whose renal clearance is by glomerular filtration, or with <sup>99m</sup>Tc-mercaptoacetyltriglycine (<sup>99m</sup>Tc-MAG3), whose clearance is predominantly via proximal tubular secretion. <sup>99m</sup>Tc-MAG3 is more efficiently excreted than <sup>99m</sup>Tc-DTPA and gives better images, particularly in patients with impaired renal function.<sup>21,22</sup>

**Figure 55-2.** Vesicoureteral reflux and secondary ureteropelvic junction (UPJ) obstruction in a 4-year-old boy first seen with urosepsis. **A**, Intravenous pyelogram (IVP) with a full bladder shows typical findings of calyceal blunting and renal pelvic dilation. Visualization of the distal ureter suggests reflux. **B**, Cystogram shows bilateral reflux. Note the marked discrepancy in left-sided anatomy between the IVP and cystogram and the kink just distal to the UPJ on the left side. **C**, Delayed film after a cystogram shows stasis and apparent obstruction on the left side. Subsequent furosemide wash-out renal scan with a bladder catheter showed no evidence of obstruction, and the child has done well after bilateral ureteral reimplantation.

The technique for diuretic renography is standardized.<sup>23</sup> Patients should be hydrated intravenously (15 mL/kg) 15 minutes before injection of the radionuclide. An indwelling catheter maintains an empty bladder and monitors urine output. The diuretic (1 mg/kg furosemide, up to 40 mg) is not administered until the activity in the hydronephrotic kidney and renal pelvis peaks. The tracer activity is then monitored for an additional 30 minutes, and a quantitative analysis is performed. Historically, persistence of more than 50% of the tracer in the renal pelvis 20 minutes after diuretic administration ( $t_{1/2} > 20$ ) is diagnostic of obstruction, although the applicability of this cutoff in pediatric patients is widely debated. False-positive results may occur when the immature neonatal kidney fails to respond to diuretic, when the patient is dehydrated, when the bladder is distended, or when the pelvis is significantly dilated.

Magnetic resonance (MR) urography can be used at any age. T2-weighted images are independent of renal function, and hydronephrosis is readily detected. The anatomic images are excellent, but a good ultrasound image often gives the same information. Enhanced MR images with gadolinium can give information regarding differential function if one kidney is anatomically and functionally normal.<sup>24</sup>

Intravenous pyelography (IVP) has limited use in the neonate because the neonatal kidney does not concentrate contrast medium well enough to provide adequate visualization of obstructed kidneys. It also is subjective with respect to the differential renal function and degree of obstruction. This test may be indicated when

more information is required regarding preoperative pelvic anatomy or to define better the level of obstruction when it is not clear from other studies.<sup>5</sup> In the child with intermittent flank pain, IVP may be diagnostic when performed during an episode of pain (Fig. 55-3).

Rarely, when imaging is equivocal, invasive pressure flow studies may be indicated.<sup>25</sup> These tests assume that obstruction produces a constant restriction to outflow that necessitates elevated pressure to transport urine at high flow rates. However, not all obstructions are constant. If the obstruction is intrinsic, a linear relation exists between pressure and flow. However, in some cases, the test results reflect only the response of the renal pelvis to distention and may be positive in the absence of obstruction.<sup>10</sup> These methods require general anesthesia in children and have limited applicability.

Retrograde urography at the time of surgical correction is helpful if uncertainty exists regarding the site of obstruction. This is rarely required because a well-performed ultrasound evaluation and radionuclide study will exclude distal obstruction.<sup>26</sup> Because risks exist when using instruments in the infant male urethra and the ureteral orifice, the routine use of retrograde studies is not recommended.

## Management

### *Indications for Surgical Intervention*

Intermittent obstruction and pain are probably the most reliable indication for surgery. However, there is no absolute or perfect definition of obstruction.

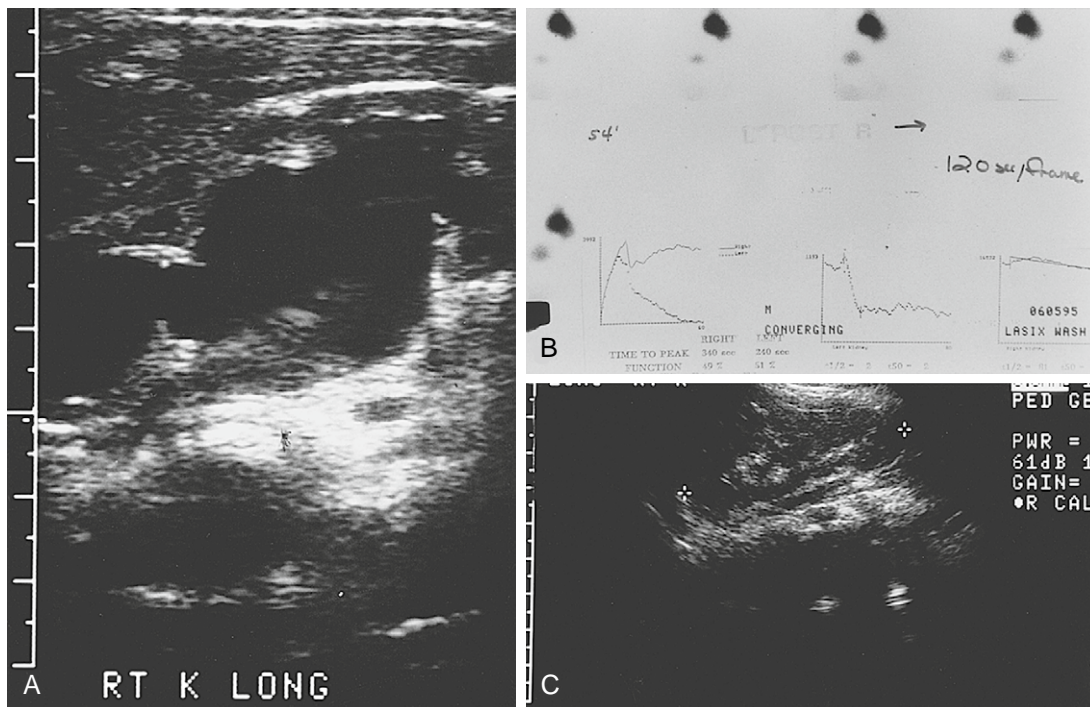

**Figure 55-3.** A prenatal ultrasound image of a male fetus showed left renal dilation. The left dilation resolved by age 3. On prior ultrasound images, the right kidney was always normal in appearance. **A**, A noncontrast CT scan was obtained in this patient at 5 years of age because of severe right-sided abdominal pain. A dilated renal pelvis (*asterisk*) is identified without urolithiasis. **B**, Intravenous pyelogram confirms a dilated renal pelvis and a kink (*arrow*) at the junction of the ureter and the renal pelvis.

Diminished function, delayed drainage, progression of dilation on ultrasound imaging, and loss of renal function are all potential indicators of obstruction. Randomization to surgical and observational arms is complicated by a difficult decision that a parent has to make for the asymptomatic child.<sup>27-30</sup> Relying on the morphologic appearance of a dilated renal pelvis by using excretory urography or ultrasonography is an insufficient basis on which to proceed with operation because many of these apparent abnormalities will completely resolve without surgical intervention (Fig. 55-4).<sup>31</sup> Neonatal hydronephrosis can be

explained by physiologic polyuria and natural kinks and folds in the ureter.<sup>32,33</sup>

The ongoing debate in the management of neonatal UPJ obstruction centers on the definition of significant obstruction.<sup>28-30</sup> Diuretic renography has limitations in the neonate, although using the “well-tempered” approach increases its value.<sup>24</sup> The accumulation of the isotope in the dilated collecting system is quite variable so that the timing of the diuretic can be premature or delayed. The standard half-time of 20 minutes for obstruction in the neonate is misleading in many cases.

**Figure 55-4.** Neonatal ureteropelvic junction (UPJ). **A**, Ultrasonography shows cortical thinning, caliectasis, and renal pelvic dilation consistent with UPJ obstruction. **B**, Furosemide washout renal scan. Computer analysis is on the bottom: Time to peak function shows symmetric uptake in the first 2 minutes. Radionuclide drains out of the left kidney before the administration of diuretic. The drainage half-time from the right kidney is prolonged and was calculated to be 81 minutes. On the basis of good renal function, observation was elected. **C**, Follow-up sonogram 1 year later is normal. Renal scan at that time showed symmetric function with normal washout (5 minutes).

Differential renal function or individual kidney uptake is the most useful information obtained during renography.<sup>22-24</sup> An indication for operative treatment is diminished renal function in the presence of an obstructive pattern on renography. The cutoff point is arbitrary, but most centers believe that less than 35% to 40% function in the hydronephrotic kidney warrants surgical correction. However, one series of patients with dilated kidneys and no more than 25% total renal function were found to improve to more than 40% of total function in all cases without surgical treatment.<sup>31</sup> Long-term studies of kidneys with greater than 40% function have shown that fewer than 15% to 20% will require surgical treatment for diminishing function, urinary tract infections, or unexplained abdominal pain.<sup>34,35</sup> Some of these kidneys will regain some of the lost function.

The ultimate concern with an observational approach is that delaying surgical intervention until measurable deterioration of renal function occurs is suboptimal. In the past, urinary stasis (infection, calculi, hypertension, pain) was the indication for correction. Whether more emphasis should be placed on stasis and less emphasis on differential renal function is an unanswered question.<sup>36</sup> Pyeloplasty can be safely performed in the infant.<sup>37,38</sup> Early intervention eliminates the indefinite period of surveillance. The decision to follow neonates nonoperatively requires vigilance and parental cooperation to avoid unnecessary complications.

If the child is first seen with acute pain or infection, it is advisable to wait 1 to 2 weeks to allow the inflammation to resolve. Percutaneous drainage for sepsis is rarely required preoperatively. It should be strictly avoided in the absence of infection because of the inflammation that a tube in the renal pelvis induces. Exploration of a poorly functioning kidney requires assessment of the renal parenchyma. If the parenchyma is grossly dysplastic or frozen-section analysis shows only dysplasia, then nephrectomy should be performed. No test accurately predicts recovery of function. Thus, nephrectomy is rarely performed in the infant with UPJ obstruction.

## Operative Techniques

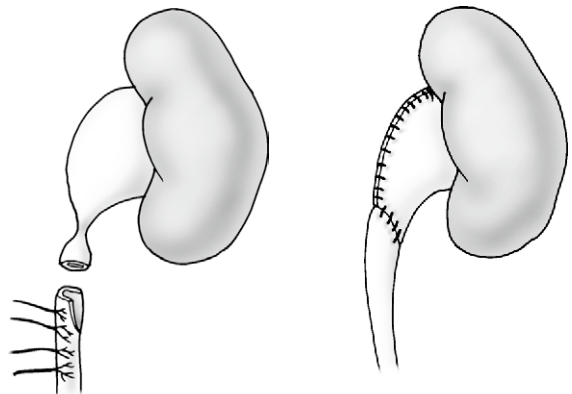

Because the flank approach is the most difficult, and it is easy to commit errors of position and rotation, the anterior extraperitoneal approach or posterior lumbotomy approach is preferred. The anterior approach involves a transverse incision from the edge of the rectus to the tip of the 12th rib.<sup>39</sup> The retroperitoneum is entered and the UPJ is exposed, with the kidney left in situ. In infants, this is a muscle-splitting incision with low morbidity. The posterior lumbotomy also can be easily performed in infancy and provides direct access to the UPJ.<sup>40</sup> The kidney does not require mobilization, and the ureter and renal pelvis can usually be brought up into the incision. In bilateral cases, the child does not need to be repositioned. The lumbotomy approach should not be used with a malrotated kidney or a kidney that has an intrarenal pelvis. Also, it is more

difficult in a very muscular patient. An anterior or flank approach is always preferred for reoperation.

The result of any pyeloplasty is a funnel-shaped, dependent UPJ complex. Older techniques, including the Foley YV-plasty and the Culp spiral flap, were designed to maintain the continuity of the ureter and the pelvis.<sup>41,42</sup> These techniques are used in unusual cases of malrotation, fusion anomalies, or long, stenotic segments. The dismembered technique consistently provides the best results (Fig. 55-5). With this approach, the renal pelvis and upper ureter are mobilized and the ureter is divided just below the obstructing segment. It is spatulated on its lateral border through the aperistaltic segment. If the segment is particularly long, this is identified before the renal pelvis is reduced, and a flap of renal pelvis can be created. Usually, it is necessary to resect some of the renal pelvis to avoid postoperative obstruction.

Gentle handling of the pelvic and ureteral tissue is important. Excessive manipulation of these tissues increases edema. Pyeloplasties are frequently performed without diversion, so it is important to be as gentle as possible. Fine chromic stay sutures allow atraumatic manipulation of the ureter and renal pelvis. A retractor is placed only after dissection is completed so that the pyeloplasty can be more appropriately designed. The anastomosis is performed with 6-0 polydioxanone or 6-0 polyglycolic acid. The anastomosis begins at the most dependent portion of the pyeloplasty with placement of interrupted everting sutures that do not bunch the tissues and cause obstruction. After the anastomosis to the dependent portion of the pyeloplasty is completed, the remainder of the ureter and pelvis can be approximated with continuous suture, taking care to irrigate any clots from the pelvis before the closure is completed. It is not necessary to pass a catheter distally into the bladder because preoperative studies should have excluded a distal obstruction.

Pyeloplasty can be safely performed without nephrostomy tubes or stents.<sup>43</sup> Even if leakage from the anastomosis occurs, a satisfactory outcome can usually be expected. A Penrose drain is left near the anastomosis and can usually be removed within 48 hours.

**Figure 55-5.** Dismembered pyeloplasty showing reduction of the renal pelvis and spatulation of the ureter (see text).

If drainage is prolonged, the child can be discharged with the drain in place.

Nephrostomy tube drainage is indicated when simultaneous bilateral pyeloplasties are performed. In small children, the ureter may be a thin diaphanous structure, in which case nephrostomy decompression will reduce the chance of postoperative obstruction. A stent (theoretically holding the ureter open and preventing synechiae formation) is usually not required. When the patient has poor preoperative renal function, a nephrostomy provides postoperative decompression and will allow a low-pressure study of the anastomosis before its removal. Once free flow across the anastomosis is demonstrated, it is unlikely that future obstruction will occur. This is reassuring when postoperative pyelography or diuretic renography is difficult to interpret because of reduced function. In reoperation, a nephrostomy is always placed because it is technically more difficult to achieve a watertight anastomosis.

Extrinsic UPJ obstruction associated with an aberrant lower-pole vessel requires division of the ureter at the UPJ and performance of a standard dismembered pyeloplasty after transposing the ureter to a nonobstructed position. In the case of an intrarenal pelvis or when significant scarring exists at reoperation, a ureterocalicostomy is a useful adjunctive technique.<sup>44</sup> Amputation of the lower pole is required to prevent a postoperative stricture. The ureter is spatulated and anastomosed to a calyx in the lower pole.

Endoscopic approaches to UPJ obstruction have been routinely used in adults for the last 10 to 15 years but have now been largely replaced by laparoscopic approaches.<sup>45,46</sup> Endoscopic relief of UPJ obstruction in children can be performed either percutaneously or retrograde by using a cutting current across the aperistaltic segment.<sup>47</sup> An indwelling ureteral stent is left for 4 to 6 weeks. The best results in children do not approach the near 100% success of open pyeloplasty. Endopyelotomy clearly has a role in recurrent UPJ obstruction, in which the success approaches 100%.<sup>47</sup>

The first laparoscopic pyeloplasty in a child was reported in 1995 by Peters.<sup>48</sup> The first series was published by Tan in 1999.<sup>49</sup> Laparoscopic pyeloplasty has been reported in children as young as 2 months.<sup>50</sup> Some pediatric urologists have been hesitant to adopt this technique owing to the difficulty of intracorporeal suturing and the increased operative time. The introduction of robotic surgery with articulating instruments and three-dimensional visualization has made intracorporeal suturing easier and more precise. The success rate with minimally invasive techniques are similar to open procedures and vary from 87% to 100%.<sup>51</sup> The benefits of laparoscopic and robotic surgery over an open approach include a decreased length of hospitalization, decreased analgesic requirements, improved cosmesis, and quicker return to normal activity.<sup>52</sup>

Laparoscopic pyeloplasties are mostly performed using the Anderson-Hynes dismembered technique. They can be performed through either a transperitoneal or retroperitoneal approach with a similar technique

once access and exposure is obtained. With both transabdominal and retroperitoneal approaches, the child is placed in a flank or modified flank position.

### *UPJ Obstruction in a Duplex Kidney*

The lower pole of a duplex kidney is most commonly affected because the segment in the upper pole lacks a true pelvis.<sup>53</sup> Ultrasonography may not be reliable for diagnosis because the duplex nature of the kidney may not be identified. A pyelogram or renogram will show a small nonobstructed upper segment.

The anatomy of the duplication influences the operation. If the ureter is incompletely duplicated and a long lower-pole ureteral segment is found, a standard dismembered pyeloplasty can be performed. If a high bifurcation with a short distal segment is found, then the end of the renal pelvis can be anastomosed to the side of the upper-pole ureter. These options can be assessed after the kidney and pelvis are exposed.

## **Surgical Results and Complications**

The results of surgical correction have been uniformly successful<sup>26,34,43</sup> when performed at children's hospitals. The rate of recurrent UPJ obstruction is less than 1%, and the nephrectomy rate is less than 2%. The most common early complications are prolonged urinary extravasation and delayed drainage through the anastomosis. When an anastomotic leak persists beyond 14 days, continuity of the renal pelvis and ureter must be assessed with an antegrade or retrograde pyelogram. If a significant leak is present, either a stent or a percutaneous nephrostomy tube should be inserted. Once diversion is instituted, the leak will usually cease within 48 hours. Late scarring at the anastomotic site is common in these situations.

Delayed opening of the anastomosis is seen most commonly when a nephrostomy tube is used. When this occurs, patience is important because 80% of these will open in 3 months. Secondary obstruction or failure of the primary procedure occurs due to scarring or fibrosis, a nondependent anastomosis, ureteral angulation secondary to renal malrotation, or ureteral narrowing distal to the anastomosis. Revision can be performed via an open incision with the same principles outlined for the initial procedure<sup>54</sup> or by using endoscopic approaches.<sup>47</sup>

A postoperative functional assessment of the anastomosis should be obtained in 2 to 3 months. Further evaluation is recommended 12 to 24 months after surgery. Problems are uncommon after this time in the absence of symptoms.

## **URETERAL ABNORMALITIES**

### **Embryology**

Ureteral development begins during the fourth week of gestation when the ureteral bud arises from the mesonephric duct.<sup>55</sup> The bud elongates, grows cephalad,

and forms the ureter, renal pelvis, calyces, and collecting tubules. The distal end of the mesonephric duct from the ureteral bud to the vesicourethral tract is called the common excretory duct and expands in trumpet fashion into the bladder and urethra to form half of the trigone. The attachment of the ureter to the mesonephric duct switches from a posterior to an anterolateral location. With expansion and absorption of the common excretory duct into the urinary tract, the orifices of the ureteral bud and mesonephric duct become independent and move away and settle in the bladder and urethra, respectively.

Alterations in bud number, position, and time of development result in anomalies. VUR results from caudal displacement of the ureteral bud, whereas ureteral ectopia and obstruction result from cranial displacement. Renal development and dysplasia are related to the ureteral orifice location.<sup>55,56</sup>

### Ureteral Duplication

Duplication is the most common ureteral anomaly. Both sides are equally affected, and girls are affected twice as often as boys. The autopsy incidence is approximately 1%, but the incidence is 2% to 4% in clinical series in which pyelograms were obtained for urinary symptoms.<sup>55,56</sup> Infection was historically the most common reason for presentation, but the majority are now detected prenatally. Many of the duplicated units show congenital dysplasia (scarring) and hydronephrosis.<sup>57</sup> Histologic evaluation of the kidneys shows an increased incidence of pyelonephritis and dysplasia. There is an increased incidence of infection because both VUR and obstruction are much more common in duplicated systems.<sup>56</sup>

A partial or complete duplication of the ureter occurs when a single bud branches prematurely or when two ureteral buds arise from the mesonephric duct. A bifid renal pelvis is the highest level of bifurcation and occurs in 10% of the population. Other incomplete duplications occur throughout the ureter (Fig. 55-6). When the bifurcation is near the bladder, urine can pass down one limb of the duplication and then

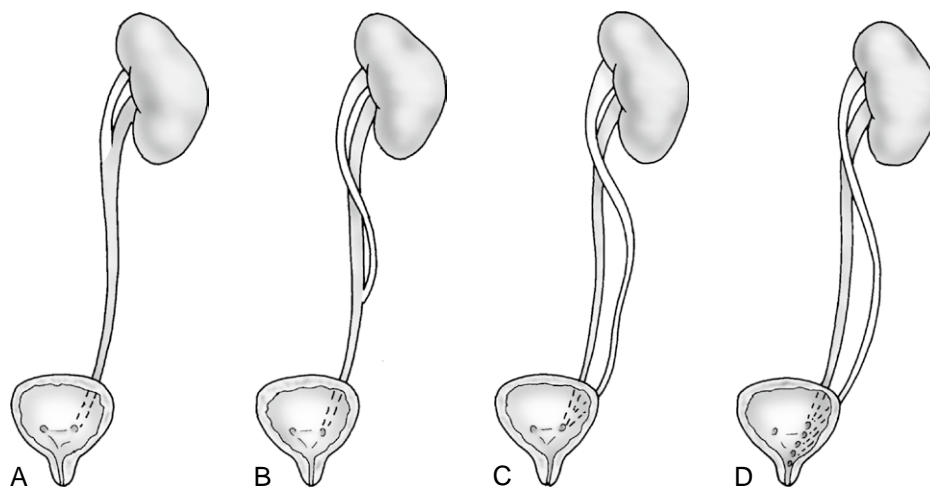

back up the other side of the Y.<sup>58</sup> This may lead to stasis with ureteral dilation or infection. Treatment involves either ureteral reimplantation or ureteropyelostomy at the renal level.<sup>59</sup> An inverted-Y ureter is the rarest of all branching anomalies.<sup>60</sup> This is presumably the result of separate ureteral buds that fuse before entering the metanephros. Treatment is directed at problems caused by the ectopic limb.

In complete duplications, reflux in the lower renal moiety is the most common cause of renal disease. The more caudal ureteral bud ends up laterally and cranially deviated in the bladder and has a shorter intramural tunnel. The upper-pole ureter enters the bladder adjacent or distal to the lower ureter, as defined by the Weigert-Meyer law.<sup>61</sup> These children are initially seen either prenatally or with urinary tract infections, and reflux is identified in up to two thirds of children with duplicated systems that appear with infection.<sup>62</sup> Reflux may occur into the upper-pole ureter if the ureteral orifices are immediately adjacent or if the upper ureter is distally located at the level of the bladder neck without any submucosal support (Fig. 55-7).

The treatment of VUR in duplicated ureters follows the same principles as that in the single system. Initial treatment includes preventive antibiotics and radiographic monitoring. Low grades of VUR are associated with the same rate of spontaneous resolution as the single system. The distal ureters share a common blood supply, so reimplantation involves mobilization and reimplantation of the common sheath.<sup>63</sup> If an associated lower-pole UPJ obstruction is noted, ipsilateral end-to-side pyeloureterostomy is an effective simultaneous management for both obstruction and reflux.<sup>64</sup> Even if significant scarring is present in the lower pole, reimplantation usually suffices, unless major ureteral dilation is present. In the latter case, lower-pole nephroureterectomy may be indicated.

### Ureteral Triplication

This is one of the rarest anomalies of the upper urinary tract and results from either several ureteral buds or early branching. In most cases all three ureters drain

**Figure 55-6.** Types of duplication. **A,** Bifid pelvis. **B,** "Y" ureter. **C,** "V" ureter. **D,** Complete duplication with various ectopic orifices.

**Figure 55-7.** Reflux is seen into an ectopic upper pole ureter (arrow) that inserts into the proximal urethra in a girl first seen at age 2 months with urosepsis.

into a single orifice.<sup>65</sup> Triplication occurs with incontinence, infection, and symptoms of obstruction and is associated with both ectopia and ureteroceles.<sup>66,67</sup> Surgical treatment is individualized. Ureteral quadruplication has also been described.<sup>68</sup>

### Retrocaval Ureter

The retrocaval or circumcaval ureter is a right ureter that passes behind the vena cava.<sup>69</sup> This is a result of a developmental error in the formation of the vena cava. The supracardinal vein (vena cava) lies dorsal to the developing ureter, whereas subcardinal veins lie ventral to the ureter. If the subcardinal vein persists

as the vena cava, the ureter passes behind the vena cava and anterior to the iliac vein. If both veins persist, the ureter passes between the duplicated vena cava.<sup>70</sup>

Even though this is a congenital abnormality, symptoms are related to chronic ureteral obstruction and infection, and rarely occur in children.<sup>71</sup> The radiographic appearance depends on the level of obstruction. The more common distal obstruction appears as a “reversed J” on IVP.<sup>72</sup> Less commonly, the ureter crosses at the level of the UPJ. Both of these can be confused with UPJ obstruction and should be suspected when pyelectasis and dilation of the upper third of the ureter are seen.

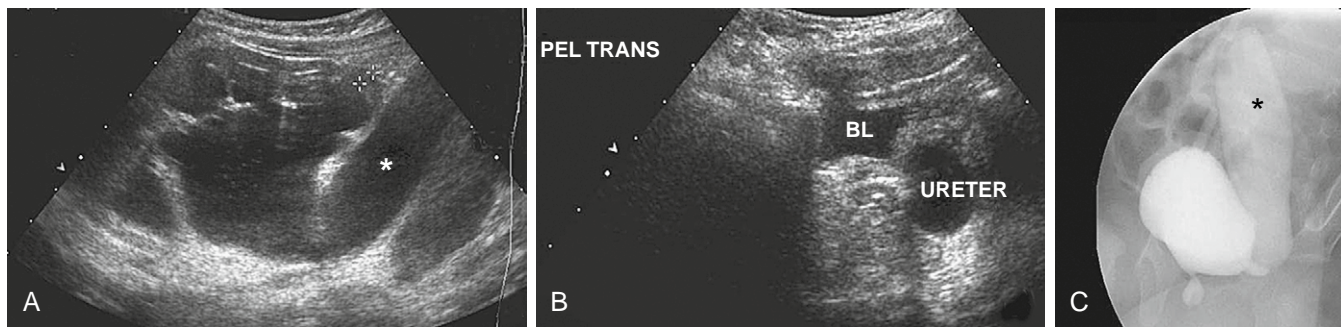

Treatment is required only when significant obstruction or symptoms are present. Reconstruction is essentially a dismembered ureteroplasty with division of the ureter and anastomosis anterior to the vena cava. The other option is division and reconstruction of the vena cava, which is more problematic.

### Megaureter

Megaureter is not a diagnosis but a descriptive term for a dilated ureter. Normal ureteral diameter in children is rarely greater than 5 mm. Ureters greater than 7 mm can be considered megaureters.<sup>73</sup> The ultrasonographic appearance of the dilated and tortuous ureter is usually striking (Fig. 55-8). Pelvicalyceal dilation and parenchymal scarring or thinning depend on the primary disease process.

These ureters can be classified as refluxing, obstructed, and nonrefluxing, nonobstructed.<sup>74</sup> Some ureters also have reflux and simultaneous obstruction.<sup>75</sup> Table 55-1 gives clinical examples of each classification. Any normal ureter will dilate if the volume of urine exceeds emptying capacity. Moreover, bacterial endotoxins and infection alone can cause dilation that will resolve after treatment of the infection.<sup>76,77</sup>

Primary obstructive megaureter is most commonly caused by a distal adynamic ureteral segment, but ureteral valves<sup>33</sup> and ectopic ureteral insertion also cause obstruction. Proximal smooth muscle hypertrophy and hyperplasia are seen. A normal-caliber catheter will

**Figure 55-8.** This patient has congenital megaureter. **A**, Renal ultrasound image shows diffuse caliectasis and cortical thinning with a markedly dilated left ureter (asterisk). **B**, Ultrasound image of the bladder confirms the markedly dilated ureter adjacent to the bladder (BL). A MAG-3 scan was performed and showed preserved renal function on the left side. **C**, The voiding cystourethrogram shows reflux into the markedly dilated left ureter (asterisk). Note that the contrast agent in the ureter is diluted (compared with the bladder), which is indicative of partial obstruction on that side.

**Table 55-1** Classification of Megaureter**Refluxing Megaureter**

Primary (congenital reflux)  
 Secondary (urethral valves, neurogenic bladder)

**Obstructed Megaureter**

Primary (adynamic segment)  
 Secondary (urethral obstruction, extrinsic mass, or tumor)

**Nonrefluxing, Nonobstructed Megaureter**

Primary (idiopathic, physiologically insignificant adynamic segment)  
 Secondary (polyuria, infection, postoperative residual dilation)

Modified from Khoury A, Bagli DJ: Reflux and megaureter. In Wein AJ, Kavoussi LR, Novick AC, et al (eds): *Campbell-Walsh Urology*, 9th ed. Philadelphia, WB Saunders, 2007, p 3468.)

usually pass through the distal 3- to 4-mm segment, but the peristaltic wave does not propel urine across this area. This absent peristalsis is not a result of a ganglionic abnormality as seen in megacolon.<sup>78</sup> The distal ureter has a variety of histologic appearances, but the common finding is a disruption of muscular continuity that prevents muscular propulsion of urine.<sup>14,79-81</sup>

As with UPJ obstruction, the majority of megaureters are now detected prenatally, although infection may also be a presentation for refluxing and obstructed megaureters.<sup>82-84</sup> Megaureter is now the second most common urinary tract abnormality detected prenatally.<sup>2</sup> These children are typically asymptomatic without any physical findings or laboratory abnormalities.

Despite the variety of possibilities, standard imaging allows classification and appropriate management. The diagnosis of a nonobstructed, nonrefluxing megaureter is the hardest to make and is established only when the secondary causes of megaureter have been excluded and diagnostic tests do not show obstruction. For years it was assumed that a dilated ureter that did not reflux was obstructed,<sup>85</sup> but developmental ureteral dilation can occur in ureters that are not obstructed.<sup>86</sup>

Diagnostic imaging begins with an ultrasound study, which almost always distinguishes megaureters from UPJ obstruction. The degree of distal ureteral dilation is often much more pronounced than the degree of renal pelvic dilation or caliectasis. A VCUG should be obtained in all patients. If significant reflux is found, delayed drainage films must be obtained to exclude simultaneous obstruction with a normal-caliber distal ureteral segment. In a partially obstructed system, the contrast density in the ureter is decreased because of dilution related to stasis in the ureter (see Fig. 55-8).

Diuretic renography is used to assess function and drainage. The markedly dilated ureters can be a significant source of stasis, and determination of drainage half-time can be difficult. Diuretic administration must be delayed because the system is so capacious and may take 60 to 90 minutes to fill. A washout time of longer than 20 minutes is historically indicative of obstruction.

**Treatment**

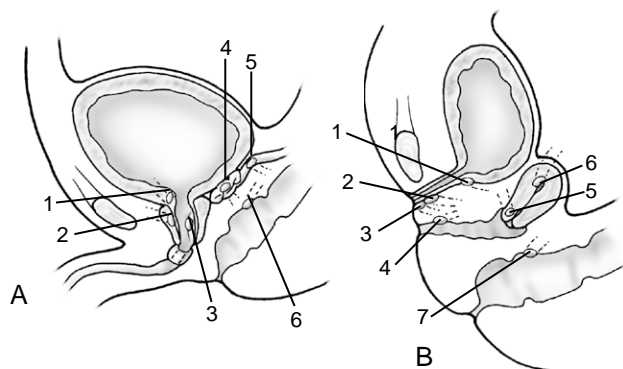

Nonoperative management is based on clearance half-time and relative renal function of the hydronephrotic and contralateral kidneys. If observation is chosen, the children are given preventive antibiotics and followed with serial ultrasound and renal scans. Neonatal megaureter with obstruction suggested by renography but with preserved function can be safely observed. Most ureters will become radiographically normal over time.<sup>82,83,87,88</sup> Surgical correction for decreasing function or recurrent infections will be needed in only 10% to 25% of patients at age 7 years. Evidence of delayed obstruction after normalization of radiographs has not been seen in these children.

The initial attempts at surgical repair resulted in significant reflux and recurrent infections. Now, it can be performed with a high expectation of success and low morbidity.<sup>89</sup> Ureteral excisional tapering with preservation of the ureteral blood supply was popularized in the early 1970s.<sup>85,90</sup> A longitudinal segment of ureter is excised and then closed over a 10- to 12-Fr catheter. When the ureter is tunneled submucosally, the suture line is positioned against the detrusor to decrease the chance of fistula formation. Initial repairs involved tailoring the entire ureter, but this was found to be unnecessary because the upper ureteral tortuosity and dilatation often disappears after tapering the distal ureter alone.<sup>91</sup> Ureteral folding techniques have been popularized because they theoretically decrease the risk of ischemic injury while achieving the decreased intraluminal diameter necessary for a successful reimplant.<sup>92,93</sup> The increased bulk is usually not a technical problem. Although dissection is usually both intravesical and extravesical, solely extravesical reimplants have been described and may be associated with lower morbidity.<sup>94</sup> A vesicopsoas hitch is a useful adjunct that helps achieve a longer submucosal tunnel length without risking ureteral kinking, although excisional tailoring usually eliminates the need for this adjunctive procedure. A nonrefluxing, nonobstructed reimplantation can be achieved in 85% to 95% of patients with megaureters.<sup>84,93</sup> Recognized complications include persistent obstruction, reflux, and urinary extravasation. Most of these can be managed nonoperatively with drainage tubes. Lower grades of postoperative VUR will often resolve.

Primary reconstruction is preferred when indicated, but temporary cutaneous diversion may be beneficial in a neonate or infant in whom the chance of successful reimplantation of a bulky ureter into a small bladder is diminished. Diversion may decrease the ureteral diameter and decrease the need for tailoring at the time of reimplantation. An end-cutaneous ureterostomy is preferred because a high diversion may require two or more procedures for correction.

**Ectopic Ureter**

An ectopic ureter is defined as one that opens at the bladder neck or more caudad rather than on the trigone. Embryologically, this results from a cranial

**Figure 55-9.** A, Ureteral ectopia in a boy. Possible sites are above the external sphincter (1-3), or into the seminal vesicle (4-5), or anorectal (6). B, Ureteral ectopia in a girl may be located at the bladder neck (1), or beyond the continence mechanism in the urethra (2), or on the perineum (3). Uterine or vaginal insertion (4-6) may also cause incontinence. Anorectal insertion (7) can also occur.

insertion of the ureteral bud on the mesonephric duct that allows distal migration with the mesonephric duct as it is absorbed into the urogenital sinus.<sup>95</sup>

The incidence of ureteral ectopia is approximately 1 in 2000.<sup>96</sup> Eighty percent of ectopic ureters are reported in association with a duplicated renal system. Because clinical problems are more common in girls with ectopia, only 15% of ectopic ureters have been reported in boys.<sup>95</sup> Ectopia is bilateral 20% of the time.<sup>96</sup> Single ectopic ureters are rare but are more common in boys.<sup>97</sup>

### Ectopic Ureter in Girls

The fundamental difference between ureteral ectopia in boys and girls arises from ureteral insertion distal to the continence mechanism in girls (Fig. 55-9). Approximately one third of ureters open at the level of the bladder neck, one third are in the vestibule around the urethral opening, and the remainder empty into the vagina, uterus, or cervix. All of these insertions are along the course of the mesonephric duct remnant (Gartner's duct).

One half of girls initially have continuous urinary incontinence in spite of what appears to be a normal

voiding pattern.<sup>95,96</sup> If the system is markedly hydronephrotic and functions poorly, leakage may occur only in the upright position and may be confused with stress incontinence. Persistent foul-smelling vaginal discharge can suggest an ectopic ureter. When the ectopic ureter is present in the urethra or the bladder neck, both obstruction and reflux are frequently present. Although prenatal diagnosis is the most common presentation, a urinary tract infection and/or sepsis may be the presenting symptom.

The diagnosis of an ectopic ureter may be obvious or can be difficult. When genital ectopy is present, the kidney may not visualize on ultrasonography if the moiety is small and atrophic and is not associated with hydronephrosis. Often significant hydronephrosis is present in the upper pole of a duplicated kidney and the ultrasound image may show a dilated ectopic ureter behind the bladder. However, the upper pole may be simply an echogenic focus (Fig. 55-10). A scan with dimercaptosuccinic acid (DMSA) is a good test for localizing a small ectopic kidney when an orthotopic kidney is not identified on standard imaging and there is a high suspicion of genital ectopy. MR urography may be the most precise method for making this diagnosis.<sup>98</sup> A VCUG should be obtained in all patients to exclude occult reflux.<sup>99</sup>

The diagnosis is confirmed with physical examination, panendoscopy, and retrograde pyelography. Dyes used to stain urine may have a role. Urine in the bladder changes color, whereas the poorly concentrated urine is evident as persistent clear leakage. Meticulous examination of the area around the urethral meatus and vagina will often reveal an asymmetry or bead of fluid coming from an opening that can be probed and injected in retrograde fashion (see Fig. 55-10). Vaginoscopy with attention to the superior lateral aspect of the vagina may reveal a large ectopic orifice.

### Ectopic Ureter in Boys

The most common sites of ectopic ureteral insertion in boys are the posterior urethra (40% to 50%) and the seminal vesicle (20% to 60%), depending on the age

**Figure 55-10.** This 3-year-old girl had continuous urinary incontinence despite a normal voiding pattern. The renal ultrasound image was essentially normal on both sides with no evidence of hydronephrosis or an echogenic upper pole. A, A ureteral catheter has been inserted into an ectopic left ureter. B, The retrograde ureterogram shows a very small upper left ureter and a small cystic calyx (arrow) in the left upper pole medial to the lower pole collecting system that was opacified through an orifice on the trigone. The patient was continent after a laparoscopic left upper pole partial nephroureterectomy.

at presentation.<sup>100</sup> Symptoms in boys may not occur until after the onset of sexual activity and include prostatitis, seminal vesiculitis, or an infected seminal vesical cyst causing painful bowel movements. The genital insertion accounts for the common presentation with epididymitis. The boy may initially have post-void dribbling secondary to pooling of urine in the prostatic urethra, but incontinence is never as pronounced as in the girl.

Diagnostic testing is similar to that used in girls. Ectopic ureters in the boy are more commonly obstructed and hydronephrotic so ultrasound examination is often more useful. If the ectopic site of insertion is outside the urethra, it is rarely identified on endoscopic examination.

### *Surgical Management of Ectopic Ureters*

Surgical treatment is dependent on the associated parenchyma.<sup>101,102</sup> Single-system ectopia to the genital system usually has poor function, and nephroureterectomy is appropriate. When the ectopic ureter is associated with a duplication, the function in the upper pole is usually poor, and an open or laparoscopic partial nephroureterectomy has historically been the most common surgical approach. The distal stump is left open. A ureteroureterostomy can then be performed to drain the ectopic system in the true pelvis. There are potential concerns regarding the size discrepancy of the ureters and injury to the recipient ureter, but large series show excellent success with a very low complication rate. This approach avoids potential injury to the lower pole of the kidney and can be performed through a small inguinal incision. The obstruction, dilation, and incontinence usually resolve with this approach. Even if the upper pole is poorly functioning, it should not cause any long-term problems. A common sheath ureteral reimplantation can be performed with tailoring of the ureter in the upper pole, but the increased morbidity and complication rate associated with ureteral tapering limit the utility of this approach.

The distal stump rarely causes a problem in genital ectopia. However, if urethral or bladder neck insertion of the ectopic ureter and reflux into the ureter is identified preoperatively, excision is indicated,<sup>102</sup> but can be tedious. If the dissection plane is kept immediately adjacent to the ureter behind the bladder, the bladder neck and sphincter should not be damaged. The stump is ligated at this point. In a postpubertal girl, this dissection can be performed transvaginally. Small stumps can be obliterated by using a Bugbee electrode.

### *Bilateral Single Ectopic Ureters*

This is a rare abnormality in which the altered ureteral embryologic development is associated with failure of normal bladder neck development.<sup>103</sup> Genital and anal anomalies are commonly present. Girls have ureteral insertion in the distal urethra and are first seen with infection or are noted to have continuous urinary leakage. The bladder is usually poorly developed because it has never stored urine. Boys have somewhat

larger bladders because some urine will have entered the bladder. However, because the bladder neck is not formed normally, they also have some degree of urinary incontinence.

The child who is incontinent with bilateral single ectopic ureters presents a major reconstructive challenge that may include ureteral reimplantation, bladder neck reconstruction, and bladder augmentation if the bladder capacity is insufficient.

## URETEROCELES

Ureteroceleles are cystic dilatations of the terminal, intravesical ureter that usually have a stenotic orifice.<sup>104-106</sup> In children, ureteroceleles are most commonly associated with the upper pole of a duplex system (80%) and an ectopic orifice (60%) in the urethra. In adults, they are usually part of a completely intravesical single system. Ureteroceleles occur four to seven times more frequently in girls and are more common in whites. Bilateral ureteroceleles are found 10% of the time.

A single embryologic theory does not explain all ureteroceleles. The most popular theory involves persistence of Chwalla's membrane at the junction of the wolffian duct and urogenital sinus.<sup>107</sup> Incomplete breakdown of the ureteral membrane causes an obstruction resulting in dilation. This theory explains the majority of ureteroceleles but does not account for the development of ureteroceleles with patulous ureteral orifices in the urethra or of ureteroceleles associated with multicystic dysplasia and atretic ureteral segments or for the presence of ectopic ureters without ureterocele formation.<sup>108</sup> This clinical finding supports a more general developmental abnormality of the ureter.

It is likely that a ureterocele is the result of an abnormal induction of the trigone and distal ureter by many of the genes and growth factors that are important in renal and ureteral growth and development. Histologic studies support this concept.<sup>108</sup> Histologic analysis of the intravesical portion of ureteroceleles shows deficiencies in the trigonal musculature of patients with ureteroceleles that were not present in ectopic ureters without ureterocele formation. This field defect results in pseudodiverticulum (ureterocele eversion) and reflux into laterally displaced, poorly supported ureters. This is supported by the clinical observation of multicystic dysplasia and the absence of hydronephrosis in association with a ureterocele.

The classification of ureteroceleles can be confusing. Pathologic classification describes four types: stenotic, sphincteric, sphincterostenotic, and cecoureterocele.<sup>108</sup> The current recommended nomenclature classifies ureteroceleles as either intravesical (entirely within the bladder) or ectopic (some portion is situated permanently at the bladder neck or in the urethra).<sup>109</sup>

## Presentation and Diagnosis

Although presentation with an infection in a system with high-grade obstruction is common, antenatal imaging is now the most common method of diagnosis

**Figure 55-11.** This 2-week-old presented with sepsis and was found to have this prolapsing ectopic ureterocele. The ureterocele was aspirated with return of purulent debris and underwent prompt decompression. Recovery was uneventful.

(60%).<sup>110-113</sup> The obstructed renal unit may be palpable in these asymptomatic infants, but most have no clinically apparent abnormality. Bladder outlet obstruction is rare because most ureteroceles decompress during micturition, but the most common cause of urethral obstruction in girls is urethral prolapse of a ureterocele (Fig. 55-11).

Abdominal ultrasonography reveals a well-defined cystic intravesical mass that is associated within the posterior bladder wall (Fig. 55-12). This can be followed to a dilated ureter in the bony pelvis and to upper-pole hydroureteronephrosis in a duplication. The thickness and echogenicity of the renal parenchyma are often consistent with dysplasia and poor function.

During cystoscopy, the bladder should be examined when both full and completely empty because compressible ureteroceles may not be evident in a full bladder or may appear as a bladder diverticulum. The dilated lower end of an ectopic ureter or megaureter may elevate the trigone, creating the cystoscopic,

radiographic, and ultrasound appearance of a ureterocele, a so-called pseudoureterocele.<sup>114</sup>

## Treatment Options

The goals of ureterocele management include control of infection, preservation of renal function, protection of normal ipsilateral and contralateral units, and continence. The natural history of an asymptomatic ureterocele is unknown. There is a subset of ureteroceles associated with multicystic dysplasia, no hydroureter, and no reflux. The multicystic moiety usually involutes and the ureterocele rarely causes symptoms and can be observed.<sup>108</sup> Up to 10% to 15% of prenatally identified ureteroceles have these clinical findings. Neonates given preventive antibiotics rarely develop a febrile urinary tract infection.<sup>111,112</sup> If significant hydroureteronephrosis is found, it should be assumed that there is significant urinary tract obstruction and preventive antibiotics should be started.

Traditional treatment of duplex ectopic ureteroceles includes upper-pole heminephrectomy through a separate flank incision, ureterocele excision, and ipsilateral lower-pole ureteral reimplant via a lower incision. The bladder-level operation may require repair of a sizable defect in the bladder base and tapering or plication of the lower ureter. The distal extent of the ureterocele and its mucosa can often be dissected through the bladder neck. Incomplete excision may result in an obstructing urethral flap. Resection of the entire ureterocele risks damaging the continence mechanisms of the bladder neck. Experienced surgeons report excellent results with low rates of reoperation (<10%) and low complication rates (<10%).<sup>115-117</sup> These approaches assume that ureterocele excision is an essential component of management. However, because the distal ureter and bladder defect may resolve without being removed or repaired, an absolute indication to proceed with a simultaneous bladder operation is rarely present. In older children, when absence of function is noted on the affected side (upper and lower pole), nephroureterectomy and reconstruction of the bladder is the initial treatment of choice.

Primary upper-pole partial nephroureterectomy may avoid bladder-level reconstruction and its potential risks.<sup>110,118,119</sup> Nearly all of the ureter can be removed through the flank incision, and the distal

**Figure 55-12.** A, Ultrasound image of the bladder demonstrates a ureterocele (asterisk). B, The ureterocele appears as a nonopacified filling defect (arrow) at the base of the bladder on the cystogram.

**Figure 55-13.** **A**, This intravesical ureterocele was found at cystoscopy. **B**, The ureterocele was punctured (black arrow) and decompressed using a 3-Fr electrode (white arrow).

ureter is left open to facilitate decompression. The need for subsequent bladder-level excision and reconstruction varies between 10% and 62%.<sup>110,112,119</sup> Although up to 45% of ipsilateral and contralateral VUR will resolve after ureterocele decompression, persistent VUR is the most common indication for bladder-level reconstruction.<sup>110</sup> Other indications for bladder-level reconstruction include ureterocele eversion acting like a diverticulum or externally compressing the bladder neck, reflux into the ureterocele, or intraluminal obstruction of the bladder neck by a cecoureterocele. The need for bladder-level intervention is directly related to the number of renal moieties that have either a ureterocele or VUR.<sup>112</sup>

Most partial nephrectomy specimens show dysplasia, but some may show only inflammatory and obstructive changes.<sup>119,120</sup> In cases with preserved function, a pyeloureterostomy or ureteroureterostomy (high or low) may be performed, along with distal ureterectomy and ureterocele decompression.<sup>101</sup> These procedures potentially place the lower-pole system at risk to salvage what may be a small percentage of total renal function.

Ureterocele incision is the least invasive technique for upper-pole preservation. “Unroofing” of the ureterocele is advocated only as a drainage procedure for an infected system before a definitive procedure because it invariably results in reflux.<sup>121,122</sup> Using a 3-Fr Bugbee electrode to drain the ureterocele just above the bladder neck is the recommended technique because reflux is not inevitable (Fig. 55-13).<sup>111</sup> Although the ureterocele opening is in the bladder, to be successful the surgeon must also drain the ectopic

urethral portion to prevent an obstructing lip at the level of the bladder neck.

Endoscopic incision successfully decompresses the ureterocele 85% of the time.<sup>111,120,123,124</sup> It is the definitive procedure in more than 90% of infants with intravesical ureteroceles. However, subsequent reconstructive surgery is required in 50% to 90% of patients with ectopic ureteroceles. Reflux into the ureterocele moiety is the most common indication for reconstruction in these infants. Previous decompression of the system makes this reconstruction easier.<sup>111</sup>

Ureterocele incision should probably be the initial procedure in most neonates because reflux into other moieties is usually present (>50%). Even when ultrasonography shows little renal parenchyma, incision can be performed. The decompressed system may require no further treatment if iatrogenic upper pole reflux does not develop. In older children, incision is best selected when associated functioning renal parenchyma is found, the ureterocele is intravesical, or the kidney is drained by a single system.

Single-system ureteroceles are more commonly seen in older children and adults and are associated with better function and less hydronephrosis than is found in duplex kidneys. Most often, they are incidental findings that require no treatment. Antenatally detected single-system ureteroceles may not show significant obstruction on a furosemide washout renal scan. Clinically, these behave like nonobstructed megaureters and can be safely followed with preventive antibiotics. If treatment is required, endoscopic incision can be the definitive procedure nearly 100% of the time.

# URINARY TRACT INFECTION AND VESICoureTERAL REFLUX

Eugene Minevich, MD • Curtis A. Sheldon, MD

## URINARY TRACT INFECTION

Urinary tract infections (UTIs) are common and a major source of morbidity in children. They constitute a significant health burden, although the actual costs are not known.<sup>1</sup>

### Diagnosis

Although clinical signs and symptoms are important indicators for childhood UTI, confirmation of the diagnosis by microscopic examination and quantitative culture of a properly collected specimen is imperative. Signs and symptoms of UTI are age dependent, and combinations of findings are more useful than individual signs and symptoms in identifying children with a UTI.<sup>2</sup> Neonates rarely present with findings specific to the urinary tract. Nonspecific symptoms such as lethargy, irritability, temperature instability, anorexia, emesis, or jaundice predominate. Bacteremia is common with neonatal UTI, and urine culture is an important part of the evaluation of neonatal sepsis.<sup>3</sup> Older infants often present with nonspecific abdominal discomfort, emesis, diarrhea, poor weight gain, or fever. Malodorous or cloudy urine may be reported. Older children frequently present with dysuria along with urinary frequency, urgency, and enuresis. [Table 56-1](#) outlines the incidence of UTI symptoms as a function of age.<sup>4,5</sup> Because the symptoms can be quite obscure, it is important that care providers have a high index of suspicion for UTIs in children.

Analysis of a properly collected urine sample is the cornerstone of the diagnosis of UTI.<sup>6</sup> Errors in diagnosis most commonly result from failure to confirm a clinically suspected UTI by culture or by reliance on a specimen that has been inadequately collected or mishandled. Specimens may be obtained by bag collection, clean-catch, urethral catheterization, or suprapubic aspiration. Although invasive, urethral catheterization (or suprapubic aspiration) clearly offers the lowest risk of contamination (false-positive culture results).<sup>7</sup>

The results of a bag specimen or clean-catch specimen are helpful only if negative.<sup>8</sup> Positive findings should be confirmed using a catheter or aspiration specimen unless the clinical presentation is unequivocal. The accuracy of positive findings from a bag specimen in infancy has been estimated at 7.5%.<sup>9</sup> The accuracy of midstream collected specimens varies with age: 42% when younger than 18 months of age and 71% from 3 to 12 years of age.<sup>10</sup> Specimens should be either analyzed and plated immediately or placed on ice to minimize bacterial multiplication before testing.

The standard for diagnosis of a UTI remains the quantitative urine culture. The accepted criterion for diagnosis is greater than  $10^5$  colony-forming units per milliliter of a single bacterial species.<sup>11</sup> The accuracy of such a positive finding on culture is estimated at 80% (single specimen) and 96% (confirmed by second culture). [Table 56-2](#) outlines the probability of infection as a function of colony count and method of collection that we use in children.<sup>12</sup> However, one must avoid applying these criteria too strictly because the colony count varies as a function of hydration (dilution) and urinary frequency (bacterial multiplication time). One study of six untreated children with proven bacteriuria found colony counts to vary from  $10^3$  to  $10^8$  over a 24-hour period.<sup>13</sup>

Although clearly most accurate, urine culture results cannot provide an immediate diagnosis, and, as a result, initial treatment is generally guided by the urinalysis. Microscopic evaluation of a urine specimen should be done immediately on collection. This practice minimizes misleading ex-vivo bacterial multiplication and deterioration of cellular elements. The identification of bacteria in an unspun urine specimen is very suggestive of significant bacteriuria.<sup>13</sup> Pyuria (more than 10 leukocytes/mm<sup>3</sup>) is suggestive<sup>14</sup> but may also be seen in such instances as vaginitis, dehydration, calculi, trauma, chemical irritation, gastroenteritis, and viral immunization. Urine Gram stain was found to be reliable in detecting UTI in young infants.<sup>15</sup>

A popular and indirect measurement of bacteriuria employs nitrite and leukocyte esterase analysis.

**Table 56-1** Presenting Symptoms in 200 Children with Urinary Tract Infection as a Function of Age

Symptom	Age			
	0-1 mo	1-24 mo	2-5 yr	5-12 yr
Failure to thrive, poor feeding	53%	36%	7%	0
Jaundice	44%	0	0	0
Screaming, irritability	0	13%	7%	0
Foul-smelling, cloudy urine	0	9%	13%	0
Diarrhea	18%	16%	0	0
Vomiting	24%	29%	16%	3%
Fever	11%	38%	57%	50%
Convulsions	2%	7%	9%	5%
Hematuria	0	7%	16%	6%
Frequency, dysuria	0	4%	34%	41%
Enuresis	0	0	27%	29%

Nitrate, normally present in urine, is converted to nitrite in the presence of bacteria. A positive colorimetric reaction between nitrite, sulfanilic acid, and  $\alpha$ -naphthylamine is thus indicative of bacteria with specificity and a positive predictive value approaching 100%.<sup>16</sup> The nitrate-to-nitrite reaction requires a relatively long incubation period. Thus, urinary frequency and hydration may produce a false-negative result. Inadequate dietary nitrate and infection caused by nitrite-negative organisms may also cause false-negative reactions.<sup>17</sup> The combination of nitrite and leukocyte esterase is more sensitive and specific than either by itself.<sup>18</sup> Overall the combination of dipstick analysis and microscopic examination for bacteria have a sensitivity of and a negative predictive value approaching 100%.<sup>16</sup>

## Classification

Classification of UTIs helps to determine the need for hospital admission and parenteral antibiotic therapy as opposed to outpatient oral antibiotic therapy. An attempt is made to distinguish between upper tract (pyelonephritis) and lower tract infections. Fever, flank pain or tenderness, and leukocytosis suggest pyelonephritis and require parenteral antibiotics to minimize the risk of renal injury. Additional findings supporting parenteral antibiotic therapy include age (< 3 months), unusual pathogens, or significant urinary anomalies. After the initial stabilization, we often complete the course of parenteral antibiotics on an outpatient basis, employing our home-based nursing service.

Laboratory studies designed to distinguish lower tract from upper tract UTI include antibody-coated bacteria assay,  $\beta_2$ -microglobulin excretion, antibodies to Tamm-Horsfall protein, and urinary lactic dehydrogenase assay and procalcitonin.<sup>19,20</sup> These tests are not sufficiently reliable for routine clinical use. Although cumbersome, direct culture by ureteral catheterization or percutaneous puncture is reliable and represents excellent options in complicated clinical problems. We have found the most usable study for localizing infection to the kidney to be an isotope image during presentation of the patient with infection (Fig. 56-1).

Another important consideration regarding classification is the distinction between reinfection and relapse. Reinfection with a new organism is very common. Relapse with the same organism, although less common, is very important because it usually implies either an ineffective therapy or a structural abnormality, such as a stone or other obstruction.

## Epidemiology

Figure 56-2 outlines the age- and gender-related incidence of UTIs. At all ages, with the exception of the neonatal period, the incidence of UTI is greater in the female than in the male. In both males and females, the incidence increases with advanced age. Although the male has one early peak in the newborn period, the female has two peaks: one is at 3 to 6 years, and the other is at the onset of sexual activity. The actual incidence of infection as a function of age and gender is difficult to determine from the literature. Table 56-3 summarizes the available data.<sup>12</sup>

## Pathophysiology

### Host Factors

The establishment of clinical infection and its consequent injury to the urinary tract results from a complex interplay between host resistance and bacterial

**Table 56-2** Criteria for Diagnosis of Urinary Tract Infections

Method of Collection	Colony Count (Pure Culture)	Probability of Infection
Suprapubic aspiration	Gram-negative bacilli: any number	>99%
	Gram-positive cocci: a few thousand	>99%
Catheterization	>10 <sup>5</sup>	95%
	10 <sup>4</sup> -10 <sup>5</sup>	Likely
	10 <sup>3</sup> -10 <sup>4</sup>	Suggestive
	<10 <sup>3</sup>	Unlikely
Clean voided (male)	>10 <sup>5</sup>	Likely
Clean voided (female)	3 specimens > 10 <sup>5</sup>	95%
	2 specimens > 10 <sup>5</sup>	90%
	1 specimen > 10 <sup>5</sup>	80%

**Figure 56-1.** Technetium-99m dimercaptosuccinic acid (DMSA) scan. The magnified view of the left kidney (L), seen by using a pinhole collimator, demonstrates defects in both poles that extend deep into the renal parenchyma (arrows), suggestive of acute pyelonephritis. The right kidney (R) has an upper pole defect (arrow) that may represent either acute or chronic pyelonephritis. (Courtesy of Michael J. Gelfand, MD.)

virulence. As a general rule, UTI-causing organisms originate from the feces of their host. Conceptually, four levels of defense are identifiable: periurethral, bladder, ureterovesical junction, and renal papillae.<sup>5</sup> These concepts are illustrated in Figure 56-3.

Bacteria generally possess an ability to adhere to vaginal mucosal cells in order to readily establish infection.<sup>21</sup> The resultant periurethral colonization then allows replication and migration, which ultimately lead to transurethral invasion to the bladder. Healthy girls have low bacterial colonizations of the periurethral region. UTI-prone girls experience more heavy colonization, especially prior to a new episode of UTI. Furthermore, the cultivated organism from the introital region belongs to the same strain as that from the urine during the UTI that ensues. Periurethral bacterial colonization is correspondingly low in UTI patients after cessation of recurrent UTIs.<sup>22</sup> A similar mechanism may apply to bacterial adherence in the prepuce of males.<sup>23</sup> This may explain why 92%

of male infants younger than 6 months old with a UTI are uncircumcised.<sup>24</sup>

A number of bladder defense mechanisms help maintain sterile urine. The most critical is the act of regular and complete voiding. The healthy bladder is capable of eliminating 99% of instilled bacteria and leaves a small residual urine that minimizes the inoculum at the onset of the following cycle.<sup>25</sup> High intravesical pressure dynamics may also potentiate infection in children. In the absence of an elevated residual urine, uninhibited bladder contractions are associated with a high risk of recurrence of UTI, which is lessened by anticholinergic therapy.<sup>26</sup> Dysfunctional elimination syndrome with abnormal voiding habits and constipation can affect the development of UTI as well.<sup>27</sup> The acid pH of urine, as well as its osmolality, further discourages bacterial growth.<sup>28</sup> The uroepithelial cells of healthy individuals suppress bacterial growth and are capable of killing bacteria. The uroepithelial cells secrete a mucopolysaccharide substance that, upon coating the surface of the uroepithelium, provides an additional barrier to uroepithelial adherence.<sup>25</sup> Glycosaminoglycans are continuously shed and thus function to entrap and eliminate bacteria.

**Figure 56-3.** Host factors that protect the urinary tract from infection and abnormalities that potentiate the establishment of invasive bacterial infection.

Abnormalities of the ureterovesical junction and altered ureteral peristalsis may allow **vesicoureteral reflux (VUR)**, which **potentiates but is not always necessary** for upper tract invasion. Distortion of the renal pyramids permits renal parenchymal invasion, which results in irreversible renal injury. The anatomy of the renal papillae usually prevents intrarenal reflux (Fig. 56-4). The papillary ducts commonly open onto the papillae with slit-like orifices that occlude with elevated intracalyceal pressure, preventing intrarenal reflux. The more circular duct orifices of compound papillae fail to accomplish this goal, allowing intrarenal reflux. The fact that compound papillae tend to occur in the upper and lower calyces and that intrarenal reflux in very young children may occur at a relatively low pressure may explain the observed polar distribution of scarring and predilection to scarring noted in these children.<sup>5</sup> Structural abnormalities that potentiate infection include phimosis, obstructive uropathy at any level, VUR, diverticula, urinary calculi or foreign bodies, and an abnormal renal papillary structure.

**Figure 56-4.** The normal oblique insertion of the collecting ducts onto the surface of simple papillae prevent intrarenal reflux (*left*). Collecting duct insertion onto the surface of compound papillae may allow intrarenal reflux (*right*). (From Ransley PG: Intrarenal reflux: Anatomic, dynamic and radiological studies. *Urol Res* 5:61, 1977.)

<b>P fimbriae—adherence</b>
Mannose sensitive (MS)
Mannose resistant (MR)

### Bacterial Factors

Several bacterial factors may potentiate urinary tract infection and are outlined in Table 56-4.<sup>5,29</sup> O antigens are lipopolysaccharides that are part of the cell wall. They are thought to be responsible for many of the systemic symptoms associated with infection. Of the more than 150 strains of *Escherichia coli* identified by O antigens, 9 are responsible for the majority of UTIs.

K antigens are also polysaccharides, and their presence on gram-negative bacterial capsules is considered to be an important virulence factor. They are thought to protect against phagocytosis, to inhibit the induction of a specific immune response, and to facilitate bacterial adherence. Bacterial strains causing UTI exhibit considerably more K antigen than those isolated from the feces. Urease, a virulence factor especially prominent with *Proteus* species, allows the breakdown of urea to ammonium. This process alkalinizes the urine and facilitates stone formation. Such bacteria are generally incorporated into the stone structure, making eradication extremely difficult. Mannose-resistant pili are important adherence factors. They promote adherence to uroepithelial cells as well as renal epithelial cells. This factor appears to counter the normal cleansing action of urine flow and allows tissue invasion and bacterial proliferation. That these factors truly are associated with virulence is shown in Figure 56-5.<sup>29</sup>

Increasingly invasive urinary infections are associated with bacteria with a high incidence of virulence factors. Figure 56-6 demonstrates the pathophysiologic changes of renal injury that may occur in the absence of significant host factors. Colonization of the feces with a virulent organism allows periurethral colonization and, ultimately, bladder entry. Uroepithelial adherence promotes bacterial proliferation and tissue invasion. This series of events is facilitated by the presence of one or more host factors (see Fig. 56-3).

**Figure 56-5.** Presence of bacterial virulence factors as a function of the clinical setting. More-invasive infections are associated with a high incidence of virulence factors, implicating these factors in pathogenesis. MR, mannose resistant; Ag, antigen; ABU, asymptomatic bacteriuria. (From Mannhardt W, Schofer O, Schulte-Wisserman H: Pathogenic factors in recurrent urinary tract infection and renal scar formation in children. *Eur J Pediatr* 145:330, 1986.)

### Investigation

Although many patients with UTI are not severely affected, the pediatric surgeon and urologist must be cognizant of several important facts. Urinary abnormalities can be found in approximately 50% of children up

to the age of 12 years who present with UTI. VUR is found in up to 35% and obstructive lesions in 8%. Non-obstructive, nonrefluxing lesions are found in 7%.<sup>30</sup>

Also, although renal scars develop in about 13% of girls and 5% of boys with unspecified infection,<sup>31</sup> they develop in up to 43% of kidneys involved in acute pyelonephritis.<sup>32</sup> Pyelonephritic scarring is responsible for 11% of cases of childhood hypertension.<sup>33,34</sup> Although hypertension is most common with bilateral scarring, it is also seen with unilateral scarring.<sup>35</sup> Pyelonephritic scarring is also an important cause of end-stage renal failure in childhood and may require specific pretransplantation treatment, especially if associated with reflux.<sup>36</sup> Additionally, approximately 50% of patients will suffer from recurrent UTIs.<sup>29</sup>

Consequently, not only infants<sup>37</sup> but older children as well of either gender should be studied at the time of their initial infection.<sup>38</sup> Although controversial, we investigate children with UTI with initial screening ultrasonography and cyclic voiding cystography.<sup>39</sup> Males require contrast voiding cystourethrography (VCUG), and females are adequately evaluated by isotope VCUG that allows a lower radiation exposure to the ovaries.<sup>40</sup> The exception is the infant girl or the girl with suspected neurogenic bladder, ectopic ureter, or ureterocele by ultrasonography. In this case, a contrast VCUG is obtained. Radionuclide scanning using technetium-99m-labeled dimercaptosuccinic acid (<sup>99m</sup>Tc-DMSA) is readily available and is used to diagnose acute pyelonephritis<sup>41</sup> and to detect renal scarring.<sup>42</sup>

**Figure 56-6.** The pathogenesis of destructive infection is shown. The process is facilitated by, but does not require, defects in the host protective factors outlined in Figure 56-3. IRR, intrarenal reflux; ABU, asymptomatic bacteriuria.

## Treatment

The treatment of an acute UTI is dependent on the clinical presentation. Patients with pyelonephritis should be treated immediately and aggressively. Prompt, effective treatment is the most important factor in preventing permanent renal injury.<sup>43</sup> We prefer to initiate therapy with intravenous ampicillin and an aminoglycoside after obtaining a reliable urine culture. Further therapy is dictated by the culture and sensitivity findings. Patients may require admission to the hospital initially. Once afebrile for 24 to 48 hours, patients with otherwise uncomplicated infections with sensitive organisms may complete a 7- to 14-day course with oral antibiotics.<sup>44</sup> Patients with resistant organisms or those with obstructions may finish the course with nursing-supervised home administration of intravenous antibiotics. Patients with obstruction or abscess who do not become afebrile undergo drainage percutaneously or, rarely, operatively.

Short treatment courses appear to be insufficient for treatment of childhood UTI.<sup>45</sup> Therefore, we prefer a 7- to 10-day course dictated by culture and sensitivity results.<sup>46</sup> Urinary retention due to a fear of voiding or dysuria is managed with phenazopyridine and hydration and allowing the child to void while sitting in a tub of warm water.

Patients who have recurrent UTIs or those who are managed nonoperatively for VUR require long-term suppressive antibiotics. The urothelial injury from recurrent UTIs takes several months to fully recover. As a result, irritative voiding symptoms, such as dysuria, incontinence, and frequency, may persist despite the finding of sterile urine. A propensity for recurrent UTI may also be present. Such patients generally require a minimum of 4 to 6 months of

antibiotic suppressive therapy to break the cycle. Table 56-5 outlines the characteristics of the drugs we most commonly employ for suppression.

## VESICoureTERAL REFLUX

VUR refers to the retrograde passage of urine from the bladder into the ureter. Although VUR was first observed in the late 1800s, its clinical importance has only been recognized in the past 5 decades. Hutch's studies, reported in 1952, demonstrated the pathophysiologic changes of VUR in the paraplegic patient. This report and the observations of Hodson in 1959, regarding the association between VUR, UTI, and pyelonephritic scarring, set the stage for the modern era of reflux management.

Although most commonly diagnosed during the evaluation of the pediatric patient with UTI, VUR may also be diagnosed during evaluation of the patient with hypertension, proteinuria, voiding dysfunction, or chronic renal insufficiency or during the evaluation of a sibling with VUR.

## Pathophysiology

Figure 56-7 depicts the various anatomic components of the competent ureterovesical junction (UVJ) as well as the abnormalities most often implicated in the genesis of VUR. The normal UVJ is characterized by an oblique entry of the ureter into the bladder and a length of submucosal ureter providing a high ratio of tunnel length to ureteral diameter. This anatomic configuration provides a predominantly passive valve mechanism.<sup>47,48</sup>

As the bladder fills and the intravesical pressure rises, the resultant bladder wall tension is applied to the

**Table 56-5** Characteristics of Commonly Used Urosuppressive Antibiotics

Drug	Therapeutic Dose	Suppressive Dose	How Supplied	Comments
Nitrofurantoin	2 mg/kg PO qid	1 mg/kg PO qd	Suspension (5 mg/mL) Capsule (25, 50 mg)	Avoid in patients < 1 mo of age Not effective if CrCl < 40 mL/min Nausea common with suspension; sprinkling macrocrystals may avoid this
Trimethoprim-sulfamethoxazole	4 mg/kg trimethoprim + 20 mg/kg sulfamethoxazole PO bid	2 mg/kg trimethoprim + 10 mg/kg sulfamethoxazole PO qd	Suspension (8 mg trimethoprim + 40 mg sulfamethoxazole per mL) Tablet (80 mg trimethoprim, 400 mg sulfamethoxazole)	Avoid in patients < 1 mo of age Contraindicated with hyperbilirubinemia May cause blood dyscrasias and Stevens-Johnson syndrome
Trimethoprim (Primsol)	5 mg/kg PO bid	2 mg PO qd	Oral solution 50 mg/5 mL	Avoid in patients < 2 mo of age
Amoxicillin	10 mg/kg PO tid	10 mg/kg PO qd	Suspension (25, 50 mg/mL) Drops (50 mg/mL)	Good alternative for neonates
Cephalexin	25 mg/kg PO bid	25 mg/kg qd	Suspension 125 mg/5 mL or 250 mg/5 mL	Alternative for neonates

**Figure 56-7.** Components of the competent ureterovesical junction. Those abnormalities most often implicated in the etiology of vesicoureteral reflux are outlined. BOO, bladder outlet obstruction; NVD, neurovesical dysfunction.

roof of the ureteral tunnel. The result is a compression of the ureter, which closes this structure to the retrograde passage of urine. Intermittent increases in bladder pressure, such as the act of voiding, upright posture, activity, and coughing, are met with an equal and immediate increase in resistance to retrograde urine flow. This effect is supplemented by the active effects of ureterotrigoal muscle contraction and ureteral peristalsis.<sup>48,49</sup>

Marginal tunnels can be made to reflux during infection owing to UVJ distortion, loss of compliance of the valve roof, and intravesical hypertension. Excessively high intravesical pressure as with neurovesical dysfunction (NVD) or bladder outlet obstruction (BOO) may also potentiate reflux, as may a neurogenically or structurally (e.g., diverticulum or ureterocele) weak detrusor floor. Because the submucosal ureter tends to lengthen with age, the ratio of tunnel length to ureteral diameter increases and the propensity for reflux may disappear.<sup>47,48</sup>

Of critical importance is the concept of intrarenal reflux (IRR), which has been demonstrated clinically<sup>50</sup> and experimentally.<sup>51</sup> The usually oblique entry of the papillary ducts onto the surface of simple papillae inhibits IRR. In contrast, the papillary duct entrance onto compound papillae facilitates IRR (see Fig. 56-4). The critical pressure for IRR is considered to be about 35 mm Hg in compound papillae.<sup>51,52</sup>

Experimentally, this same pressure may cause scar formation in the absence of infection.<sup>51,53,54</sup> When occurring intravesically, this pressure has been associated with an increased risk of renal deterioration. Higher pressure is thought to be necessary to induce IRR in simple papillae.

The combination of infection and IRR is particularly devastating. Focal scarring appears to be explained by the different susceptibility of renal papillae to IRR. The polar distribution of compound papillae corresponds closely to the predominant occurrence of renal scarring in the upper and lower poles of the kidney.

## Classification

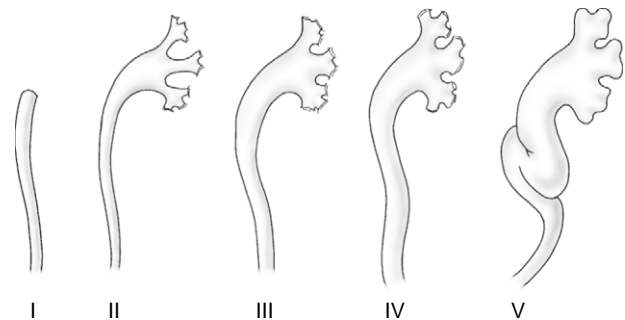

Many attempts at classification have been advanced. Reflux has been described as low pressure (occurring during the filling phase of the VCUG) or high pressure (occurring only during voiding). Reflux due to a congenitally deficient UVJ is referred to as *primary* reflux, whereas reflux due to a BOO and neurogenic bladder is referred to as *secondary* reflux. Further classification includes simple reflux and complex reflux. Complex reflux would include the refluxing megaureter, the refluxing duplicated ureter, the refluxing ureter associated with a diverticulum or ureterocele, and the occasional refluxing ureter associated with ipsilateral ureteropelvic or ureterovesical obstruction. The most clinically pertinent classification systems, however, have attempted to quantitate the degree of reflux. At the present time, VUR is graded according to the international classification system depicted in Figure 56-8.<sup>55</sup> This classification system is based not only on the proximal extent of retrograde urine flow and ureteral and pelvic dilatation but also on the resultant anatomy of the calyceal fornices.

Grade I VUR refers to the visualization of a non-dilated ureter only, whereas grade II VUR refers to visualization of a nondilated renal pelvis and calyceal system in addition to the ureter. Grade III reflux involves mild to moderate dilatation or ureteral tortuosity with mild to moderate dilatation of the renal pelvis and calyces. The fornices, however, remain sharp or only minimally blunted. Once the forniceal angle is completely blunted, grade IV reflux has developed. Papillary impressions in the majority of calyces can still be appreciated. Loss of the papillary impressions along with increased dilatation and tortuosity is referred to as grade V reflux.

## Epidemiology

The incidence of VUR in otherwise normal children has been estimated to be approximately 1%.<sup>56</sup> Also apparent from these data is the fact that the incidence of VUR is also small in neonates and infants.

A much higher incidence of VUR (between 30% to 40%) is reported in patients undergoing evaluation for UTI.<sup>57-59</sup> This incidence rises with decreasing age.<sup>60</sup>

**Figure 56-8.** The international grading system for vesicoureteral reflux. See text for description. (From The International Reflux Committee: Medical versus surgical treatment of primary vesicoureteral reflux. *Pediatrics* 67:396, 1987.)

Thus, the infant who is most vulnerable to the combination of UTI and VUR is precisely the pediatric patient in whom this combination is most likely to occur.

Although the majority of reflux patients are female, a few important characteristics of males with VUR require consideration. Although males account for approximately 14% of patients with VUR,<sup>61</sup> an increased incidence of VUR (30%) is found in those males presenting with UTI.<sup>58</sup> Boys with VUR tend to present at a relatively young age (25% if younger than 3 months), and younger children tend to have the most severe degrees of reflux.<sup>61</sup>

Multiple studies have documented a significant risk of VUR in family members of children with reflux. The reported risk of sibling reflux ranges from 27% to 34%,<sup>62-64</sup> whereas as many as 66% of offspring of women with reflux also have VUR.<sup>65</sup> As a result of these studies, it has been suggested that siblings, especially those younger than 2 years of age, undergo screening investigation.

A particularly important subset of patients with reflux includes those who have secondary reflux. Most have NVD or BOO as their primary disease. Many patients, however, have reflux not because of increased bladder pressure alone but rather because UVJ problems appear to be part of the spectrum of their congenital deformity. Examples include imperforate anus,<sup>66</sup> ureterocele,<sup>67</sup> and bladder exstrophy. Although a significant incidence of NVD exists in patients with imperforate anus, this is not a prerequisite for VUR.<sup>68</sup> The diagnosis of VUR in imperforate anus thus assumes a critical importance to the pediatric surgeon. Not only may the association of NVD potentiate an increased severity of reflux and the development of infection, the presence of a rectourethral or rectovesical fistula provides the opportunity for severe urinary contamination. Consequently, we believe that the patient with a rectovesical or rectourethral fistula should be managed with a completely diverting colostomy. Although many infants with posterior urethral valves have reflux due to or exacerbated by high intravesical pressure, the incidence of VUR in these patients is only approximately 50%. Many have congenitally abnormal ureteral insertions into the bladder.<sup>69</sup>

In addition to these structural associations, important functional problems exist as well, including florid NVD, as seen in myelodysplasia,<sup>70</sup> and a variety of more subtle voiding disturbances.<sup>71-73</sup> A particularly important subset of VUR patients are those who have uninhibited detrusor contractions (UDCs). There are three important components needed for successful toilet training. Growth in bladder volume, development of volitional control over the striated muscle sphincter, and control over the smooth muscle in the bladder are required for the infantile bladder, which empties as a simple spinal reflex, to mature. Many children with reflux and recurrent UTI have UDCs. Such involuntary or uninhibited bladder contractions are not caused by neurologic disease. Intense voluntary constriction of the striated sphincter occurs in an attempt to ensure continence and results in excessively high intravesical pressures. Pressures exceeding 150 cm H<sub>2</sub>O have

been seen with resultant intravesical distortions, such as diverticula, saccules, trabeculations, and abnormal ureteral orifices.<sup>74</sup> Reflux occurred in almost half of the children studied with UDC and UTI. Abnormal ureteral orifices were seen in 30% of children without reflux.

All patients with VUR must be screened for frequency, urgency, and incontinence, all of which suggest UDCs. Vincent's curtsy, a squatting maneuver spontaneously employed to prevent incontinence, is particularly suggestive.<sup>73</sup> That these UDCs may cause reflux is suggested by an enhanced resolution of reflux with anticholinergic drug therapy. Equally important is the potential for UDCs to cause a false-negative cystogram. During the performance of a VCUG, the child is generally encouraged to void when the urgency to do so occurs. In the presence of UDCs, voiding may occur prematurely, and VUR, which might otherwise occur under conditions of volitional detrusor-sphincter dyssynergia, may be masked.

## Diagnostic Evaluation

The diagnosis of VUR is made by a cyclic VCUG, with either contrast medium or isotope.<sup>75,76</sup> Great care is taken to avoid technical factors that may themselves produce or enhance reflux. Body temperature contrast material, which is not excessively concentrated, is instilled into the bladder through a small catheter by gravity flow of modest pressure in a nonanesthetized child.

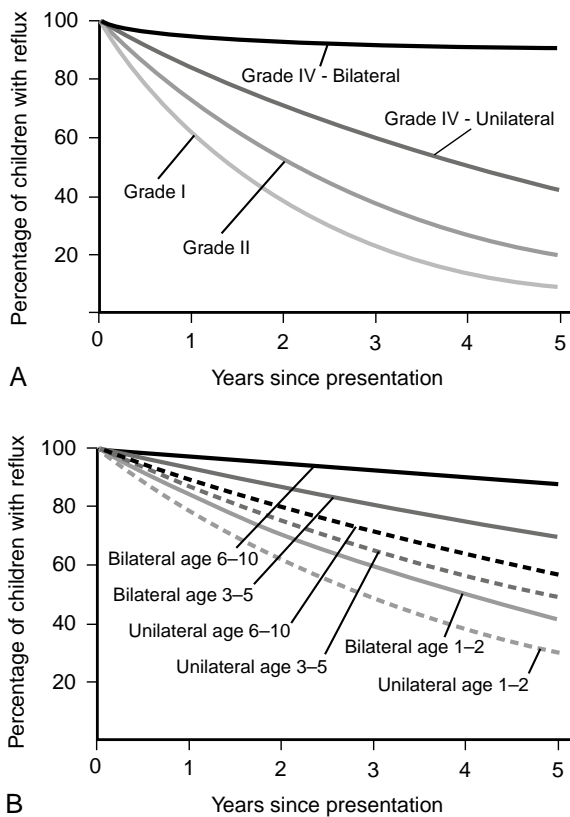

Imaging of the upper tracts is extremely important and may be accomplished by ultrasonography and/or isotope renography. All may detect scarring, but isotope renography is particularly sensitive in our experience. Ultrasonography is helpful in quantitating renal growth or atrophy.

Patients with frequency, urgency, incontinence, and Vincent's curtsy should be considered strongly for urodynamic studies. The presence of UDCs or detrusor-sphincter dyssynergia should be resolved before consideration is given to antireflux surgery.

## Natural History

The natural history of VUR is extremely variable, from spontaneous resolution to clinically silent scar formation to hypertension and end-stage renal failure. Numerous factors may contribute to the potential for resolution, including the patient's age, the grade of reflux, the appearance of the ureteral orifice, the length of the ureteral submucosal tunnel, and the intravesical dynamics. The American Urological Association (AUA) Pediatric Vesicoureteral Reflux Guidelines Panel analyzed 26 reports, comprising 1987 patients with conservative follow-up, to estimate the probability of reflux resolution (Fig. 56-9).<sup>77</sup> In general, a lower reflux grade correlated with a better chance of spontaneous resolution.

Younger children are thought to have better prognoses for resolution of reflux. This tendency for resolution may be due to the trigonal growth, but the

**Figure 56-9.** A, Percentage chance of reflux persistence, grades I, II, and IV, for 1 to 5 years after presentation. B, Percentage chance of reflux persistence by age at presentation, grade III, for 1 to 5 years after presentation. (From Elder JS, Peters CA, Arant BS, et al: Report on the Management of Primary Vesicoureteral Reflux in Children. Baltimore, American Urological Association, 1997.)

diminishing prominence of UDCs with age is also important. Spontaneous resolution is relatively independent of grade in secondary reflux, implicating management of the primary bladder dysfunction as the primary prognostic variable (Fig. 56-10).<sup>78</sup>

Renal injury due to VUR may take the form of focal scarring, generalized scarring with atrophy, and failure of renal growth.<sup>79</sup> As a result, kidneys drained by refluxing ureters should be observed not only for scarring but also for renal growth.<sup>80</sup> Reflux-induced renal injury is usually a result of the association of VUR with UTI.<sup>81</sup> It is generally considered that such injury is most likely in children younger than the age of 2 years.<sup>60</sup> It is now clear, however, that the risk of renal injury from VUR extends well beyond this age.<sup>59,81-83</sup> Reflux appears capable of causing renal injury in the absence of UTI, because of the pressure effects from NVD and BOO. The ability of high intravesical pressure, when associated with VUR, to cause renal injury has been confirmed experimentally.<sup>84</sup>

Infants have been seen, however, with significant renal injury in the absence of BOO, NVD, and UTI.<sup>85</sup> The ureteral bud theory states that VUR associated with displacement of the ureteral orifice is associated with anomalies of renal differentiation.<sup>86</sup> Such ureters probably do not arise from the appropriate segment of wolffian duct and consequently make ectopic

**Figure 56-10.** The rate of spontaneous resolution of secondary vesicoureteral reflux as a function of reflux grade. (From Cohen RA, Roston MG, Belman AB, et al: Renal scarring and vesicoureteral reflux in children with myelodysplasia. J Urol 144:541, 1990.)

contact with the nephrogenic cord, resulting in abnormal renal development. Although such a mechanism may be present in some patients, it is now clear that congenital VUR-associated renal injury in the absence of BOO, NVD, and UTI may occur in the presence of a normally positioned ureteral orifice.<sup>87</sup> This finding implies that in-utero VUR may injure the developing kidney.

In a longitudinal study of 923 children, high-pressure bladder dynamics, severity of reflux, and frequency of UTIs were the chief contributing factors in the development of new scars or the worsening of old scars.<sup>83</sup>

**Figure 56-11.** The risk of development of new scars or progression of old scars increases with increasing grades of vesicoureteral reflux. The number of ureters in each grade is indicated numerically.<sup>83</sup>

Children with low-grade VUR were relatively unlikely to develop progressive renal injury as compared with those children with grades IV and V reflux (Fig. 56-11). A similar relationship is seen in pediatric patients with secondary reflux (Fig. 56-12). When monitoring such children for progression of renal injury as an indicator of success of a therapeutic regimen, one must be aware that radiographic evidence of new renal injury may take up to 8 months to manifest.

Beyond the silent progression of renal scarring lies a spectrum of symptomatic nephropathy, most notably renal parenchymal hypertension and end-stage renal disease. The significance and predominance of reflux nephropathy as a cause of renal parenchymal hypertension has been reviewed.<sup>88</sup> Thirty to 65 percent of childhood hypertension is associated with reflux nephropathy. Reflux nephropathy is an important cause of end-stage renal failure in children and adults.<sup>89-91</sup> Many patients so affected will not have had recognized prior infection or will have the first recognized infection at or near the time of diagnosis of end-stage renal disease.<sup>89</sup> Because histologic evidence of chronic pyelonephritis is found, preceding infection is likely, underscoring the silent progressive nature of reflux nephropathy and the need for meticulous long-term follow-up of children with VUR. Much data exist to suggest that glomerular lesions play an important role in the progression of reflux nephropathy. There is a clear association between reflux nephropathy, "heavy" proteinuria, and glomerular lesions that resemble focal segmental glomerulosclerosis.<sup>92</sup> Although the mechanisms of this disease remain uncertain, immunologic injury, macromolecular trapping with mesangial injury, vascular alterations with hypertension, and glomerular hyperfiltration have

**Figure 56-12.** The prevalence of renal scarring as a function of reflux grade in patients with secondary reflux. Risk of renal scarring increases with increasing grades of reflux. The number of ureters in each grade is indicated numerically.<sup>83</sup>

been implicated. The latter theory of glomerular hyperfiltration is presently favored.

## Treatment

Nonoperative management of VUR (Table 56-6) is successful in the majority of patients. Such management may be considered in four stages: (1) diagnostic evaluation, (2) avoidance of infection, (3) voiding dysfunction treatment, and (4) surveillance. Diagnostic evaluation has been previously reviewed. However, it

**Table 56-6** General Guidelines for the Nonoperative Management of Vesicoureteral Reflux

Treatment
Hydration
Hygiene
Perineal hygiene
Avoid:
Harsh soaps during tub baths
Bubble baths
Shampoos
Bowel management
Avoid constipation
Treat encopresis
Suppressive antibiotics
Observation without antibiotics
Anticholinergics, spasmolytics
Surveillance
Urine culture
Monthly for 3 mo after last UTI
Thereafter, every 2 to 3 mo
Renal imaging every 6 to 12 mo
Renal size (ultrasound, IVU)
Focal scarring (renal scan, IVU)
Voiding cystourethrography (yearly)
Radiographic VCUG
Initial (male, female suspected NVD)
Follow-up (NVD)
Isotope VCUG
Routine surveillance
Record growth yearly (height, weight)
Blood pressure
Routine (yearly)
Renal scarring (quarterly)
Renal function tests
BUN, creatinine (yearly if bilateral RN)
GFR estimated (yearly if azotemic)
$\frac{\text{height (cm)} \times 0.55}{\text{serum creatinine}} = \text{GFR (mL/min/1.73 m}^2\text{)}$
Maximum urine osmolality (yearly if bilateral RN)
Cystoscopy
Done at time of antireflux surgery; otherwise rarely necessary
Urodynamic evaluation
History of voiding dysfunction

BUN, blood urea nitrogen; GFR, glomerular filtration rate; IVU, intravenous urogram; NVD, neurovesical dysfunction; RN, reflux nephropathy; UTI, urinary tract infection; VCUG, voiding cystourethrogram.

is important to stress that evaluation and treatment of voiding dysfunction and BOO are imperative. Patients with problematic uninhibited detrusor contraction should undergo suppression therapy. We employ oxybutynin in the majority of these pediatric patients. NVD with retentive characteristics may require intermittent catheterization. Good hydration, perineal hygiene, and bowel management are crucial and apply to all patients. With the exception of the older boy with low-grade reflux, most children require suppression antibiotics (see Table 56-5). Although antibiotics are generally well tolerated, the long-term implications of chronic suppression remain incompletely investigated.

Once a nonoperative regimen is selected, the patient is committed to long-term, strict surveillance. Renal imaging is performed every 6 to 12 months, depending on the age at diagnosis and the stability of the disease. Attention is directed at both renal growth and focal scarring. Voiding cystourethrography is generally performed yearly. The child's growth, renal function, and blood pressure are monitored. The role of urodynamics has been previously outlined. Cystoscopy is rarely necessary except at the time of antireflux surgery when it is done to exclude urothelial inflammation and to confirm the position and number of ureteral orifices.

Although the actual decision to perform antireflux surgery must be carefully individualized, we feel the absolute indications for surgical correction of VUR are (1) progressive renal injury, (2) documented failure of renal growth, (3) breakthrough pyelonephritis, and (4) intolerance or noncompliance with antibiotic suppression. Other relative indications for surgical correction of VUR are grade IV-V reflux, pubertal age, and failure to respond to 4 to 5 years of suppression therapy.

The AUA Pediatric Vesicoureteral Reflux Guidelines Panel published their recommendations for management of VUR in children (Table 56-7).<sup>77</sup> There is still no consensus on the management of VUR in patients aged 10 or older or on the length of time that the clinician should wait before recommending surgery. The actual decision must be carefully individualized.

The established surgical principles of successful ureteral reimplantation include (1) adequate ureteral exposure and mobilization, (2) meticulous preservation of the blood supply, and (3) creation of a valvular mechanism whose submucosal tunnel length to ureteral diameter ratio exceeds 4:1. These goals can be attained by a variety of procedures, as shown in Figure 56-13.

Important differences exist between these operative procedures. Variables include (1) presence or absence

Recommendations were derived from a survey of preferred treatment options for 36 clinical categories of children with vesicoureteral reflux (VUR).

The recommendations are classified as follows:

*Guidelines*, Treatments selected by eight or nine panel members, given the strongest recommendation language.

*Preferred options*, Treatments selected by five to seven of nine panel members.

*Reasonable alternative*, Treatments selected by three to four of nine panel members.

*No consensus*, Treatments selected by no more than two of nine panel members.

\*For patients with persistent uncomplicated reflux after extended treatment with continuous antibiotic therapy.

†No consensus was reached regarding the role of continued antibiotic prophylaxis, cystography, or surgical treatment.

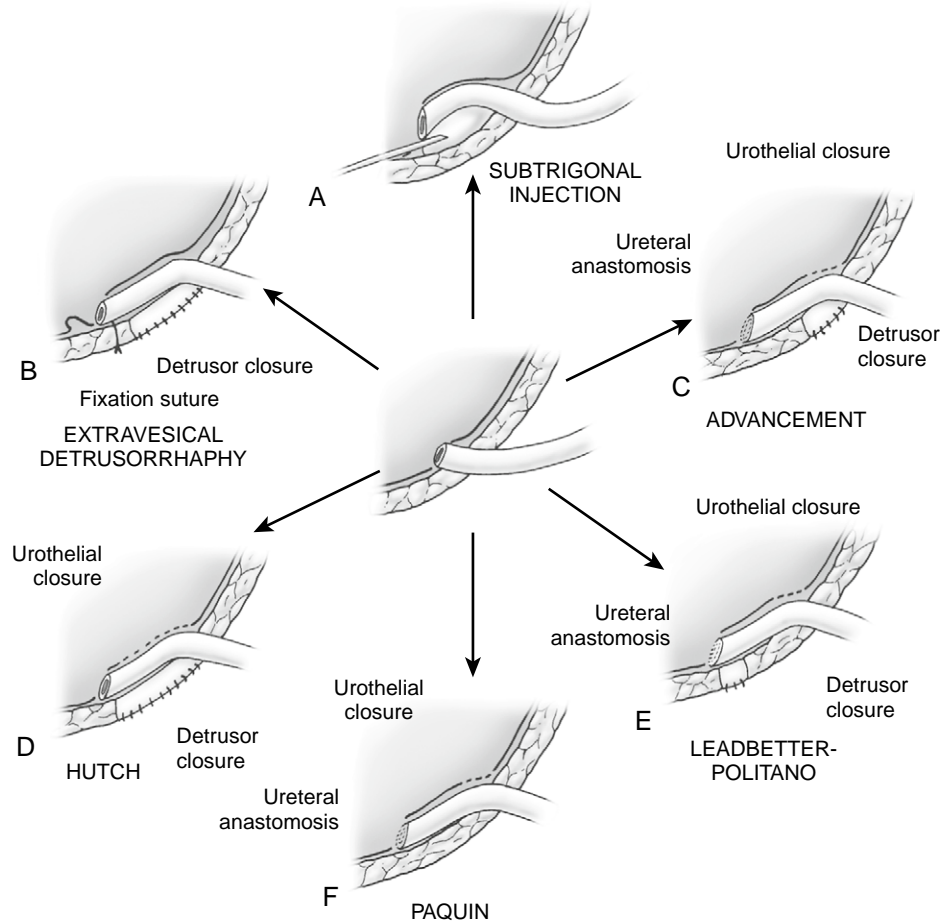

From American Urological Association: Report on the Management of Primary Vesicoureteral Reflux in Children. Baltimore, American Urological Association Pediatric Vesicoureteral Reflux Clinical Guidelines Panel, 1997.

of ureteral anastomosis, (2) need for detrusor closure, (3) transgression of urothelium, and (4) whether the neohiatus is fashioned by an appropriately sized detrusor incision or by closing the detrusor muscle around the ureter.

Performance of a ureteral anastomosis increases the risk of postoperative obstruction, whereas the need for detrusor closure increases the risk of diverticular development. Table 56-8 outlines the specific advantages and disadvantages of some of the procedures. Three of the most commonly employed operations for primary VUR are diagrammed in Figures 56-14 through 56-16.

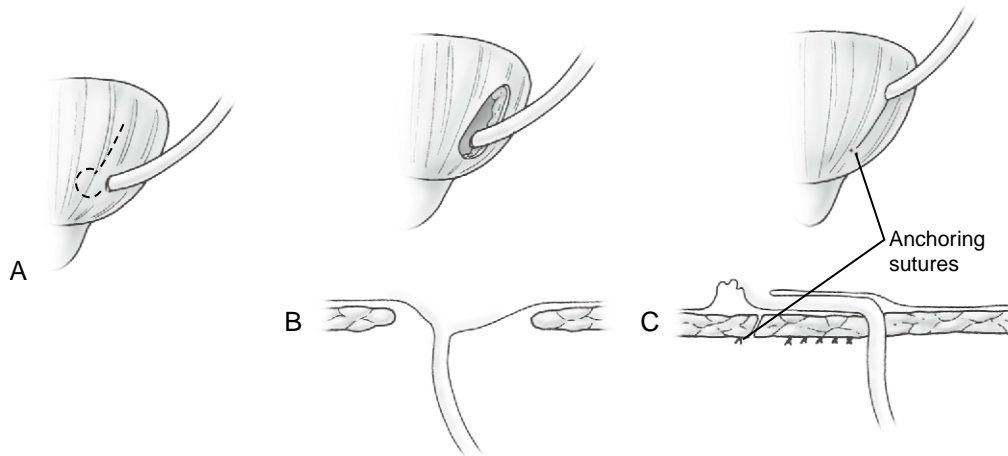

In general, excellent results are attained with the majority of open procedures. A review of 86 reports, including 6472 patients (8563 ureters), found overall operative success to be 96%.<sup>77</sup> Resolution of the reflux was achieved in 99% with grade I, 99.1% with grade II, 98.3% with grade III, 98.5% with grade IV, and 80.7% with grade V.

We prefer the extravesical detrusorrhaphy approach.<sup>93-95</sup> Because the lumen of the bladder is not entered, there is minimal postoperative hematuria, few bladder spasms, and a short postoperative hospitalization. The absence of a ureteral anastomosis decreases the risk of postoperative obstruction. No ureteral stents, suprapubic tubes, or drains are utilized. The bladder catheter is removed on the first day after unilateral correction and the second day after a bilateral procedure. The extravesical approach for bilateral ureteral reimplantation has been questioned because of a reportedly high incidence of postoperative urinary retention.<sup>96</sup> In our experience with a large group of patients, we found acceptable rates of postoperative urinary retention (4%), which is transient and has minimal morbidity.<sup>97</sup> The use of extravesical detrusorrhaphy has been successfully expanded to include megareter repair,<sup>94</sup> reimplantation of the ureters associated with paraureteral Hutch diverticula,<sup>98</sup> as well as

**Figure 56-13.** Conceptual comparison of techniques to correct reflux. A common theme is the achievement of a long length of intravesical ureter based on a strong detrusor floor and covered with compressible urothelium.

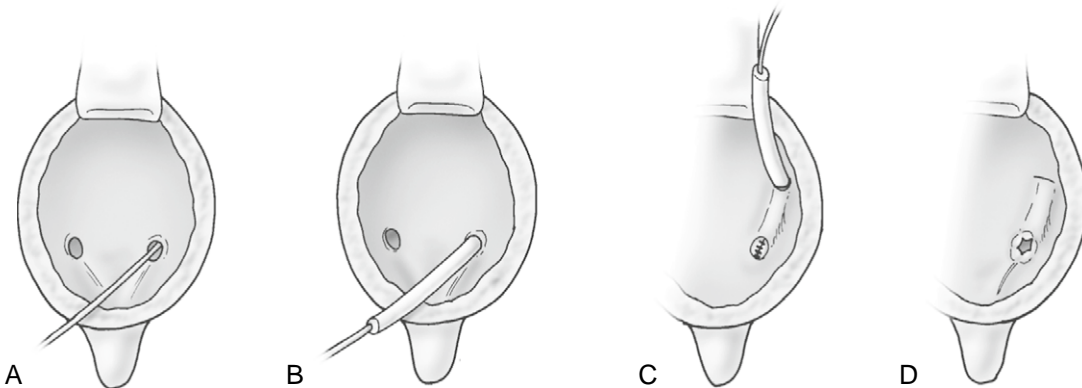

Table 56-8 Specific Advantages and Disadvantages of Commonly Performed Antireflux Procedures		
Procedure	Advantages	Disadvantages
Subtrigonal injection	Endoscopic procedure	Material injected: Teflon: migration, granuloma formation Collagen: uncertain durability
Extravesical detrusorrhaphy	Bladder never opened No hematuria No ureteral anastomosis Minimal bladder spasms Endoscopically accessible ureteral orifices	
Advancement Cohen (transtrigonal) Glenn-Anderson	Avoids complications of neohiatus formation in Leadbetter-Politano reimplantation	Transtrigonal: difficult to access ureter endoscopically Glenn-Anderson: limited length of tunnel achievable
Hutch	No ureteral anastomosis Good alternative with large associated congenital diverticulum	
Leadbetter-Politano	Excellent ureteral tunnel dimensions with endoscopically accessible ureteral orifices	Risk of ureteral obstruction Risk of sigmoid colon injury with left reimplantation
Paquin	Versatility, extremely useful during complex reconstructive procedures	

**Figure 56-14.** The extravesical detrusorrhaphy antireflux technique conceptually viewed from behind the bladder. **A**, The detrusor is incised. **B**, The dissection is continued until the plane between urothelium and muscle has been developed. **C**, The ureter is advanced and fixed into position with anchoring sutures. The detrusor is closed.

**Figure 56-15.** The Cohen cross-trigonal ureteral reimplantation. **A**, The ureter is intubated and the mucosa is incised circumferentially around the ureteral orifice. **B**, The ureters are dissected from the muscular attachments and mobilized until free within the retroperitoneum. **C**, Cross-trigonal tunnels are created by scissor dissection. **D**, The ureteral anastomoses are completed.

**Figure 56-16.** The Leadbetter-Politano ureteral reimplantation. **A**, The ureter is intubated. **B**, The ureter is mobilized. The hiatus is dilated, and the retroperitoneal ureter is mobilized. Under direct vision the peritoneum is reflected from the outer surface of the bladder. **C**, The neohiatus is created, and the ureter is internalized into the bladder. The tunnel is created by scissor dissection, and the original hiatus is closed. **D**, The ureteral anastomosis is completed.

correction of VUR associated with duplicated collecting systems.<sup>99</sup> The four major principles of a successful extravesical detrusorrhaphy are (1) complete encirclement and mobilization of the ureter, (2) distal fixation of the ureter with long acting absorbable sutures, (3) wide mobilization of the muscular flaps to enable firm approximation of the detrusor over the ureter, and (4) development of sufficient tunnel length.

Complications of ureteral reimplantation are not common.<sup>77,100</sup> The most common complication is de novo contralateral reflux,<sup>101</sup> whereas the most common technical complications are ureteral obstruction, persistent reflux, and diverticula formation. Persistent reflux may be caused by an insufficient tunnel length/ureteral diameter ratio. However, the greatest risk of postoperative reflux is related to the high-pressure voiding dynamics due to uninhibited bladder contraction, detrusor sphincter dyssynergia, and urinary retention. Ureteral obstruction may be due to ureteral kinking (at the neohiatus or obliterated umbilical artery), an excessively high placed neohiatus, construction of a tight neohiatus, twisting, anastomotic stricture, devascularization, and a tight tunnel. With attention directed toward the avoidance of technical

complications and the selection of a procedure associated with the lowest complication rate, ureteral reimplantation remains a safe and highly successful operation.

Since the initial report in 1984 of successful endoscopic subureteral injection of polytetrafluoroethylene for correction of VUR,<sup>102</sup> this endoscopic technique has been widely used worldwide with different injectable materials.<sup>103-105</sup> This ambulatory procedure performed under a brief general anesthetic has the lowest morbidity and children return to full activity the next day. The only injectable substance with U.S. Food and Drug Administration approval is dextranomer/hyaluronic acid copolymer (Deflux, Q-Med Scandinavia, Princeton, NJ).<sup>106</sup> This substance is biodegradable, has no immunogenic properties, and seems to have no potential to cause malignant transformation. Results vary, but most studies indicate a success rate of around 80% for curing VUR.<sup>106-109</sup> Long-term reflux resolution rates are not known because it is difficult to re-study patients who are doing well, but there appears to be a low recurrence rate after 1 year.<sup>110</sup> However, recent studies suggest long-term recurrence of VUR may be more common than originally thought.<sup>111</sup>

# BLADDER AND URETHRA

Patrick C. Cartwright, MD • Brent W. Snow, MD • M. Chad Wallis, MD

## ANATOMY AND PHYSIOLOGIC FUNCTION

The lower urinary tract consists of the bladder and urethra, which normally function as a coordinated unit to store and discharge urine from the body. Both structural and functional disorders of the bladder or urethra may be responsible for bleeding, incontinence, infection, discomfort, pain, and obstruction that can cause upper tract deterioration to the point of compromising renal function. In this chapter we focus on the major diseases and dysfunctional states of the bladder and urethra as a unit and on the management of such problems.

The bladder and upper urethra are composed of bundles of smooth muscle fibers arranged in a reticular lattice, the outermost bundles being more circular and the inner bundles more longitudinal in orientation at the bladder neck.<sup>1</sup> The smooth muscle bundles blend into the striated muscle of the external urethral sphincter, which is derived from the pelvic diaphragm. The bladder is lined by transitional epithelium, which is sensitive to irritants such as bacterial toxins and various urinary crystals. The urethra and trigone are especially sensitive, and the presence of any irritant in these areas can create significant discomfort.

Normal innervation and bladder function are intimately related. Proper function of the lower urinary tract depends on intact autonomic and somatic nervous innervation. The detrusor muscle of the bladder proper is innervated by both sympathetic and parasympathetic fibers. Storage functions are mediated by the sympathetic component, which arises from spinal levels T10-L1 and descends through the sympathetic chain to reach the bladder. The chemical mediator of this storage process is norepinephrine, which acts on  $\alpha$ -adrenergic receptors in the fundus of the bladder and causes muscle relaxation to aid in low-pressure storage of urine. The same sympathetic stimulus acts on predominantly  $\alpha$ -adrenergic receptors of the trigone, bladder neck, and proximal urethra to provide an increase in internal sphincter activity and further promote continence during the storage process by maintaining

outlet resistance.<sup>2,3</sup> The external urinary sphincter, innervated by the pudendal nerve, maintains progressively increasing tone as the bladder fills. This “guarding” provides an additional continence mechanism during the storage of urine.<sup>4</sup> As the child develops, the external sphincter may be consciously contracted at times of urgency or stress to prevent the unwanted passage of small amounts of urine. Properly coordinated function of the external urinary sphincter relies on an intact sacral reflex arc (afferents, sacral micturition center, pudendal efferents). This should be intact and well developed in normal infants, but is variably functional in infants with spinal cord or pelvic lesions.

The sensation of bladder fullness initiates a response in mature humans that causes them to seek an appropriate location for the discharge of urine. When ready, the parasympathetic nervous system, with acetylcholine as the mediator, causes cholinergic fibers of the detrusor to contract, resulting in a widened and shortened proximal urethra, eliminating its resistance to outflow. When coupled with relaxation of the volitional external sphincter, the bladder empties by sustained and complete contraction of the detrusor, leaving a residual urine volume in the bladder of less than 5 mL.

Spinal pathways connect the sacral micturition center with three centers in the brain stem, collectively called the *pontine micturition center*.<sup>5</sup> This center functions to inhibit urination during the storage phase and to produce external sphincter relaxation when sustained detrusor contraction occurs during the voiding phase. Above this level are areas of cerebral cortex, which oversee and modulate the autonomic process. It is the mature, integrated function of all these components that produces urinary continence.

Conscious control of the bladder (toilet training) is, in large part, a learned phenomenon. It requires adequate recognition by the brain that micturition would be inconvenient or socially unacceptable in a given situation. As the child grows older, the bladder gains capacity, allowing for longer intervals between voiding. The approximate bladder volume in ounces may be estimated in a child as age in years plus 2. It

may also be calculated by a more precise formula if needed.<sup>6</sup> It has been observed that the young infant voids 20 times per day, which decreases to about 10 times per day by age 3 years.<sup>7</sup> Along with this change, the child also learns to resist the urge to void by voluntary contraction of the external sphincter until the detrusor contraction passes and the bladder once again relaxes. Thus, toilet training depends on the development of voluntary detrusor sphincter dyssynergia, which at times can persist as a pathologic process.<sup>8</sup> Finally, full bladder control relies on the child developing volitional control over the spinal micturition reflex so that he or she can initiate or inhibit detrusor contractions. The majority of children have attained day and night continence by 4 years of age.

The inappropriate discharge of urine (enuresis) may be in part due to immaturity of the bladder and its nervous system connections. The usual sequence of bladder development is linked to that of the bowel development and is as follows:

1. Control of bowel at night
2. Control of bowel during the day
3. Control of bladder during the day
4. Control of bladder at night

Many lesions interfere with the ideal storage and emptying functions of the bladder. The application of appropriate diagnostic measures can lead to appropriate management decisions, which ultimately lead to continence and to preservation and protection of the upper urinary tract.

## CHILDHOOD INCONTINENCE

*Incontinence* is the term used for the unintentional loss of urine beyond toilet training. The following definitions are clinically useful<sup>9</sup>:

*Enuresis* or *nocturnal enuresis*: intermittent incontinence while sleeping

*Primary nocturnal enuresis*: never been continent at night

*Secondary nocturnal enuresis*: night-time incontinence after a dry period of at least 6 months

*Daytime incontinence*: daytime wetting after toilet training

*Stress incontinence*: urine leakage due to physically stressful activities such as coughing

*Urge incontinence*: unintentional loss of urine when bladder urgency occurs

The discussion of incontinence is divided into sections on nocturnal enuresis and daytime incontinence, realizing that some children have both. The current recommendation for children with nocturnal enuresis and daytime incontinence is to focus on daytime treatments first followed by nocturnal enuresis treatments.

## NOCTURNAL ENURESIS

Fifteen to 20 percent of children at 5 years of age continue to have bed wetting.<sup>10-12</sup> Because so many children still wet the bed at night before this age, it is

considered within the range of normal and not termed nocturnal enuresis. Night wetting, thereafter, resolves at the rate of about 15% each year, and by age 15 years, 99% of children remain dry.<sup>13</sup>

## Etiology

Children with monosymptomatic nocturnal enuresis are, in general, physically and emotionally similar to their peers. The difference lies in their inability to awaken during sleep when their bladder is full or contracts. The etiology of this disorder is likely complex, and several factors should be considered.

## Genetic

Family history is often strong, with multiple members having had childhood nocturnal enuresis. If both the parents have a history of bed wetting, 77% of their offspring will also. If only one parent had the problem, then 44% of the offspring exhibit the behavior. When neither parent has a history of nocturnal enuresis, then only 15% of their children have this problem.<sup>14</sup>

## Psychological

Psychological stress is observed to induce nocturnal enuresis in certain children. Secondary nocturnal enuresis often raises this concern. Common factors are divorce, changing of homes, birth of a new sibling, trouble at school, or just starting school.

## Developmental

As children grow, bladder capacity increases significantly each year at a proportion greater than urine volume produced.<sup>15,16</sup> Volitional control over the bladder and sphincter also may mature at variable rates and may be related to subtle delays in perceptual abilities or fine motor skills.<sup>17</sup>

## Urodynamic

Studies show that enuretic episodes simulate normal awake voiding when the bladder is full.<sup>16</sup> Although patients with nocturnal enuresis have more night-time unstable bladder contractions than do non-enuretic patients, the contractions are at low pressure and do not cause leakage.

When observed scientifically, night-time wetting appears to occur in three scenarios: wetting associated with significant restlessness with visceral and somatic activity (deep respirations); wetting with a quick contraction and minimal movement; and wetting with no central nervous system response (parasomnia).

## Sleep Disorders

Parents of children with nocturnal enuresis are generally convinced that these children sleep deeply and are difficult to arouse. However, controlled studies consistently find this not to be true. Enuretic patients sleep

no more deeply than age-matched controls, wet in all stages of sleep, and show no difference in awakening patterns. Wetting episodes occur as the bladder fills throughout the night.<sup>18</sup>

### *Antidiuretic Hormone*

Antidiuretic hormone (ADH) is released from the pituitary in a circadian rhythm so that levels are higher at night, and thus urine output is diminished. Some children appear to undersecrete ADH at night. Therefore, by not concentrating their urine at night, urine volume may overwhelm the bladder capacity and bed wetting results.<sup>19-22</sup> Although some patients follow this pattern, others do not. The altered circadian patterns appear to normalize with maturation.<sup>23</sup>

### **Evaluation**

Children usually are seen by their pediatrician when either the child becomes socially embarrassed or the parents are either “fed up” or worried that a pathologic process is present. The screening evaluation should include a history, physical examination, and, always, urinalysis. If these results are normal, then no other evaluation is needed because organic disease rarely causes monosymptomatic nocturnal enuresis. Routine radiographic evaluation or cystoscopy is not necessary. Children with an associated anomaly or problem such as urinary tract infection (UTI), evidence of sacral anomalies, or complex enuresis patterns often warrant medical imaging.

### **Treatment**

The treating physician should recognize enuresis as a symptom and not a disease. Realizing that there may be more than one cause permits the physician to consider more than one treatment option. Specific treatment is generally discouraged before the age of 7 years. Certain measures are sensible in all patients with nocturnal enuresis: void just before getting into bed, avoid huge fluid loads during the evening hours, and avoid caffeine after 3:00 PM.

### *Enuretic Alarms*

Wetting alarms are devices that fit in the underwear of the patients. When the device is moistened, an electrical contact is made and the alarm is sounded. This is conditioning therapy requiring a motivated patient and parents. A variety of products are available with an audio alarm, a vibrating alarm, or both. In our experience, the best alarm is simply one that is easy to set up and is able to awaken the child when it goes off. The parent may need to help arouse the child, take him or her to the bathroom, and reset the alarm. This may occur multiple times each night.

A compilation of 16 published series showed an initial cure rate of 82%.<sup>24</sup> The average length of treatment to achieve dryness varied between 18 nights and 2.5 months. Relapse does occur in 20% to 30% of children,

but re-treatment can be successful.<sup>25</sup> In a 1995 study, 1 year after instituting nocturnal enuresis treatments, wetting alarms were shown to give the best long-term results as compared with other treatments.<sup>26</sup> A more recent review confirms these findings.<sup>27</sup>

### *Imipramine*

Tricyclic antidepressants such as imipramine have been used for many years to treat bed wetting. The exact mechanism of action is unknown. Initial success has been reported in the 50% range. However, a 2003 Cochrane review found that only one fifth of children became dry during treatment and the relapse rate was 96% after cessation of treatment.<sup>28</sup> Clinical practice reveals that the longer the initial treatment, the more benefit before the effect wanes. It is suggested that the medication be weaned slowly rather than stopped abruptly.

Side effects include anxiety, insomnia, dry mouth, nausea, and personality changes. An imipramine overdose can cause fatal cardiac arrhythmias and conduction blocks that are untreatable. Therefore, medication safety in the home becomes a significant issue.<sup>29</sup> Some suggest that imipramine may improve response rates with the enuretic alarm.

### *Desmopressin*

Desmopressin is an analog of ADH that mimics its urine-concentrating activity without the vasopressor effect.<sup>19</sup> It is currently given orally. The effect of desmopressin is dose dependent, usually requiring 20 to 40 g/day for success.

Complete dryness rates vary with desmopressin therapy and may be highest in patients with a strong family history of bed wetting. In three multicenter trials in the United States, response rates were reported in 24% to 35% of children who had failures associated with other forms of treatment.<sup>30</sup> In a study in which dose titration was watched closely, 70% dryness was reported.<sup>31</sup> Desmopressin may occasionally have side effects, including electrolyte changes, nasal irritation, and headaches. It remains available as a nasal spray, but this formulation of the medication lost its indication for treating nocturnal enuresis owing to a higher incidence of severe hyponatremia. Parents should be warned to limit the amount of fluids a child drinks during the evening of treatment to avoid this side effect.

### *Anticholinergics*

Oxybutynin is the most common drug used in this category for enuresis. It is effective when daytime and night-time wetting occur in the same patient but has no benefit over placebo when night-time wetting is the only symptom.<sup>32</sup>

### *General Approach*

Although many parents consider bed wetting a problem, they often do not consider it significant enough to treat, especially when medications are being

considered. If therapy is desired, it is often most reasonable to begin with an enuretic alarm. This has the highest response rate, no side effects, and the lowest relapse rate. Combination therapy with imipramine may be considered when use of the alarm is unsuccessful. If desmopressin has proved successful in a specific patient, the patient and family may choose to keep it available and use it only on specific nights when dryness is especially desired (e.g., sleepovers, campouts). Some patients do not respond to therapy, and time, reassurance, and a caring approach are all that can be offered.

## DAYTIME INCONTINENCE

Daytime incontinence is the undesired loss of urinary control while awake. The patient history is of paramount importance in sorting out the various categories of daytime incontinence.<sup>33,34</sup> The physical examination and evaluation should always assess for an abdominal mass or tenderness, distended bladder, normal genitalia, signs of spina bifida occulta, perineal sensation, sacral reflexes, gait, lower extremity reflexes, and urinalysis. Radiographic evaluation, usually voiding cystourethrogram (VCUG) and renal ultrasonography, are necessary in patients with UTI or complex incontinence patterns.

### Bladder Instability

Bladder instability is by far the most common diagnosis in children with persistent daytime wetting.<sup>35</sup> These children are usually toilet trained but later develop increasing “accidents” associated with urgency. They describe not knowing that the bladder contraction was coming. They dash to the bathroom or try to “hold it in.” Boys grab and compress the penis, and girls often cross their legs and dance around or squat with the heel compressed over the perineum (Vincent’s curtsy). In our experience, children with hyperactivity disorders or a willful disposition appear prone to this dysfunctional voiding pattern.

By urodynamic studies, these children demonstrate significant unstable contractions during bladder filling that cause leakage before sphincter contraction (or posturing) can control it. Because these unstable contractions or spasms occur frequently during the day, a retentive pattern develops by using the external sphincter to “hold on.” When these children do get to the bathroom and try to void, the sphincter relaxes poorly or only intermittently, with resultant stop-and-go voiding, difficulty initiating a urinary stream, straining, and poor emptying, which is described by the term *voiding dysfunction*. The elevated pressure during voiding and the poor emptying may result in secondary vesicoureteral reflux (VUR) and UTI. Finally, the overactivity of the urinary sphincter may carry over to the function of the anal sphincter, making stool retention and encopresis commonly associated findings.

## Treatment

Treatment rests on managing all aspects of this condition simultaneously. Mild encopresis is treated with dietary changes, fiber, laxatives, or mineral oil after initial bowel clean out. Recurring UTIs are managed with prophylactic antibiotics. Bladder instability is treated with timed voiding at frequent intervals (an alarm watch for the child is helpful) and with anticholinergics such as oxybutynin or tolterodine.<sup>36-38</sup>

Biofeedback has gained in popularity for the treatment of the voiding dysfunction that often accompanies bladder instability. Electrodes placed on the perineum near the genitourinary diaphragm can be attached to monitors, an audio signal, or a computer display so the child can learn to relax the external sphincter voluntarily, resulting in better voiding coordination.<sup>39,40</sup> The process typically requires 4 to 8 visits on a weekly basis with follow-up sessions as needed. As acceptance of this treatment modality has grown, it is becoming more available.

Unfortunately, initial success with any treatment program is often followed by later relapse. If initial treatment is unsuccessful, it may be successful if tried again later. Patients older than age 8 years who fail treatment should be considered for urodynamic testing. Secondary VUR may be present due to elevated bladder pressures and is managed in the usual manner with a high probability for resolution (80%) as bladder function improves.<sup>41</sup> The unstable bladder of childhood is almost always outgrown, and adults generally do not demonstrate this type of wetting problem.

## ISOLATED FREQUENCY SYNDROME

A separate, and much less common, group of children present with fairly acute onset of urinary frequency. They appear healthy, are normal on examination, and have normal urinalysis and culture. They do not have true urgency or any wetting but feel that they must urinate frequently, sometimes every 5 to 10 minutes. They void a very small amount each time. Most sleep through the night and void a large amount on awakening. The pattern may come and go over weeks or months.

The cause is unclear but may relate to emotional stress in many cases. Careful assessment is crucial, and reassurance to the parent and child is paramount. Sometimes, setting an alarm to progressively lengthen voiding intervals with a reward for success is helpful. This condition is benign and self-limited, although it may persist intermittently for months. Anticholinergics have no benefit, and further evaluation is not required.

## INFREQUENT VOIDER/UNDERACTIVE BLADDER

On the other end of the voiding spectrum are those children who void only once or twice daily and may not urinate until the afternoon.<sup>42</sup> These children

have developed urinary retentive behavior without any bladder instability and have dilated, high-capacity, low-pressure bladders.<sup>43</sup> Some show an aversion to bathrooms or exhibit excessive neatness, whereas many others appear reasonably adjusted. They may be somewhat prone to UTIs and stress incontinence.

Evaluation must demonstrate no neurologic cause and no structural obstruction to emptying. Ultrasonography may show good emptying if performed before and after voiding. A timed voiding regimen is usually required to get these children to void regularly if problems are occurring. This pattern tends to improve with maturation.

## CONTINUOUS INCONTINENCE

Patients who present with total incontinence and constant dribbling of urine have a higher probability of urinary tract anomaly pathology, and require radiographic and possibly urodynamic evaluation.

## HINMAN'S SYNDROME

A small number of children demonstrate persistent incontinence, repeated febrile UTIs, reflux, high bladder storage pressures, and very poor emptying.<sup>44</sup> This appears to be a deeply ingrained "learned" disorder of severe voluntary detrusor-sphincter dyssynergia. In these patients, the urinary tract has the appearance of that in a patient with neurogenic bladder. There is hydronephrosis, a trabeculated bladder, reflux, and sometimes progressive loss of renal function (Fig. 57-1).

Aggressive therapy with prophylactic antibiotics, anticholinergics, urodynamic biofeedback training, timed voiding, or intermittent catheterization may be needed.<sup>45</sup> Some recalcitrant cases may require bladder diversion or augmentation to avoid renal failure. As with many "functional" disorders, the severity of Hinman's syndrome tends to wane with maturation, but progressive deterioration may not allow the surgeon to wait.

## NEUROGENIC BLADDER

True neurogenic dysfunction of the bladder in childhood results from acquired or congenital lesions that affect bladder innervation. Acquired lesions may occur from trauma to the brain, spinal cord, or pelvic nerves, or as a result of tumor, infection, or vascular lesions affecting these same structures. Congenital lesions include spina bifida and other neural tube defects (most common), degenerative neuromuscular disorders, cerebral palsy, tethered cord, sacral agenesis, imperforate anus, VACTERL (vertebral, anal, cardiac, tracheal, esophageal, renal, and limb) syndrome, and other causes.<sup>46</sup>

The most practical way to classify neurogenic bladder abnormalities is by a simple functional system: failure to store, failure to empty, or a combination of both.<sup>47</sup> Failure to store urine may be caused by the detrusor muscle itself or by the bladder outlet. Detrusor hyperactivity or poor compliance during bladder filling causes elevated bladder pressures and incontinence on this basis. Inadequate outlet resistance secondary to an incompetent bladder neck or urethral sphincter mechanism can cause failure to store urine even if storage pressures are reasonable. Failure to empty can suggest either a bladder muscle or bladder outlet etiology as well. The hypotonic, neurogenic bladder may not generate enough pressure with detrusor contraction to empty. Alternatively, the outlet may exhibit increased resistance secondary to striated or smooth muscle sphincter dyssynergia. The advantage of this classification is that treatment can be based on urodynamic data.

## Myelomeningocele

The most common cause of a neurogenic bladder in childhood is the group of neural tube defects, which ranges from occult spinal dysraphism to myelomeningocele.<sup>48,49</sup> Myelomeningocele is the most severe and the most common, reported in about 1 in 1000 live births with notable geographic variations and a

**Figure 57-1.** A, This cystogram shows the typical findings in a patient with Hinman's syndrome: trabeculated bladder and severe reflux. B, This voiding study in the same patient demonstrates dilation of the posterior urethra (asterisk) as a result of chronic contraction of the external sphincter during voiding.

declining occurrence over the past decade.<sup>50,51</sup> The etiology is multifactorial, with a clear familial association (2% to 5% sibling risk) and evidence that periconceptual folic acid supplementation (0.4 mg/day) reduces the risk by 60% to 80%.<sup>52</sup> Improved care of the neurosurgical aspects of this lesion since the late 1970s has increased the survival rate of children with this condition. Thus, continued urologic care is very important. Ninety percent of neonates with myelomeningocele have normal upper tracts. However, if no care is administered to the bladder, at least half of these patients show signs of upper tract deterioration or reflux within 5 years.<sup>53</sup> It is therefore critical that early urologic evaluation of children with myelomeningocele is undertaken.<sup>54,55</sup>

### ***Evaluation of the Neonate with Myelomeningocele***

There have been reports over the past decade from centers performing fetal closure of myelomeningocele recognized by prenatal ultrasonography<sup>56-58</sup>. Unfortunately, there has been little to suggest that this has improved lower extremity, bowel, or bladder function for these patients, but the need for ventriculoperitoneal shunting may be reduced by 50%. A multi-institutional randomized controlled trial is under way in the United States, and further outcomes will be watched with interest.

Generally, the neonate with myelomeningocele has had a thorough neurologic assessment, closure of the back defect, and possibly even ventriculoperitoneal shunting before any evaluation of the urinary tract. The level of the bony defect does not predict the functional cord level because lesions may be partial and patchy. Before discharge, a renal and bladder ultrasound evaluation should be performed to evaluate parenchymal quality, the presence of hydronephrosis, and the size and emptying ability of the bladder. About 5% of patients have an abnormality on ultrasonography, in which case a VCUG and an evaluation of upper tract function and drainage by renal scan should be performed. If the ultrasonogram is normal, other studies can probably be delayed a few months, although we prefer to proceed with VCUG before hospital discharge mainly for logistical reasons. About 10% of these patients have reflux. Children are placed on amoxicillin prophylaxis (10 mg/kg once daily), and the serum creatinine concentration is followed during the initial hospitalization period. Many children experience poor emptying for a few days or weeks after the initial back closure, and postvoid residuals should be measured before discharge from the hospital. Intermittent catheterization is begun if the residual urine is consistently greater than 15 mL. Credé's maneuver should be avoided because it is ineffective in emptying the bladder and magnifies the detrimental effects of high intravesical pressure if reflux is present.

Neonatal urodynamic evaluation has since been shown to have prognostic value in determining which children are likely to develop upper tract dilation and VUR. Children with bladder pressures higher than 40 cm

H<sub>2</sub>O at the point of urinary leakage and those with detrusor-sphincter dyssynergia are much more likely to show upper tract deterioration or VUR.<sup>2,54</sup> Other factors shown to indicate bladder "hostility" include the presence of reflux, hyperreflexic contractions, and poor detrusor compliance.<sup>55</sup> Therefore, early urodynamic evaluation (typically by 12 weeks of age) is useful for determining the frequency of follow-up studies and the timing of initiation of bladder therapy programs.

If the radiographic evaluation is normal and no infection is present, the patient can be managed by spontaneous voiding into the diaper, especially if leak-point pressures are low. Follow-up studies are planned with a urine culture and renal ultrasound evaluation at 6 months. If leak-point pressures are high or sphincter dyssynergia is present, a VCUG again at 6 months is reasonable. Ultrasonography and urine cultures should be repeated yearly if the urinary tract is stable, with or without VCUG, depending on the relative risk of the upper tract as determined by urodynamics. If reflux or upper tract deterioration occurs at any time, intervention with clean intermittent catheterization (CIC), anticholinergic therapy, or temporary cutaneous vesicostomy may be warranted.

### ***Childhood Management***

Periodic reassessment of the anatomy and function of the urinary tract is important because the clinical and urodynamic picture may change with growth and spinal cord re-tethering.<sup>59</sup> Initiation of a bladder management program is generally undertaken when there is worsening reflux, upper tract dilation, deterioration of urodynamics, or infection. If the urinary tract is stable, such management may be delayed until social continence is desired.

The cornerstone of treatment programs for neurogenic bladder in most children is CIC. Popularized in the early 1970s, CIC has revolutionized the treatment program for these children.<sup>60</sup> The purpose of CIC is to provide periodic low-pressure emptying of the bladder, which can prevent or improve existing deterioration of the upper tracts, including that secondary to reflux.<sup>61,62</sup> In younger children, this task is performed by the caretaker. As children become older and more responsible, they can assume the task themselves. Motivation is important in adhering to a good bladder program. Therefore, it is sometimes better to wait until social pressures influence the child's desire for continence before initiating a bladder program, unless it is required for the treatment of bladder deterioration.

CIC is associated with a high incidence of bacteriuria (when followed with serial culturing), varying greatly in different series.<sup>63,64</sup> Bacteriuria is eventually found in about 60% of cases, with most patients becoming culture positive within 1 year, often with one or two symptomatic episodes per year.<sup>61</sup> In patients with no reflux and with normal intravesical pressure, asymptomatic bacteriuria appears to have little clinical significance. However, in patients with high storage pressures, reflux, or a combination of the two, the potential for

upper tract deterioration increases significantly with bacteriuria.<sup>65</sup> Infection with urea-splitting organisms (usually *Proteus* species) is of concern, owing to the potential for struvite stone formation.

Pharmacologic therapy for neurogenic bladder is usually coupled with CIC and is aimed at decreasing the pressures in the hypertonic, noncompliant bladder or increasing bladder outlet resistance to improve continence. Anticholinergic drugs, such as oxybutynin, propantheline, or tolterodine,<sup>66</sup> are used to lower bladder storage pressures by blocking hypertonic detrusor activity. Imipramine may also be useful alone or in combination with the anticholinergic agents because it can both relax detrusor and tighten the outlet. Inadequate vesical outlet resistance may also respond to  $\alpha$ -adrenergic medications such as pseudoephedrine. Often, the combination of anticholinergics,  $\alpha$  agonists, and CIC is required to gain adequate continence. Side effects of the anticholinergics may sometimes limit their use. Tolterodine and extended-release oxybutynin are purported to cause fewer side effects than other anticholinergics. Instillation of oxybutynin dissolved in water directly in the bladder can lessen the side effects and still maintain a therapeutic response. The recently developed oxybutynin cutaneous patch may offer an improved therapeutic index to these patients as well.<sup>67</sup> Finally, cystoscopic injection of botulinum toxin type A has recently been applied to children with neurogenic bladder in an effort to decrease bladder pressures and increase compliance. The effects of the injection are short-term, and repeated injections are required.<sup>68,69</sup>

Urodynamic assessment helps the clinician select medications and other modalities for the neurogenic bladder and to monitor their effects.<sup>3</sup> This study may be elaborate in certain situations, but is more often a simple measurement of the pressure-volume relationship of the bladder during filling. It is performed using a double-lumen catheter in the bladder and usually involves simultaneous assessment of external sphincter function with a perineal electrode patch. Urodynamic assessment can be performed with contrast material and monitored fluoroscopically to add information. Noting parameters such as bladder compliance, hyperreflexic contractions, leak-point pressure, stress leak-point pressure, and sphincter dyssynergia can be extremely valuable in helping to choose among treatment options. Figure 57-2 demonstrates the effect of anticholinergics in shifting the pressure-volume curve to the right and thus permitting the bladder to store more urine at any given pressure. Figure 57-3 shows the effect of  $\alpha$ -adrenergic receptors on raising the leak-point pressure and thus permitting storage to a higher pressure.

It is crucial to understand that when bladder pressures remain greater than 35 to 40 cm H<sub>2</sub>O, ureteral peristalsis does not effectively empty the upper tracts. Hydronephrosis and eventual renal insufficiency result. Thus, coupling cystometric data with a particular patient's estimated (or measured) hourly output permits the clinician to decide what CIC interval would keep bladder pressures in a safe range. Medications

**Figure 57-2.** Bladder filling pressure-volume curve in a patient with a neurogenic bladder. Note the shift of the curve to the right (A to B) when anticholinergics relax the detrusor, allowing lower pressure at any given volume.

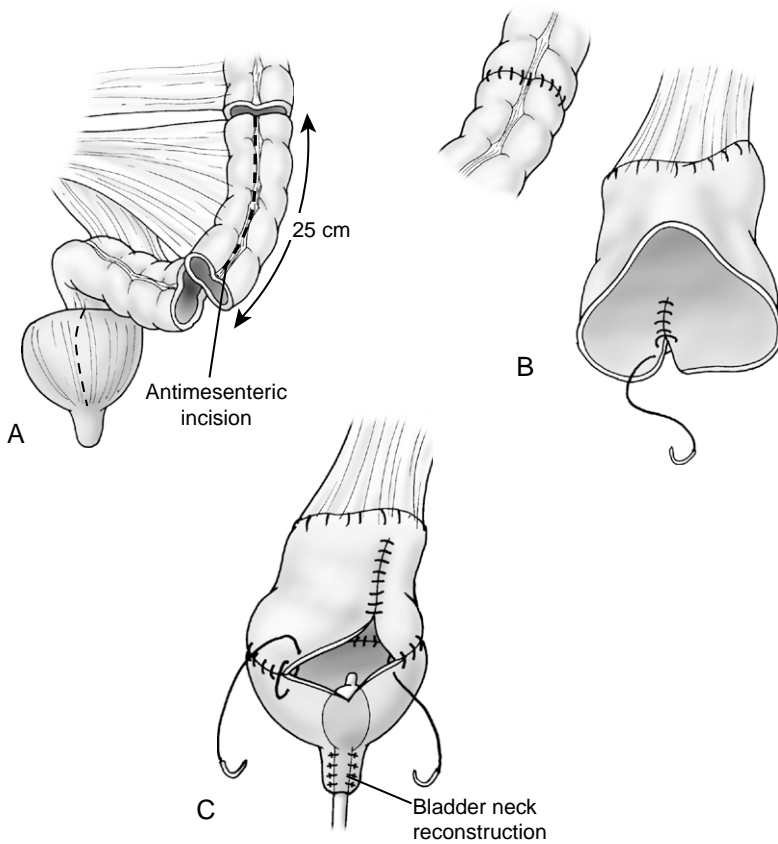

can then be sensibly adjusted to extend CIC intervals, achieve dryness, and avoid development or progression of hydronephrosis.

Transurethral electrical stimulation of the bladder has been used in several treatment centers in an effort to produce conscious urinary control in the patient with neurogenic bladder.<sup>70</sup> It is a time-consuming treatment program with sometimes hundreds of sessions required before a response. Although some series have shown variably encouraging results, especially concerning the improvement in bladder compliance,<sup>70-71</sup> others have found the results disappointing.<sup>72,73</sup> More experience is necessary, but this technique may be applicable in selected children. Selective sacral nerve root rhizotomy and electrical stimulation of the sacral nerve roots may also have some limited potential for treatment in certain children.<sup>74-76</sup>

In children with high bladder storage pressures and deterioration of the upper tracts that cannot be managed by CIC or pharmacologic therapy, temporary diversion with cutaneous vesicostomy may be necessary.<sup>77,78</sup> Protection of the upper urinary tracts from high bladder pressures is thus accomplished until such time that other treatments can be initiated. We reserve this treatment for infants who have serious deterioration of the upper tract and those who, for social, medical, or anatomic reasons, cannot be

**Figure 57-3.** Bladder filling pressure-volume curve demonstrating a higher leak point pressure (from A to B), sometimes achieved with  $\alpha$ -adrenergic agents such as pseudoephedrine and imipramine. The effect is to decrease incontinence at lower pressures.

**Figure 57-4.** Bladder enlargement by enterocystoplasty (sigmoid) and bladder neck reconstruction. Enterocystoplasty enlarges the bladder nicely but has significant potential complications, including occasional perforation, first seen as acute abdominal pain.

managed with the other aforementioned forms of medical treatment. As an alternative, some advocate urethral dilation in girls to diminish the leak-point pressure. A surprising persistence of benefit has been noted in some series.<sup>79</sup>

### Surgical Treatment

Although most patients with neurogenic bladder can be managed adequately without surgical intervention, those with reflux, a poorly compliant bladder, or refractory incontinence may benefit from operative intervention.

Treatment of reflux in the neurogenic bladder is much the same as that for the normal bladder.<sup>80</sup> It is imperative, however, that the bladder be adequately treated for poor compliance and hyperreflexia (CIC and anticholinergics) before and after surgical intervention to diminish the high recurrence risk.<sup>81</sup>

In other clinical circumstances, bladder augmentation or enlargement may be required. Bladder augmentation is designed to create a reservoir with good compliance and adequate capacity to store urine until it can be emptied by CIC at socially appropriate intervals. Detubularized segments of large or small bowel employed as a patch and detubularized cup on the widely opened bladder (enterocystoplasty) are the current standards for augmentation (Fig. 57-4). Other techniques for bladder augmentation include gastrocystoplasty, which has been repopularized since

1988.<sup>82,83</sup> It is a technically acceptable procedure and shows advantages over enterocystoplasty with respect to a decrease in mucus formation, a possible decrease in infection rate, and maintenance of electrolyte balance in patients with renal insufficiency. Unfortunately, the hematuria-dysuria syndrome may affect up to one third of patients, and limits its applicability.<sup>84</sup> This and other complications of enterocystoplasty such as metabolic derangements secondary to the absorption of urine by the gastrointestinal tract, excessive mucus production, stone formation, and even an increased risk of bladder cancer have led to a search for different approaches.

Bladder autoaugmentation or detrusorectomy is an alternative augmenting technique that may prove useful in selected patients (Figs. 57-5 and 57-6).<sup>85</sup> The procedure involves removal of the detrusor muscle over the superior portion of the bladder, leaving the underlying bladder mucosa intact. This creates a large compliant surface, essentially a large diverticulum, which decreases bladder pressures and increases bladder capacity on filling. The advantage of this technique is that the bladder epithelium is preserved and not replaced with gastrointestinal epithelium as in bowel augmentation. This change eliminates the problems associated with the secretory and absorptive functions of bowel mucosa. Long-term follow-up data on large numbers of children are lacking, but this technique appears to be a viable alternative for use in bladders with a reasonable capacity and mainly poor

**Figure 57-5.** Radiographic (A) and ultrasonographic (B) images of a patient with spina bifida showing a small, poorly compliant bladder and worsening hydronephrosis (B).

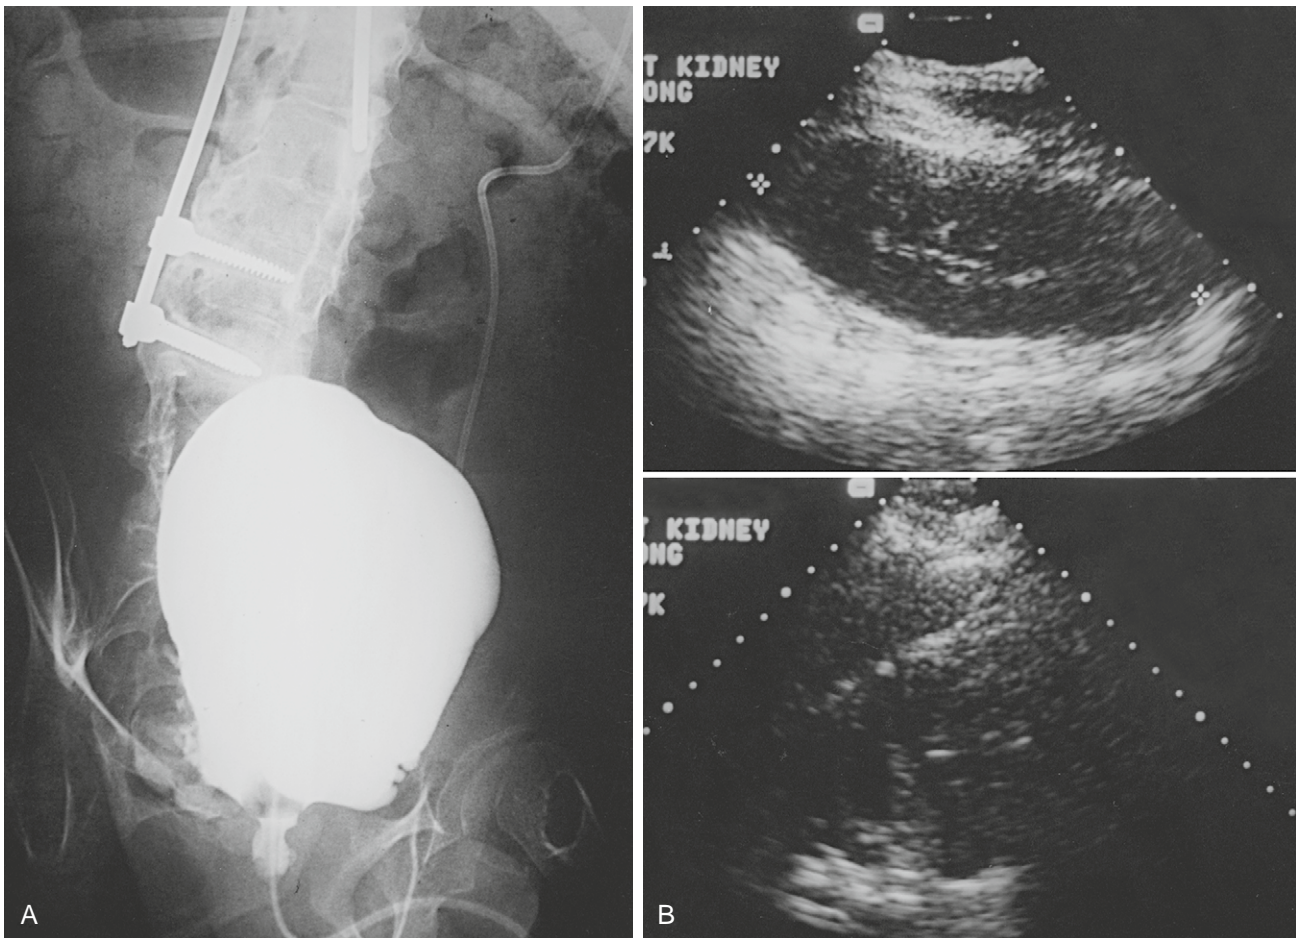

compliance.<sup>86</sup> The concept has been extended to create “composite” bladders by placing demucosalized bowel or stomach patches over the urothelial bulge created in autoaugmentation.<sup>87,88</sup> This concept of urothelial preservation during augmentation is carried forward by current innovative approaches to replace the bladder wall with biodegradable scaffolds, typically seeded with urothelial and detrusor smooth muscle cells.<sup>89</sup> The future of bladder reconstruction may be greatly enhanced by these efforts.

Persistent incontinence, despite adequate treatment of the bladder to lower pressures and increase compliance and capacity, may require surgery on the bladder outlet to increase resistance. Bladder neck reconstructions of the Young-Dees type, which lengthens the urethra by infolding and tubularizing the trigone of the bladder, have generally lost favor but still have some advocates.<sup>90</sup> Kropp’s procedure uses a tubularized anterior bladder strip reimplemented in the submucosa of the trigone to gain continence by a flap valve mechanism.<sup>91</sup> Continence is commonly achieved, but catheterization is sometimes difficult.<sup>92</sup> The Pippi-Salle procedure creates a similar (but easier to catheterize) flap valve by onlaying an anterior bladder wall flap onto a posterior incised strip up the middle of the trigone.<sup>93</sup> Owing to the lack of the popoff mechanism in both these procedures, if the bladder becomes overfilled, the potential for bladder rupture of an augmented bladder or for upper tract deterioration due to high pressures is increased.

One of the more popular forms of increasing urethral resistance in the neurogenic bladder is by the pubovaginal or puboprostatic fascial sling.<sup>94-98</sup> This procedure has many advocates and involves securing a rectus fascial strip (or other material) around the urethra and suspending it from the anterior rectus fascia or pubis. This elevates and compresses the urethra to increase outlet resistance. Suprapubic bladder neck suspension with periurethral sutures is also advocated but has a lower success rate than the fascial sling technique, especially in the urethra that is widely open with little resistance.

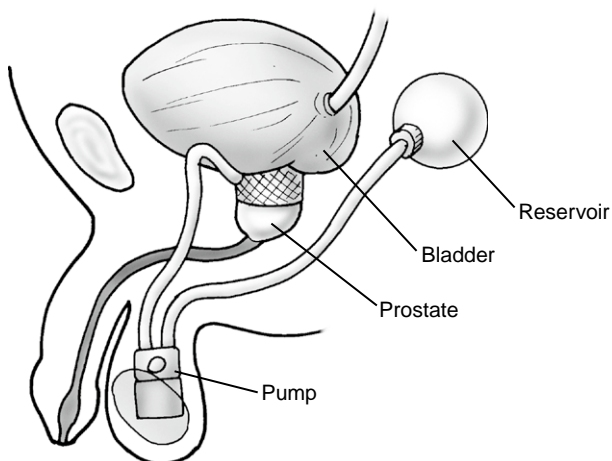

The artificial urinary sphincter works by way of a fluid-filled pressurized cuff around the urethra, which can be deflated by a pump-reservoir device that permits the urethra to open and the bladder to drain (Fig. 57-7). This artificial sphincter can also be used in higher-pressure bladders in conjunction with bladder augmentation.<sup>99</sup> The main disadvantage is that it is a mechanical device that can erode into the urethra and malfunction over time. If the devices are left in place long enough, virtually all eventually need revision. Thus, we prefer to use autologous tissue techniques in children, when possible.

The periurethral injection of dextranomer/hyaluronic acid copolymer (Deflux), Teflon, or polydimethylsiloxane represents a simple, safe technique for enhancing urethral resistance in selected patients with poor intrinsic sphincter tone. It appears to be most applicable in patients requiring only a minimal increase in stress leak-point pressure. Long-term

**Figure 57-6.** Radiographic (A) and ultrasonographic (B) images in the patient shown in Figure 57-5 after bladder autoaugmentation, demonstrating improved bladder capacity and better compliance, which resulted in continence and diminished hydronephrosis (B).

improvement rates are disappointing, and the usefulness of this approach in children is questionable.<sup>100,101</sup> With all procedures to enhance resistance at the bladder outlet, it is crucial that the storage pressures of the bladder be considered as well. When the bladder outlet

**Figure 57-7.** Typical artificial urinary sphincter. The scrotal pump moves fluid from the cuff to the reservoir to permit bladder emptying.

is tightened but the bladder is unable to store increasing volumes at low pressure, hydronephrosis or reflux results. When the surgeon is considering bladder outlet surgery, it may be necessary to occlude the bladder neck with a urinary balloon catheter during preoperative urodynamic assessment to determine how much the bladder can hold and what the storage pressures are. This maneuver helps judge whether augmentation is needed simultaneously.

One surgical adjunct of great benefit in patients unable to self-catheterize the urethra (e.g., owing to spinal deformity, discomfort, or false passage) is the creation of a continent catheterizable stoma. This may be performed using the appendix or another small tubularized structure implanted into the bladder and anastomosed to the skin (Mitrofanoff principle).<sup>102,103</sup> The implanted conduit can be hidden at the base of the umbilicus (Fig. 57-8), and CIC may then be carried out through this segment.<sup>104</sup> The appendix may alternatively be left in continuity with the cecum and brought to the skin as a catheterizable channel for irrigation/enemas of the neurogenic colon. In this circumstance, a small segment of ileum may be refashioned as a catheterizable Monti-Yang stoma.<sup>105</sup> This has been a great adjunct to simplify catheterization for wheelchair-bound patients.

**Figure 57-8.** Umbilical positioning of an appendicovesicostomy permits easy access for clean intermittent catheterization. Some patients can remain in their wheelchairs and drain the bladder into the toilet through a catheter extender.

Cutaneous urinary diversion by ileal or colon conduit or by cutaneous ureterostomy is considered a last resort option in these children. Long-term deterioration of the upper tracts is well documented in refluxing ileal conduits.<sup>106</sup> Some protection of the upper tracts is afforded by a nonrefluxing colon conduit, but the prognosis beyond 2 decades is uncertain.<sup>107</sup> Therefore, avoidance of diversion, if possible, is the best course in children with neurogenic bladders. All reasonable efforts should be made to maintain ureteral drainage into the bladder, if possible.

Continent urinary diversion has evolved over the past several years as a popular alternative in treating incontinence. The intestinal segments for urinary reconstruction in children with neurogenic bladders generally are of neurogenic bowel as well. These children may not tolerate a loss of large segments (especially ileocecal segments) without developing loose stools. In children who are dependent on constipated stools for fecal continence, loose stools may be more devastating than the original urinary incontinence.

## URETHRAL DISORDERS

### Urethral Prolapse

Urethral prolapse occurs in girls at a mean age of 5 years, with those of African descent being particularly prone to this disorder.<sup>108</sup> Urethral prolapse presents as dysuria, blood spotting of the underwear, and a bulging concentric purplish ring of prolapsed urethra seen at the urethral meatus (Fig. 57-9). Mild prolapse can be treated with an antibiotic ointment or estrogen cream applied to the area several times a day along with sitz baths. There are times when a urinary catheter is needed temporarily. In unusual persistent cases, excision of the prolapsing tissue with reanastomosis of

the skin edges is needed. Also, simple ligation of the prolapsing urethral epithelium over a urinary catheter, permitting necrosis, is another option.

### Meatal Stenosis

Meatal stenosis is the narrowing of the male urinary meatus after circumcision. It is thought to be due to exposure and irritation of the meatus in the diaper.<sup>108,109</sup> For reasons that are uncertain, the stenosis is always on the ventral aspect of the meatus, causing dorsal deflection of the urinary stream that is fine and forceful. It is important for the physician to not only examine the meatus but also watch the child void. If the stream is not narrow in caliber or is not dorsally deflected, then the meatal stenosis is not physiologically significant enough to require treatment. Occasionally, voiding causes the web to tear, resulting in dysuria or a drop of blood after urination. Some patients will have ongoing inflammation around the meatus that will respond to topical corticosteroid application (betamethasone 0.05%).

Meatotomy may be necessary and can be performed under general anesthesia or as an office procedure. In the office, topical lidocaine/prilocaine cream can be applied topically, covered with a bio-occlusive dressing, and left in place for 1 hour before meatotomy with oral midazolam for sedation in selected patients. This has resulted in a painless office procedure.<sup>109</sup> Following topical, local, or general anesthesia, the ventral web is clamped with a hemostat for 1 minute, which results in adequate hemostasis. The ventral web is

**Figure 57-9.** Urethral prolapse is usually seen as a circumferential, purplish bulge at the meatus.

**Figure 57-10.** A scaphoid megalourethra is seen in a boy with prune-belly syndrome.

then incised one half the distance to the coronal margin. Parents are asked to spread the meatus and apply ointment several times daily for 2 to 3 weeks. Meatal stenosis rarely recurs. Imaging studies and cystoscopy are not needed in these boys.

## Megalourethra

Megalourethra is a rare genital anomaly causing a deformed and elongated penis occurring in two forms: fusiform and scaphoid (Fig. 57-10). These differ in embryology and appearance. Megalourethra is seen more commonly in patients with prune-belly syndrome and has been reported in association with the VACTERL complex.<sup>110</sup>

The less severe and most common form of this anomaly is the scaphoid variety, in which spongiosal tissue fails to invest the urethra.<sup>111</sup> The more severe fusiform variety is caused by failure in the development of the penile mesoderm, so that there is neither spongiosal tissue nor properly formed corpora cavernosa within the penis.<sup>112</sup> The fusiform type of megalourethra has been reported in patients with severe forms of prune-belly syndrome, stillborn fetuses, and patients with cloacal anomalies.<sup>113,114</sup> Associated urologic anomalies have been described, including megaureter, megacystitis, reflux, bladder diverticula, and renal dysplasia.<sup>114</sup> Upper tract assessment is indicated in all cases. Repair of the megalourethra relies on hypospadias techniques that tailor the urethra to a more normal size.

## Urethral Duplication

Urethral duplications occur in a wide variety of forms and can be broadly classified as dorsal or ventral to the normal meatus.<sup>115-117</sup> Duplication may be complete, but incomplete forms predominate. Occasionally, side-by-side duplications occur, usually associated with a duplicated phallus and bladder. Most commonly, the two channels form in the sagittal plane. The urethral channel closest to the rectum is generally the more

functional channel, having more normal spongiosal tissue and sphincter mechanism.<sup>118</sup> The more dorsal urethra is often small and poorly developed and will commonly be in an epispadiac position and associated with a dorsal chordee. Partial duplications that course along the penile urethra have been called *Y-type duplications*.<sup>119</sup> When the duplicated opening is in the perineum, it has been termed an *H-type duplication*.<sup>120</sup>

The treatment of a urethral duplication must be individualized. When only a minor septum is present, cystoscopic division of the septum has been successful. Traditionally, with more significant duplications, efforts have been made to lengthen the ventrally placed urethra to the tip of the penis using various hypospadias reconstruction techniques. Progressive dilation of the dorsal urethral channel to make it functional has also been advocated.<sup>121</sup>

## Congenital Urethral Fistula

A congenital urethral fistula may occur in the anterior urethra where incomplete development of the spongiosum has occurred, permitting a small diverticulum to form that can rupture antenatally.<sup>122</sup> These are uncommon and difficult to repair due to the lack of spongiosal tissue surrounding the fistula.

## Urethral Strictures and Stenosis

Most urethral strictures are acquired. Instrumentation and catheter passage by medical personnel, trauma, and inflammatory diseases are common causes. Congenital urethral stenosis is rare and generally focal. These stenoses are usually in the bulbar urethra, within the area of embryologic joining of the bulbous urethra arising from genital folds and the posterior membranous urethra arising from the urogenital sinus. If this junction is misaligned or incompletely canalized, a discrete stricture may develop.<sup>122</sup>

Both of these conditions can be treated with an internal urethrotomy, resection and end-to-end anastomosis, or a pedicle flap/free graft urethroplasty. Recent data would suggest a single internal urethrotomy for short strictures followed by an open repair for failures as best therapy.<sup>123</sup>

## Urethral Atresia

When urethral atresia occurs, in order to be compatible with life, a patent urachus must be present. Reconstruction can be difficult. A vesicostomy with a subsequent catheterizable stoma may be the best alternative.<sup>102</sup>

## Urethral Diverticulum or Anterior Urethral Valve

A urethral diverticulum occurs ventrally if the spongiosum is absent or has been thinned. The distal lip of the diverticulum functionally serves as an anterior urethral valve, blocking the urinary stream as it flows antegrade (Fig. 57-11). The diverticulum progressively fills and further compresses the urethra during

**Figure 57-11.** This voiding cystogram shows an anterior urethral diverticulum (*asterisk*) that functions as a valve, causing outflow obstruction. Note the bladder trabeculation.

urination. This valvular effect can cause marked proximal dilation.<sup>124-126</sup> In some cases, there is a diverticulum with a narrow neck that does not function as a valve. Such a diverticulum may allow stasis of urine and may be a site of urethral infection.

The diagnosis is made either by urethrogram or cystoscopy. Treatment can be accomplished by endoscopic incision of the distal lip of the neck of the diverticulum or, if more pronounced, by open excision and closure of the urethral defect.<sup>127</sup>

### Cowper's Duct Cyst

Cowper's glands are a pair of 5-mm glands located within the urogenital membrane. The ducts from these glands course distally and enter the ventral wall of the proximal bulbar urethra. These are the homologs of the female Bartholin gland. Occasionally, these ducts can become occluded, producing bulbar urethral filling defects and, rarely, modest obstruction.<sup>128</sup> Cystoscopically, this appears to be a thin membrane over a fluid-filled cyst, sometimes called a *syringocele*.<sup>129</sup> If contrast medium enters a Cowper duct, tubular characteristic channels can be seen coursing parallel to the bulbar urethra. Treatment of Cowper's duct cysts is endoscopic unroofing and is unnecessary unless the radiographic finding is associated with clinical symptoms.

# POSTERIOR URETHRAL VALVES

Jack S. Elder, MD • Ellen Shapiro, MD

Posterior urethral valves (PUV) comprise the most common congenital anomaly causing bladder outlet obstruction in boys, with an incidence of 1 in 5000 to 1 in 8000 male births. Although the majority of boys with PUV are diagnosed before birth, in 24% to 45% renal insufficiency will develop during childhood or adolescence. PUV are the most common obstructive cause of end-stage renal disease in children.

## EMBRYOLOGY AND ANATOMY

At 5 to 6 weeks' gestation, the orifice of the mesonephric duct normally migrates from an anterolateral position in the cloaca to Müller's tubercle on the posterior wall of the urogenital sinus. This event occurs simultaneously with the division of the cloaca. Remnants of the mesonephric duct normally remain as small distinct, paired lateral folds termed the *inferior urethral crest* and *plicae colliculi*. When the insertion of the mesonephric ducts into the cloaca is anomalous or too anterior, normal migration of the ducts is impeded and the ducts fuse anteriorly. This results in the formation of abnormal ridges, which are the PUV. Valves with a smaller aperture between the leaflets cause more obstruction and upper tract damage than do those with a larger aperture and a less prominent anterior component.<sup>1</sup>

Three distinct types of PUV have been described. The type I valve is an obstructing membrane that radiates distally and anteriorly from the verumontanum toward the membranous urethra (the segment of urethra that traverses the urogenital diaphragm or striated sphincter), fusing in the midline. Approximately 95% of PUV are type I, in which the valves are thought to be a single membranous structure with the opening positioned posteriorly near the verumontanum. The type III valve appears as a membranous diaphragm with a central aperture at the verumontanum. The obstructing tissue also has been termed a *congenital obstructing posterior urethral membrane*.<sup>2</sup> It is thought that instrumentation with a urethral catheter might disrupt the posterior aspect of the membrane,

resulting in the appearance of a type I valve. Type II valves are prominent longitudinal folds of hypertrophied smooth muscle that radiate cranially from the verumontanum to the posterolateral bladder neck, but these are nonobstructive and clinically insignificant.

## PRENATAL DIAGNOSIS, MANAGEMENT, AND OUTCOMES

About 10% of prenatally diagnosed obstructive uropathy is due to PUV, and approximately two thirds of PUV are diagnosed prenatally. Typical findings include bilateral hydronephrosis, a distended bladder, and a dilated prostatic urethra, called a "keyhole" sign.<sup>3</sup> Discrete focal cysts in the renal parenchyma are diagnostic of renal dysplasia. Amniotic fluid volume is variable. Those with normal or slightly reduced amniotic fluid have a better prognosis. In contrast, oligohydramnios suggests significant obstructive uropathy or renal dysplasia (or both) and pulmonary hypoplasia is common. The gestational age at which hydronephrosis is recognized also influences prognosis. In one study, fetuses with PUV and normal-appearing renal anatomy after 24 weeks were much more likely to have normal renal function than were those with hydronephrosis recognized before 24 weeks.<sup>4</sup> Prenatally, PUV, prune-belly syndrome, urethral atresia, and bilateral high-grade vesicoureteral reflux (megacystis-megaureter syndrome) may have a similar appearance. The presumptive diagnosis of PUV cannot be confirmed until postpartum radiologic studies are performed.

In the fetus with suspected PUV and normal amniotic fluid volume, serial fetal sonograms are necessary to monitor the status of the hydronephrosis and amniotic fluid volume. If oligohydramnios develops, prenatal drainage of the bladder may be beneficial. It is thought that oligohydramnios prevents normal fetal movement, chest mobility, and lung development in utero. Pathologically, this process results in reduced branching of the bronchial tree and reduced numbers and size of alveoli.<sup>5</sup>

In the fetus with suspected PUV, a karyotype should be obtained because chromosome abnormalities occur in about 12% of fetuses with bilateral hydronephrosis and bladder distention.<sup>6</sup> Moreover, it is important to verify that the fetus is a male. Fetal renal function also must be assessed. Discrete renal cysts are diagnostic of renal dysplasia. Assuming renal cysts are absent, fetal urinary electrolytes and  $\beta_2$ -microglobulin provide the most accurate means of evaluating fetal renal function. Normally, fetal urine is hypotonic, with sodium less than 100 mEq/L, chloride less than 90 mEq/L, and osmolality less than 210 mEq/L.<sup>3</sup> Elevated fetal urine electrolytes and  $\beta_2$ -microglobulin levels are an indication of irreversible renal dysfunction. Sequential bladder aspiration every 48 to 72 hours should be performed, because the initial sample may be stale and new urine that forms more accurately reflects the function of the fetal kidneys.<sup>7,8</sup>

If fetal urine is hypotonic, and oligohydramnios is present, then fetal intervention should be considered, with a goal of preventing life-threatening pulmonary hypoplasia. This procedure has been performed in the first trimester,<sup>9</sup> although the majority of fetuses are in the second trimester. No evidence exists that drainage of the fetal bladder obstructed by PUV will improve renal or bladder function. Therefore, the family should understand that even if the drainage procedure is successful the infant may have limited renal function or end-stage renal disease. If the gestational age of the fetus is 32 weeks or more, early delivery is advisable. If the fetus is less than 32 weeks' gestation, however, the urine may be diverted into the amniotic fluid with a percutaneously placed vesicoamniotic shunt, which has a pigtail on each end. In a few centers, in-utero cutaneous vesicostomy or ureterostomy has been performed.<sup>10</sup> Percutaneous in-utero endoscopic ablation of PUV also has been reported,<sup>11-13</sup> but few centers have the instrumentation or technical expertise to perform this procedure.

Vesicoamniotic shunts have limitations.<sup>5,6</sup> They become obstructed or displaced in 25% of cases, necessitating additional procedures that increase morbidity to the mother and fetus and a 5% procedure-related rate of fetal loss. In addition, ommental or bowel herniation through the fetal abdominal wall may occur. Despite adequate bladder drainage, renal function may be so limited that the amniotic fluid volume remains low. In one study of high-risk fetuses identified in the first trimester with severe bilateral hydronephrosis, bladder distention, and oligohydramnios managed with a vesicoamniotic shunt, a 60% overall survival rate and a 33% incidence of renal failure were found.<sup>14</sup> In a review of 14 fetuses with proven PUV and favorable fetal urinary electrolytes undergoing fetal intervention at a mean gestational age of 22.5 weeks, six deaths occurred before term delivery and 8 survived, with a mean follow-up of 11.6 years.<sup>10</sup> Of these 8 neonates, 3 had end-stage renal disease, and the other 5 had an elevated serum creatinine value. In a more optimistic study of 20 boys with "lower urinary tract obstruction" managed by in-utero vesicoamniotic shunt, the overall 1-year survival was 91%. In this study, the

mean birth weight was 2574 g, 40% had acceptable renal function, 20% had mild renal insufficiency, and 30% required dialysis.<sup>15</sup> Of this group, 7 had PUV and 7 had prune-belly syndrome, a nonobstructive condition. Clearly, patient selection is highly important. Consequently, when counseling families, one must emphasize that intervention may assist in keeping the fetus viable to term but will most likely not prevent the long-term sequelae of severe renal dysplasia associated with PUV.

## CLINICAL PRESENTATION

Neonates with PUV who are not diagnosed before birth may appear in the nursery with delayed voiding or a poor urinary stream.<sup>5</sup> Respiratory distress secondary to pulmonary hypoplasia may be the only manifestation of severe urethral obstruction. Other common signs and symptoms include a palpable abdominal mass, failure to thrive, lethargy, poor feeding, urosepsis, and urinary ascites. A urinary tract infection (UTI) often develops in infants. Older boys may have persistent diurnal incontinence or abdominal distention as their only manifestations. Physical examination in the newborn typically discloses a palpable walnut-sized bladder, which corresponds to the hypertrophic detrusor muscle. If urinary ascites is present, significant abdominal distention is typical.

## RADIOGRAPHIC EVALUATION

Postnatal ultrasonography usually shows significant bilateral hydronephroureteronephrosis. Demonstration of the corticomedullary junction is a favorable prognostic sign regarding renal functional potential (Fig. 58-1). Conversely, finding echogenic kidneys or subcortical cysts and the inability to see the corticomedullary junction on the initial and follow-up ultrasound studies are unfavorable signs. Suprapubic or perineal ultrasonography may demonstrate a dilated prostatic urethra, which is pathognomonic for PUV.

The voiding cystourethrogram (VCUG) remains the only radiographic study that definitively establishes the diagnosis of PUV (Fig. 58-2). The valve appears as a sharply defined perpendicular or oblique lucency in the distal prostatic urethra. The posterior urethra is dilated and elongated and has the appearance of a shield. The bladder is trabeculated with clear delineation of the bladder neck, which appears as a thick muscular collar because of hypertrophy. Vesicoureteral reflux (VUR) is present in 50%.

Renal nuclear scintigraphy with a technetium-99m-labeled dimercaptosuccinic acid (<sup>99m</sup>Tc-DMSA) or mercaptoacetyl triglycine (<sup>99m</sup>Tc-MAG3) scan should be performed if either kidney shows thin or abnormal parenchyma. These functional studies are useful in demonstrating baseline differential renal function. However, if renal function is poor, visualization of the kidneys is poor and the study should not be obtained. An alternative to renal scintigraphy is dynamic

**Figure 58-1.** This renal sonogram demonstrates a hydronephrotic kidney with intact corticomedullary junction (arrow) in an infant with posterior urethral valves.

contrast-enhanced magnetic resonance urography. This study is being performed at a few pediatric urology centers and provides high-resolution renal images and assessment of differential renal function.<sup>16</sup>

## INITIAL MANAGEMENT

The initial treatment of neonates suspected of having PUV is to decompress the urinary tract with a 5- or 8-Fr feeding tube passed transurethraly during the first ultrasound study immediately after birth. The catheter can be difficult to pass because of significant dilation of the prostatic urethra and hypertrophy of the bladder neck. A catheter coiled in the prostatic urethra will result in the majority of urine draining around the catheter. Ultrasonography confirms the placement of the catheter within the bladder. Insertion of a Foley catheter is discouraged because the inflated balloon can obstruct the ureteral orifices

when the thick-walled bladder is decompressed, and it can cause severe bladder spasm that can obstruct the intramural ureters. Ampicillin or cephalexin prophylaxis should be initiated. Renal function, electrolytes, and fluid status should be monitored carefully. The serum creatinine concentration at birth reflects maternal renal function. With satisfactory newborn renal function, the creatinine value should gradually decrease to 0.3% to 0.4 mg/dL. However, with limited renal function, the creatinine value may increase, even with bladder drainage. Metabolic acidosis and hyperkalemia are common complications if renal function is impaired. Co-management of the patient with the pediatric nephrology service is often beneficial.

Neonates with respiratory distress may require immediate pulmonary resuscitation with endotracheal intubation and positive-pressure ventilation, which may cause a pneumothorax or pneumomediastinum. In rare cases, extracorporeal membrane oxygenation (ECMO) may be needed to support life until the diagnosis and prognosis are clearly defined.<sup>17</sup> If urinary ascites is seen, paracentesis may be necessary to correct fluid and electrolyte imbalance.

Renal ultrasonography and a VCUG should be performed expeditiously to determine whether the patient has PUV. Circumcision should be performed to reduce the risk of a UTI.

## Primary Valve Ablation

Endoscopic valve ablation is performed after the neonate is stabilized medically. Well-lubricated infant urethral sounds should be passed gently to calibrate and stretch the urethra slightly. The neonatal male urethra usually accepts an 8-Fr endoscope. Overly aggressive dilation of the urethra to pass a larger instrument may lead to urethral trauma with subsequent stricture formation and should be avoided. Vigorous dilation may result in iatrogenic hypospadias due to splitting of the glans to the subcoronal level.<sup>18</sup>

An 8- or 9-Fr cystoscope typically is used with a Bugbee electrode on low cutting current inserted through the operating channel. The valve leaflets should be incised by using a low cutting current at the 5- and

**Figure 58-2.** These two voiding cystourethrograms show varying degrees of obstruction from posterior urethral valves. In both studies the location of the valves is marked with an arrow and the posterior urethra is identified with an asterisk. **A,** There is no evidence of vesicoureteral reflux. **B,** There is massive, bilateral grade V reflux.

**Figure 58-3.** This cystoscopic view shows valve ablation with an electrode placed through the operating channel of the cystoscope.

7-o'clock positions (Fig. 58-3). Incision at the 12-o'clock position where the valve leaflets fuse also may be helpful. An alternative method of PUV ablation is to use the neodymium:yttrium-aluminum-garnet (YAG) laser.<sup>19</sup> In a premature or small neonate, a cystoscope as small as 6.9 Fr may be used, although the visualization of the PUV may be suboptimal. In a large infant, a pediatric resectoscope may be used. If urethral bleeding occurs, coagulation should be performed carefully,

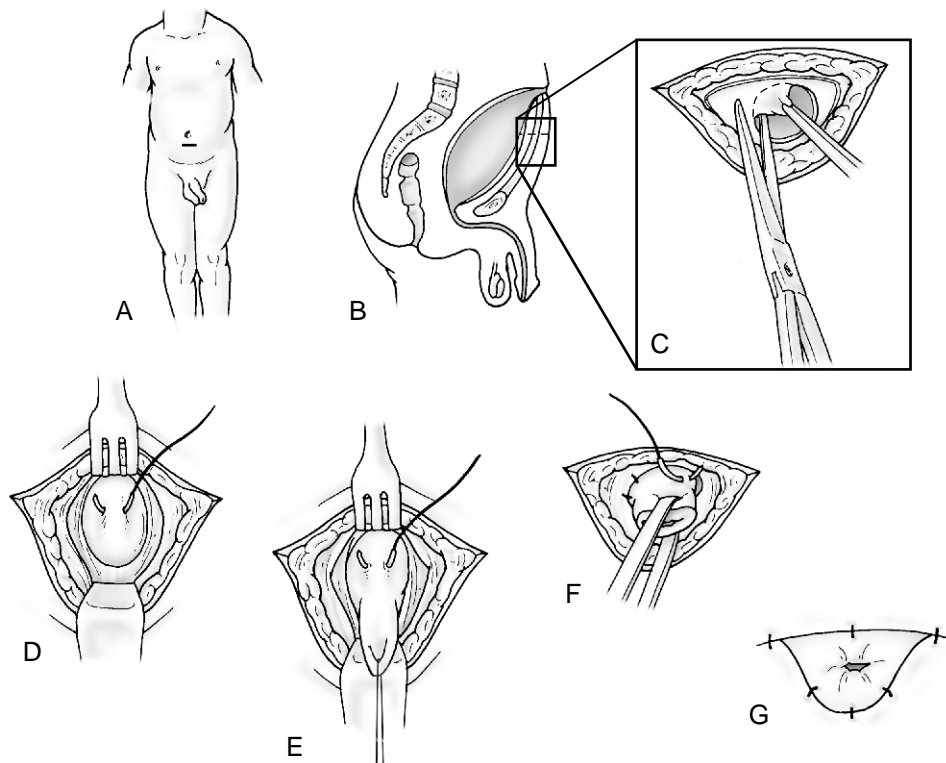

because urethral injury may occur with overzealous cautery. After valve ablation, a pediatric feeding tube is left indwelling for 1 to 2 days. In premature or small neonates, a temporary perineal urethrostomy for passage of the cystoscope or resectoscope may be helpful. Valve ablation also may be performed antegrade through a percutaneous cystostomy.<sup>20</sup>

A VCUG and renal sonogram should be obtained 2 to 4 weeks after ablation to confirm satisfactory valve disruption. In addition, renal function should be monitored carefully. PUV ablation is successful in more than 90% of patients. The most common complication is incomplete valve ablation, in which case repeat cystoscopy and valve incision is necessary. Urethral stricture is uncommon with the use of smaller endoscopic instrumentation and better optics.

One recent prospective study suggested that incision of the bladder neck at the time of valve ablation may be beneficial.<sup>21</sup> Boys who underwent bladder neck incision had a significantly lower rate of detrusor overactivity and a lower maximum voiding detrusor pressure when compared with age-matched boys who underwent valve ablation alone. Whether long-term differences will remain and whether these boys will experience retrograde ejaculation in adulthood is uncertain. Furthermore, these results need to be confirmed with other reports.

### Temporary Urinary Diversion

An alternative to primary valve ablation is cutaneous vesicostomy (Fig. 58-4). This approach is appropriate in a small or premature neonate when the pediatric cystoscope is too large for valve ablation or if severe

**Figure 58-4.** Technique of cutaneous vesicostomy. **A to C,** Transverse incision is made midway between the umbilicus and pubic symphysis. **D and E,** Traction sutures are placed through the bladder, and it is mobilized superiorly to the dome of the bladder. **F,** The detrusor should be fixed to the rectus fascia. The bladder is opened, and the mucosa is sutured to the skin. **G,** Completed vesicostomy should be calibrated to 24 Fr.

hydronephrosis, urinary ascites, or high-grade reflux with poor renal function is present. In these cases, optimal drainage is necessary to maintain existing renal function. The most popular technique was described by Blocksom and popularized by Duckett.<sup>22</sup> A small transverse incision is performed midway between the umbilicus and pubic symphysis, and the dome of the bladder is brought to the skin. The vesicostomy should calibrate to 24 to 26 Fr to avoid stenosis. Daily dilation of the stoma with a plastic medicine dropper helps prevent contraction of the stoma. The vesicostomy drains into the diaper, and no urinary collection device is necessary. Complications include stomal stenosis, if the stomal size is less than 24 to 26 Fr, and prolapse, if the anterior wall of the bladder is exteriorized rather than the bladder dome.

When a cutaneous vesicostomy is performed, valve ablation should not be performed simultaneously because the urethra may remain dry and urethral stricture is likely. A vesicostomy allows the bladder to cycle and grow with voiding at low pressure through the stoma and does not reduce bladder capacity. These neonates should be maintained on antibiotic prophylaxis.

In the past, proximal high diversion with cutaneous pyelostomy or cutaneous ureterostomy was advocated for neonates and infants with severe hydronephrosis and a persistent elevated creatinine after catheter drainage.<sup>22a</sup> Theoretically, proximal diversion provides better renal drainage than does a vesicostomy, particularly with ureterovesical obstruction, and optimizes the potential for ultimate renal function and somatic growth. However, this form of therapy has not been shown to prevent end-stage renal disease, because at least 85% of these patients have renal dysplasia.<sup>23</sup> In addition, by diverting the urine away from the bladder, regular cyclic vesical filling and contraction does not occur and results in a smaller, less compliant bladder.<sup>24</sup> Consequently, proximal diversion is reserved for the rare case in which valve ablation or vesicostomy fails to improve upper tract drainage or if urosepsis occurs secondary to pyelonephritis.

The preferred method of proximal diversion is the Sober-en-T ureterostomy, in which the proximal ureter is divided and brought out to the abdominal wall (Fig. 58-5). The proximal end of the distal ureteral segment is then anastomosed to the renal pelvis. The advantage of this form of diversion is that it allows some urine to drain into the bladder and thus allows bladder cycling, while providing excellent upper tract drainage.<sup>25</sup> In one retrospective study of 36 boys who underwent bilateral Sober ureterostomies, the mean duration of diversion was 55 months. Bladder compliance was normal in 69%, and bladder capacity was normal in 80%.<sup>26</sup>

Total urinary reconstruction with valve ablation, ureteroneocystostomy, and excision of large bladder diverticula is another option in the initial management of the PUV patient. However, this approach is rarely indicated because significant improvement often occurs in VUR and bladder diverticula after ablation of the obstructing valve leaflets.

**Figure 58-5.** This diagram describes the Sober-en-T cutaneous ureterostomy, which is the authors' preferred method for proximal diversion in patients with posterior urethral valves. The proximal ureter is divided and exteriorized on the abdominal wall. The proximal end of the distal ureteral segment is then anastomosed to the renal pelvis.

## Urinary Extravasation

A special management issue is urinary extravasation, which occurs in 5% to 15% of neonates with PUV.<sup>27,28</sup> Forniceal rupture or renal parenchymal blowout with transperitoneal transudation or intraperitoneal leakage after bladder rupture may occur. Some infants develop a perirenal urinoma, whereas others have urinary ascites (Fig. 58-6). In one recent retrospective series of urinomas in boys with PUV, there was no increased risk of end-stage renal disease or VUR compared with unaffected boys.<sup>28</sup> Moreover, the differential renal function of involved and uninvolved kidneys was similar. However, with urinary ascites, significant electrolyte abnormalities may result from urinary reabsorption and respiratory compromise may occur. The goals of initial management are to determine the site of extravasation and the level of function of the kidneys.

Evaluation for extravasation begins with ultrasonography, VCUG, and renal scintigraphy. The early uptake phase of a <sup>99m</sup>Tc-MAG3 renal scan often demonstrates which kidney is extravasating. Inserting a 5- or 8-Fr feeding tube into the bladder may decompress the bladder and upper urinary tract sufficiently that the forniceal extravasation stops. If the VCUG shows a bladder rupture, a cutaneous vesicostomy may be necessary. If the urinoma or ascites increases in volume, if the serum creatinine concentration continues to increase, or if respiratory compromise, infection, hypertension, or significant parenchymal compression is seen, percutaneous aspiration is needed. If extravasation continues,

**Figure 58-6.** Posterior urethral valves and ascites. **A**, Prenatal ultrasound image demonstrating a perirenal urinoma around the right kidney, which is not hydronephrotic. **B**, Prenatal ultrasound image showing ascites and stretched umbilical vessels (arrow). **C**, Plain radiograph of the abdomen in a neonate with a distended abdomen from ascites.

an upper tract procedure is usually required. If extravasation from a hydronephrotic kidney occurs, insertion of a percutaneous nephrostomy often solves the problem. Unfortunately, with forniceal extravasation, typically the kidney is decompressed. In these cases, the involved kidney should be explored through a small flank incision. The renal parenchyma should be inspected for evidence of rupture, and the parenchymal disruption should be repaired. In most cases, the kidney will be intact, indicating that the extravasation is from one of the calyceal fornices. A temporary cutaneous pyelostomy or ureterostomy may be performed to decompress the kidney. However, in most cases, mobilizing the kidney, separating it from the adjacent peritoneum, and leaving a Penrose drain in the retroperitoneum will allow the leak to resolve, provided PUV ablation or a cutaneous vesicostomy has been performed to decompress the lower urinary tract.

### Follow-up after Initial Therapy

Antibiotic prophylaxis should be continued until the upper tract dilation improves, which may take several years. In addition, if the child has reflux, antibiotic prophylaxis should be continued until the VUR resolves spontaneously or is corrected surgically. Most patients benefit from long-term urologic management and nephrologic care initiated at birth. Common clinical problems include significant polyuria secondary to an inability of the kidneys to concentrate urine, metabolic acidosis (which may complicate somatic growth), renal insufficiency with hypocalcemia and hyperphosphatemia, and hypertension. If the patient remains clinically well with good somatic growth, periodic follow-up with ultrasonography, measurement of electrolytes, blood urea nitrogen, and creatinine, urinalysis, and blood pressure evaluations will ensure satisfactory growth and development.

### PROGNOSIS AFTER INITIAL THERAPY

The prognosis for satisfactory renal function may be predicted from several factors. A serum creatinine concentration less than 0.8 mg/dL 1 month after initial treatment or at age 1 year is associated with favorable ultimate renal function.<sup>29</sup> Others have shown that the serum creatinine level after 4 to 5 days of catheter drainage is also predictive of long-term renal function.<sup>30</sup> Visualization of the corticomedullary junction on renal ultrasonography has been associated with a favorable outcome (see Fig. 58-1).<sup>31</sup> This radiologic finding may not be present on the initial ultrasound study but may become apparent during the first few months of life. Achieving diurnal continence by the age of 5 years indicates that minimal or no bladder dysfunction is present and is a favorable parameter.<sup>32</sup> Another favorable prognostic feature is the presence of a pressure pop-off mechanism such as massive reflux into a nonfunctioning kidney (termed *the VURD syndrome*: valves, unilateral reflux, dysplasia), urinary ascites, or a large bladder diverticulum (Fig. 58-7).<sup>33</sup> The concept is that the high intravesical pressure is dissipated, allowing more normal renal development. Although short-term studies have suggested that these mechanisms may allow more normal renal development, at age 8 to 10 years only 30% of boys with the VURD syndrome had a normal serum creatinine value.<sup>34</sup> One important favorable prognostic sign is a normal appearance of the contralateral kidney at diagnosis. These boys had no UTIs or incontinence with long-term follow-up.<sup>35</sup> Finally, absence of reflux on the initial VCUG is a favorable sign.

Adverse prognostic factors include bilateral VUR, persistence of the serum creatinine higher than 1.0 mg/dL after initial therapy,<sup>36</sup> identification of small subcapsular renal cysts (indicative of renal dysplasia), renal echogenicity,<sup>37</sup> and failure to visualize the corticomedullary junction.<sup>31</sup> In addition, failure to

**Figure 58-7.** The VURD syndrome. A 7-year-old boy was found to have posterior urethral valves and a bladder diverticulum. **A**, The voiding cystourethrogram demonstrates a large, dilated posterior urethra (*asterisk*) secondary to the valves. **B**, The lateral view of this study shows a trabeculated bladder with a large bladder diverticulum (*asterisk*). **C**, The excretory urogram shows normal upper urinary tracts and deviation (*arrow*) of the distal left ureter due to the large bladder diverticulum. This boy underwent endoscopic valve ablation, excision of the bladder diverticulum, and left ureteroneocystostomy.

achieve diurnal continence is an indication of instability and detrusor sphincter dyssynergia, which can result in elevated upper urinary tract pressures and gradual deterioration in renal function and is associated with poor renal function.<sup>2,26</sup> Another adverse prognostic factor is the presence of the D allele in the angiotensin-converting enzyme genotype. These patients had a higher risk of renal scarring and breakthrough UTI.<sup>38</sup>

Review of studies of long-term renal functional outcome is difficult because of variable follow-up among study patients. In one report of 27 boys diagnosed between 1956 and 1970 with 31- to 44-year follow-up, 18% died at an early age and 11% were lost to follow-up.<sup>39</sup> Of the remaining surviving men, 32% were uremic, 21% had moderate renal insufficiency, and 40% had signs of bladder dysfunction. This study does not reflect the impact of early diagnosis with prenatal ultrasonography. For example, in a study of 79 cases of PUV prenatally diagnosed between 1987 and 2004, 65 had live births and all were managed with primary valve ablation. In follow-up, only 17% had renal failure and 76% of toilet-trained children were completely continent.<sup>40</sup> Early gestational age at diagnosis and presence of oligohydramnios were negative prognostic factors. In a prospective study of 46 cases of PUV, half were diagnosed prenatally and renal outcome was similar among those with prenatal versus postnatal diagnosis.<sup>41</sup>

The impact of late diagnosis also has been studied. In two large retrospective reports of late diagnosis of PUV (after age 5 years in one study and after age 2 years in the other), those with late diagnosis had a significantly higher creatinine concentration but bladder function was similar among the two groups.<sup>42,43</sup>

## VESICOSTOMY CLOSURE

The decision to close the cutaneous vesicostomy should be made carefully. If breakthrough febrile UTIs have been noted, vesicostomy closure is important because

it will reduce the risk of bacterial contamination of the urinary tract. In other patients, it may be necessary as a prerequisite to renal transplantation. In most cases, vesicostomy closure is performed after the upper urinary tracts have stabilized and the child is large enough to undergo simultaneous valve ablation, generally between ages 6 months and 3 years. Preoperatively, a VCUG should be obtained through the vesicostomy to assess whether significant vesicoureteral reflux is present and to evaluate the bladder appearance. In selected cases, urodynamics are helpful to assess bladder compliance.<sup>44</sup> If significant reflux is seen and the child is quite young, it is usually safe to simply close the vesicostomy and delay reflux correction until the child is older and the bladder is larger. After closure of the vesicostomy, the upper tracts should be monitored carefully to ascertain whether hydronephrosis is worsening and to be certain that the child is emptying the bladder satisfactorily.

## VESICoureTERAL REFLUX

VUR is present in approximately 50% of boys with PUV at presentation, with half being bilateral and half unilateral. After valve ablation, nearly all patients will show improvement in reflux grade 1 year later.<sup>24,45</sup> Approximately 25% develop spontaneous resolution of the reflux. However, the reflux may not resolve for as long as 3 years after initial treatment, and resolution of high-grade reflux is unlikely.<sup>46</sup> Antibiotic prophylaxis is continued, and periodic upper tract imaging and cystography should be performed. Renal deterioration without infection may be a sign of bladder dysfunction. Lower tract evaluation with video-urodynamics is important.

Reflux should be repaired surgically if breakthrough infections occur or if it remains high grade. The efficacy of endoscopic injection therapy has not been proved, but its use remains an option. Most pediatric

**Figure 58-8.** Technique of ureterocystoplasty. **A**, Left nonfunctional kidney and ureter is exposed. **B**, After the left kidney is removed, the ureter is spatulated medially. **C**, Left ureter is folded into a “U” and sutured to opened bladder.

urologists are adept at performing ureteral reimplantation surgery, but reimplanting thick, dilated ureters into the abnormal valve bladder can be most challenging. A 15% to 30% complication rate has been reported, most often persistent reflux or ureteral obstruction.<sup>47,48</sup> If bilateral high-grade VUR is found, a transureteroureterostomy may be performed in conjunction with a single, long, tapered reimplant and a psoas hitch. However, if the single reimplanted ureter becomes obstructed, the upper tracts may deteriorate rapidly. If unilateral high-grade reflux into a kidney with reasonable function occurs, transureteroureterostomy into the nonrefluxing ureter is an option.

In boys with the VURD syndrome, a nephrectomy should be performed at some point. The ureter should be removed, unless the bladder is small and/or poorly compliant. In this case, a ureterocystoplasty can be considered (Fig. 58-8). After this procedure, the remaining kidney should be monitored carefully for the development of hydronephrosis because the pressure “pop-off” mechanism has been removed.

## BLADDER DYSFUNCTION AFTER INITIAL THERAPY

The prognosis for boys with PUV depends on the status of the kidneys and the bladder at the time of diagnosis and the method of bladder management as the child grows. In as many as 40% with PUV, end-stage renal disease or chronic renal insufficiency develops, and the vast majority of these boys have voiding dysfunction.<sup>32</sup> Many boys with PUV have a spectrum of urodynamic abnormalities that change. For example, in a study of 16 prepubertal boys seen before age 1 year and observed from ages 4 to 14 years, initial bladder instability was observed.<sup>49</sup> Over time, however, the instability improved and the bladder capacity increased. In this study, postpubertal boys had high-capacity bladders with low contractility, causing difficulties in detrusor emptying. Other groups have reported similar findings.<sup>50,51</sup>

The cause of the bladder dysfunction is incompletely understood, but experimental evidence suggests that fetal urethral obstruction causes irreversible changes in the smooth muscle cells of the bladder<sup>52,53</sup> and results in deposition of type III collagen in the bladder wall. The bladder abnormalities are manifested as incontinence or persistent hydronephrosis (or both). Boys with significant urodynamic abnormalities are most likely to experience severe renal functional impairment.<sup>54</sup>

As many as half of boys with PUV have ongoing daytime incontinence into late childhood.<sup>32,55</sup> In the past, it was thought that incontinence resulted from sphincteric incompetence from urethral maldevelopment or injury to the sphincter during valve ablation. However, it has become apparent that significant urodynamic abnormalities may persist after very satisfactory relief of bladder outlet obstruction.

Several potential causes for urinary incontinence are known in boys with PUV,<sup>18,56</sup> including the following:

1. Detrusor abnormalities such as (a) an overactive bladder secondary to uninhibited detrusor contractions, (b) overflow incontinence, (c) poor compliance, and (d) myogenic failure
2. High-pressure voiding secondary to incomplete valve ablation
3. Detrusor-sphincter dyssynergia in which the sphincter muscle fails to relax during bladder contraction
4. Polyuria secondary to a concentrating defect as a result of long-standing obstructive uropathy that causes renal tubular damage
5. Valve bladder, which is a bladder with poor compliance resulting from fibrosis secondary to long-standing obstruction. This clinical situation may cause secondary ureteral obstruction with worsening hydronephrosis if the bladder pressure is greater than 35 cm H<sub>2</sub>O pressure.

Consequently, long-term therapy for the boy with PUV includes management of the bladder as well as attention to renal function.

**Table 58-1** Pathophysiologic Changes in the Valve Bladder Syndrome

Organ	Pathologic Process	Clinical Effect
Kidney	Dysplasia, renal tubular dysfunction Urine concentrating defect (polyuria)	Poor renal function; polyuria Rapid filling of bladder, causing persistent hydroureteronephrosis and incontinence
	Renal tubular acidosis	Impaired somatic growth, bone demineralization
Ureters	Dilated with poor peristalsis	Large dead space Increased risk of urinary tract infection
	Fibrosis secondary to previous surgical procedures or infection	Poor drainage of upper tract Possible obstruction after ureteral reimplantation
Bladder	Poor compliance; small volume Reduced sensation to high pressure	High bladder pressure most of the time Progressive renal functional damage Incontinence
	Myogenic failure	Progressive renal and bladder damage
Bladder neck	Hypertrophy	Poor bladder emptying Voiding dysfunction Incontinence

From Close CE: The valve bladder. In Gillenwater JY, Grayhack JT, Howards SS, et al (eds): Adult and Pediatric Urology, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2002, pp 2311-2318.

## The Valve Bladder

An understanding of the pathophysiology of the obstructed bladder allows one to develop an effective therapeutic approach to treatment. Several factors are present in patients with persistent hydroureteronephrosis after valve ablation: (1) the hydroureteronephrosis is associated with a noncompliant thick bladder wall; (2) most have diurnal incontinence; (3) incontinence is secondary to increased urine output and decreased bladder compliance; (4) acquired diabetes insipidus is the cause of the high urine output; and (5) the high urine output contributes to the hydroureteronephrosis.<sup>57</sup>

In 1982, the valve bladder syndrome was described.<sup>58,59</sup> In one series of 70 boys with PUV, 16 had polydipsia, polyuria, incontinence, hydroureteronephrosis without VUR, poorly sensate bladders, and poorly compliant bladders with high pressure at low urine volumes.<sup>58</sup> Normally the bladder stores urine at low pressure, allowing unimpeded drainage from the kidneys. With a poorly compliant bladder, however, as the bladder fills, the intravesical pressure increases quickly, causing a functional barrier to upper tract drainage, resulting in progressive hydroureteronephrosis. This high intravesical pressure contributes to the gradual deterioration in renal function.

The spectrum of physiologic abnormalities in boys with the valve bladder syndrome is shown in Table 58-1. The obstructed kidney often develops an irreversible urinary concentrating defect secondary to tubular injury. Despite fluid restriction, an enormous obligate urine output can be seen and may be as high as 3 L/day. This polyuria causes decompensation of the bladder, incontinence, and persistent back-pressure on the upper urinary tracts, with persistent hydroureteronephrosis.

Persistent ureteral dilation causes inefficient ureteral wall coaptation and poor peristalsis, which

predisposes to UTI. Fibrosis from previous infection or previous ureteral surgery may result in inefficient ureteral peristalsis and increases the risk of obstruction after ureteral reimplantation. In the past, persistent hydroureteronephrosis was thought to result from ureterovesical junction obstruction. Upper tract pressure/volume (Whitaker test) studies with the bladder empty and full have demonstrated that in the vast majority of cases unimpeded drainage into the bladder occurred with the bladder empty. As the bladder filled, with increasing intravesical pressure, increasing hydroureteronephrosis and increasing renal pelvic pressure were found.<sup>58</sup> Consequently, ureteral reimplantation in these patients with the goal of relieving ureterovesical junction obstruction has a high risk of failure and worsening hydronephrosis. In a recent series of 71 boys with PUV, persistent hydroureteronephrosis was noted in 20 patients (28%).<sup>60</sup> All of the patients with persistent hydroureteronephrosis had abnormal urodynamic findings, primarily poor compliance and instability. Aggressive treatment showed dramatic improvement or complete resolution of upper tract changes and urodynamic parameters.

Boys with a poorly compliant or unstable bladder often tolerate high intravesical pressures without discomfort. As a result, they delay voiding and experience overflow incontinence. Because of the high intravesical pressure, ongoing renal functional damage occurs. In addition, polyuria causes volume stress and contributes to chronic overdistention of the bladder. Effective bladder emptying is difficult to accomplish because of poor detrusor function and rapid refilling of the bladder. Double or triple voiding often is necessary to empty the bladder and the upper tracts, but compliance with this regimen often is not very good.

Bladder neck hypertrophy is a component of the overall detrusor hypertrophy that results from bladder outlet obstruction. After valve ablation, significant residual muscular hypertrophy may persist, resulting

in functional bladder outlet obstruction with poor emptying. In the past, YV-plasty of the bladder neck was performed, but incontinence and upper tract changes persisted because of the aforementioned factors. In addition, a late complication of this procedure is retrograde ejaculation. Consequently, bladder neck surgery should be avoided unless urodynamic and radiographic documentation of intractable bladder neck obstruction is found.

### Can the Valve Bladder Be Prevented?

Several clinical observations allow one to formulate a treatment plan to try to minimize the risk of developing a valve bladder. One factor relates to the primary form of therapy. In many boys with PUV, severe hydronephrosis and an elevated serum creatinine concentration are present. In the past it was thought that performing cutaneous pyelostomies in the most severe cases would result in optimal upper tract decompression and give the kidneys the best chance of having unimpeded drainage. Indeed, evidence was found that these boys had better somatic growth compared with boys who underwent valve ablation alone.<sup>22</sup> However, it is difficult to document any case in which cutaneous pyelostomies have prevented end-stage renal disease. In addition, it became apparent that boys with proximal diversion ultimately had a small bladder that required augmentation cystoplasty. On the other hand, after valve ablation or cutaneous vesicostomy, the bladder typically grows satisfactorily, presumably because of urinary growth factors and ongoing cycling of the bladder.<sup>61-63</sup>

### Management of Bladder Dysfunction

Close follow-up is important after valve ablation. A VCUG should be performed to document that bladder outlet obstruction has been relieved. Serial renal sonograms and serum creatinine and electrolytes are necessary. Renal scintigraphy is necessary if evidence of renal dysfunction on either side is found. If VUR is present, serial VCUGs are necessary until the reflux is minimal or absent. Urodynamic evaluation is important with persistent hydronephrosis to confirm that resting and filling bladder pressures are in a safe range, less than 30 cm H<sub>2</sub>O. Furthermore, detrusor instability or hypocontractility can be documented. In addition, uroflowmetry and sonographic assessment of postvoid residual urine volume are helpful. Having these patients followed by a pediatric nephrologist is invaluable because renal tubular acidosis, renal insufficiency, end-stage renal disease, and somatic growth abnormalities are common.

If significant polyuria and incontinence are found, timed voiding every 1 to 2 hours is beneficial. In addition, double or triple voiding provides more efficient emptying of the bladder and upper urinary tracts.

If a poorly functioning or nonfunctioning hydro-nephrotic kidney is noted, nephrectomy or nephroureterectomy should be performed. Usually this procedure can be performed laparoscopically. Before

proceeding, however, the potential need for lower urinary tract reconstruction should be assessed because the dilated ureter can be used to augment the bladder. This augmentation procedure can be incorporated into the overall reconstruction.

If urodynamic studies demonstrate detrusor instability, anticholinergic therapy is necessary. Several medications may be used. Oxybutynin chloride suspension or tablets are effective but may cause side effects such as dry mouth, facial flushing, constipation, and blurring. The medication lasts 4 to 6 hours and generally is administered three times daily. The maximum dosage is 1 mg per year of age, three times daily, with a maximum of 5 mg, three times daily. Sublingual hyoscyamine also may be effective, has fewer side effects than oxybutynin, but is given four times daily. In recent years, tolterodine has been useful in children older than age 6 years, given in doses of 1 to 2 mg twice daily. Tolterodine has fewer side effects than oxybutynin chloride. There are also long-acting forms of oxybutynin and tolterodine with fewer side effects.

If bladder hypocontractility is present, clean intermittent catheterization usually is necessary. Learning this technique initially may be difficult for boys and their families. With persistence and support from the medical team, however, most adapt to intermittent catheterization, particularly if it improves or cures their incontinence. Intermittent catheterization tends to reduce bladder instability and improves bladder compliance.<sup>51</sup> In some cases, a continent appendicovesicostomy (Mitrofanoff procedure) can be performed to allow intermittent catheterization with less patient discomfort.

If detrusor-sphincter dyssynergia with inadequate bladder neck relaxation is found, treatment with an  $\alpha$ -adrenergic blocker may be beneficial. In a study of 55 children with a variety of causes of non-neuropathic voiding dysfunction, administration of doxazosin, 0.5 to 2.0 mg daily, resulted in a significant improvement in urine flow rate, reduction in postvoid residual urine volume, and improvement in incontinence.<sup>64</sup> Few had significant side effects.

An important recent concept is that some of the changes that result in the valve bladder syndrome result from bladder overdistention at night, secondary to polyuria and failure to empty the bladder regularly during sleep. To address this issue, overnight catheter drainage has been used with moderate success, resulting in significant improvement in hydronephrosis and improved voiding dynamics during the day.<sup>65,66</sup> This therapy should be strongly considered in boys with valve bladder syndrome.

If urodynamic studies demonstrate a poorly compliant or small-capacity bladder (or both), then augmentation cystoplasty is indicated. This procedure may alter voiding dynamics. Moreover, the addition of a noncontractile patch to the bladder in a boy who is emptying satisfactorily may result in a situation in which clean intermittent catheterization is necessary. In boys with PUV who undergo ureterocystoplasty, most need to perform intermittent catheterization after the operation.

Consequently, creation of a “back-up” continent stoma (appendicovesicostomy) in conjunction with an augmentation cystoplasty should be considered.

Several options exist for augmentation cystoplasty. Ureterocystoplasty results in the fewest long-term complications, but a dilated ureter is a prerequisite for this procedure (see Fig. 58-8). Ureterocystoplasty generally is performed in conjunction with removal of a nonfunctioning kidney. In these cases, the entire ureter can be used to augment the bladder. If both kidneys have satisfactory function, another option is to use the lower half of the dilated ureter for bladder augmentation and to perform a proximal transureteroureterostomy. The ureter is opened on its medial border through the ureterovesical junction. If the dilated ureter is long, then it may be folded onto itself in the shape of a “U” and sutured to the opened bladder. Although long-term results with this procedure are favorable, in one recent series 23% subsequently needed an ileocystoplasty.<sup>67</sup> If a dilated ureter is unavailable or the bladder needs more significant augmentation, then ileocystoplasty is the best option, assuming renal function is relatively normal.<sup>68</sup> Electrolyte abnormalities from absorption through the small bowel patch are uncommon. However, a generous amount of mucus is produced and regular bladder irrigation is necessary to prevent bladder calculi. Other potential long-term complications include chronic or recurrent bacteriuria and spontaneous bladder perforation from chronic overdistention. If renal function is limited, gastrocystoplasty should be considered. The advantage of this procedure is that the gastric patch secretes the hydrogen ion, and metabolic acidosis can be reversed or improved with the operation. In addition, unlike with small bowel, the patch is not absorptive. Furthermore, because the pH of the urine is low, the risk of UTI is reduced. The disadvantages of gastrocystoplasty include the need to extend the incision superiorly to the xiphoid process and the risks of severe metabolic alkalosis. In addition, some patients develop the hematuria/dysuria syndrome, characterized by intermittent severe dysuria and hematuria.<sup>69</sup> Furthermore, if the child has incontinence, a significant chance exists that he will experience a burning sensation where the urine leaks. Despite these potential problems, however, the long-term results with gastrocystoplasty are favorable.<sup>70</sup> Another option in patients with limited

renal function is bladder augmentation with a patch of both ileum and stomach (gastroileocystoplasty), which avoids most of the problems associated with gastrocystoplasty.<sup>71</sup>

## RENAL TRANSPLANTATION

Despite optimal management of boys with PUV, end-stage renal disease develops in 30% to 40%.<sup>32</sup> In many cases, impaired renal function can be stabilized during childhood. However, during adolescence, there is insufficient renal reserve and dialysis or renal transplantation becomes necessary. Retrospective studies of boys with PUV undergoing renal transplantation have suggested that the valve bladder may have a detrimental effect on graft survival. For example, in one study, a significantly worse 5-year graft survival was noted for patients undergoing transplantation for valve-related renal failure than was found in patients with nonobstructive abnormalities.<sup>72</sup> Other recent studies, however, demonstrated no difference in graft survival or serum creatinine levels between boys with PUV and children with nonobstructive causes of renal failure.<sup>73,74</sup> These data suggest that with intensive management of bladder function, a favorable long-term outcome can be expected.

## FERTILITY

Few long-term studies have evaluated the reproductive status of men who were born with PUV. Theoretically, prostate function might be affected because of elevated urethral pressure during embryonic development and ongoing voiding dysfunction. In addition, some boys with PUV also undergo orchiopexy for cryptorchidism, which is associated with reduced fertility. Finally, in the past, some men have undergone YV-plasty of the bladder neck, which results in retrograde ejaculation. In one study of eight adolescents, sperm count was satisfactory in five, but most had abnormal sperm agglutination and a higher percentage of immotile sperm.<sup>75</sup> Three of the eight failed to ejaculate. In a long-term study, the ability to father children was dependent on whether the man was uremic.<sup>39</sup> In another study of 10 men, sperm counts were within the fertile range in all, but only 3 had initiated pregnancies.<sup>76</sup>

# BLADDER AND CLOACAL EXSTROPHY

Michael Mitchell, MD • Richard Grady, MD

The exstrophic anomalies, often referred to as the exstrophy-epispadias complex,<sup>1</sup> are considered a spectrum of embryologic abnormalities related by certain anatomic features, including:

- *Epispadias*—considered the least severe anomaly in this spectrum; the urethra is a partial or complete open plate on the dorsal surface of the phallus.
- *Classic bladder exstrophy*—the most common of these unusual anomalies; the bladder is an open plate on the low abdominal wall and the urethra is epispadias.
- *Cloacal exstrophy*—the bladder and the ileocecal junction of the bowel are an open plate on the lower abdomen. This condition, commonly associated with other malformations, is also known as the omphalocele/exstrophy/imperforate anus/spinal defect (OEIS) complex.
- *Exstrophy variants*—partial manifestations are seen of the above anomalies.

Bladder exstrophy occurs at a rate of 1 per 10,000 to 1 per 50,000 live births.<sup>2,3</sup> This anomaly has long been recognized to occur more commonly in males than females, with a ratio of 3 to 6:1 reported in the literature.<sup>4,5</sup> Cloacal exstrophy occurs even more rarely, with an incidence of 1 in 200,000 to 1 in 400,000 live births<sup>6</sup> but is higher in stillborns at 1 in 10,000 to 1 in 50,000.<sup>7</sup>

## BLADDER EXSTROPHY

Definite historical descriptions of bladder exstrophy date back to at least 1597 with von Grafenberg's description of this congenital defect. Possible depictions of exstrophy also exist on Assyrian tablets from 2000 BC. Chaussier first coined the term *exstrophie* to describe this defect in 1780 after detailed descriptions of it by Mowat in 1748. The natural history of bladder exstrophy is well known. The anomaly is not lethal, although it is associated with significant morbidity. Since the 19th century, various efforts to manage this condition have been described. Because exstrophic

conditions are rare, these approaches were empirical and often unsuccessful. Until the 20th century, no effective surgical remedy was available to consistently ameliorate the morbidity associated with bladder exstrophy.

Bladder exstrophy occurs because the anterior portion of the bladder and/or urethra and the abdominal wall structures are deficient. Also, the pubic symphysis is widely separated from the midline in the majority of exstrophy anomalies. Initially, the bladder and urethra are herniated ventrally. The deformity has been described as "if one blade of a pair of scissors were passed through the urethra of a normal person. The other blade was used to cut through the skin, abdominal wall, anterior wall of the bladder and urethra, and the symphysis pubis; and the cut edges were then folded laterally as if the pages of a book were being opened" (Fig. 59-1).<sup>8</sup> Most of the exstrophic defects are typically found in isolation. Other organ systems are infrequently affected. However, children with bladder exstrophy typically have an anteriorly located anus. Female genital anatomy is altered with a more vertically oriented vaginal opening after closure and a wider and shorter vagina than normal. The anterior component of the penis is also foreshortened in males compared with the general population.

Currently, this spectrum of birth anomalies represent some of the most complex that pediatric urologists and surgeons manage. Although great strides in management have been made, many challenges still exist.

## Diagnosis

The diagnosis of bladder exstrophy can be made antenatally, although many affected fetuses are not suspected to have exstrophy before birth.<sup>9</sup> Ultrasonography can reliably detect exstrophy before the 20th week of gestation.<sup>10,11</sup> Absence of the bladder is the hallmark of exstrophy. Other ultrasound findings include:

- A semisolid mass protruding from the abdominal wall<sup>12</sup>
- An absent bladder

**Figure 59-1.** Bladder exstrophy in a male. The urethral mucosa is marked with the arrow. The corporeal bodies lie posterior to the urethral mucosa.

- A lower abdominal protrusion
- An anteriorly displaced scrotum with a small phallus in male fetuses
- Normal kidneys in association with a low-set umbilical cord<sup>13</sup>
- An abnormal iliac crest widening<sup>10</sup>

Subtle findings such as low umbilical cord insertion and the location of the genitalia will be seen only if the fetus is examined in a sagittal alignment with the spine.<sup>14</sup> Because exstrophy affects the external genitalia, the diagnosis is easier to make in males than females. Iliac crest widening can also be seen during the routine prenatal evaluation of the lumbosacral spine performed to evaluate for myelomeningocele. The iliac angle will be about 110 degrees rather than the 90 degrees that is normally seen.<sup>14</sup> Because urine production is normal for these fetuses, amniotic fluid levels should be normal.

Prenatal diagnosis allows optimal perinatal management of these infants. The infant can be delivered near a pediatric center equipped to treat neonates with this unusual anomaly. As importantly, prenatal diagnosis also allows the parents the opportunity to discuss early management of the patient. Prenatal counseling should include the expertise of a pediatric urologist or surgeon experienced in the treatment of bladder exstrophy. The overall prognosis for these children can be quite good if they are treated at medical centers with experience with this condition.<sup>15</sup>

In many areas of the developing world, early treatment remains problematic due to lack of health care infrastructure and resources to care for these patients.

As a result, early diagnosis may not result in early treatment in these regions of the world. Management of these patients often includes delayed closure and adds another level of challenge to achieve optimum outcomes in this patient group. A recent overview from the KwaZulu-Natal region of South Africa highlights this problem.<sup>16</sup> Fifty-eight percent of the patients presented in a delayed fashion, and mortality rates approached 42% owing to concomitant medical conditions and poor primary health care.

## Pathogenesis

In the scientific era, the cause of exstrophy was attributed to trauma to the unborn child causing ulceration of the abdominal wall down to the bladder. Today, we know that the developing human embryo does not normally pass through a stage that corresponds to exstrophy. This knowledge excludes arrested development as the cause and implicates an error in embryogenesis involving the cloacal membrane.<sup>17</sup> This membrane serves to separate the coelomic cavity from the amniotic space in early development and can be identified during development at 2 to 3 weeks of gestation. By the fourth week, it forms the ventral wall of the urogenital sinus with the unfused primordia of the genital tubercles sitting cephalad and lateral to it. With further development, the primordia grow and fuse in the midline and the mesoderm grows toward the midline, creating an infraumbilical abdominal wall. Simultaneous to this process, the urorectal septum develops medially and caudally to separate the cloaca into the urogenital sinus and rectum.<sup>18</sup>

One theory suggests exstrophy occurs because of a persistent cloacal membrane during fetal development.<sup>19</sup> Persistence of the membrane would create a wedge effect that keeps the medially encroaching mesoderm from fusing in the midline.<sup>17</sup> To further study this hypothesis, an animal model of cloacal exstrophy using the developing chick embryo was created. By placing a plastic graft in the region of the tail bud, cloacal exstrophy develops, perhaps due to persistence of the cloacal membrane.<sup>17</sup>

Other experimental models implicate the cloacal membrane in the pathophysiology of exstrophy as well but postulate that early disruption rather than persistence causes exstrophy. A model of cloacal exstrophy in the developing chick embryo created by using a CO<sub>2</sub> laser to create an early dehiscence in the tail bud caudal to the omphalomesenteric vessels suggests that exstrophy may be caused by failure of the mesodermal ingrowth between the ectoderm and endoderm of the cloacal membrane, which later ruptures to produce exstrophy. They hypothesize that such an event could be caused by early hypoxemic infarction in the region of the tail bud with subsequent cellular loss of the mesoderm and herniation of the developing bladder or cloaca.<sup>20</sup> This type of ischemic injury has been implicated as the cause of gastroschisis and could explain the spectrum of the exstrophy/epispadias complex.

Other proposed theories for exstrophy include caudal displacement of the paired primordia of the genital

tubercles. According to one theory, exstrophy occurs when the primordia of the genital tubercles fuse caudal to their usual location relative to where the urorectal fold divides the cloaca into the urogenital sinus and rectum.<sup>21</sup> This theory readily explains the spectrum of variation seen in the exstrophy/epispadias complex. However, it fails to explain the higher incidence of bladder exstrophy compared with epispadias. One would anticipate a higher incidence of epispadias if caudal displacement were the underlying cause of exstrophy/epispadias because it would represent the least severe form of this phenomenon.<sup>8</sup>

A new maldevelopment theory was put forth recently for cloacal exstrophy based on a suramin-exposed chick model.<sup>22</sup> When these chick embryos were examined at 1 or 2 days after pericardial injection of suramin, approximately 8% were noted to have a midline infraumbilical opening into the cloaca and allantois, abnormal leg bud abduction, hypoplastic tail and allantois, broad infraumbilical pelvic region, and large aneurysmal dilation of the paired dorsal aortae at the level of the leg buds. The aortic dilation is transient, resolving 2 to 3 days after drug exposure but leaving maldevelopment. These authors implicate the aneurysmal paired dorsal aortae as the primary defects leading to cloacal exstrophy in this animal model. Pelvic maldevelopment has also been implicated in the pathogenesis of bladder exstrophy and explains both the bony abnormalities as well as soft tissue anomalies involved in this defect.<sup>23</sup>

The chick model to study bladder exstrophy has inherent limitations. Chicks normally possess a cloaca. Therefore, this precludes the creation of a bladder exstrophy versus a cloacal exstrophy. Other animal models to study bladder exstrophy have been difficult to create. In an exstrophy sheep model, a significant increase in the ratio of collagen to smooth muscle was noted in exstrophic versus normal control bladders ( $P < .05$ ). There was no significant difference in the ratios of types I and III collagen in the two groups of sheep bladders. These histologic changes are similar in part to changes seen in human bladder exstrophy tissue.<sup>24,25</sup>

To date, the underlying cause of human exstrophy remains in question regarding whether the inciting event is related to an environmental exposure, an infectious pathogen, or another cause in genetically susceptible individuals. Epidemiologic studies, in fact, implicate a role for inherited susceptibility. Because of the associated physical anomalies with this condition, patients with bladder exstrophy often have to overcome significant obstacles to reproduce. Men may need to resort to assisted reproductive techniques (e.g., intracytoplasmic sperm injection<sup>26</sup>) because their seminal emissions drain from their ejaculatory ducts located at the base of their bladder plate, if at all. Furthermore, sexual intercourse due to the accompanying deformity of the phallus can be difficult for some of these patients, although the majority have the capacity for satisfactory sexual relations.

In the 1800s, males with bladder exstrophy were considered incapable of sexual activity because of the associated deformities of the penis.<sup>27</sup> Women with

exstrophy are prone to uterine prolapse and miscarriage. Difficulty with conception and pregnancy are still a problem today despite in-vitro fertilization and careful obstetric care.<sup>28,29</sup> When combined, these issues may explain, in part, why familial patterns of inheritance of exstrophy-epispadias complex are noted infrequently. To date, 37 familial cases of bladder exstrophy have been reported, the most recent of which describes a mother and son with bladder exstrophy.<sup>30</sup> Five cases of an affected parent-child pair have been reported.<sup>30-32</sup> Another 18 cases with bladder exstrophy have been reported in twin pairs.<sup>30</sup> In 1984, a survey of pediatric urologists and surgeons reported 9 cases related to 2500 index cases of bladder exstrophy. This same series also reported on cases of twins and noted discordance in both fraternal as well as identical twinships.<sup>32</sup> Furthermore, in a study population of greater than 6 million births with 208 reported cases of exstrophy, no case had a family history for this anomaly.<sup>33</sup>

Current recommendations on counseling about the risk of recurrence in a sibling of a patient with exstrophy cite an estimate of about 1% and a 1:70 chance of transmission to the progeny of an affected parent.<sup>31</sup> A Florida population-based study found multiple births had a 46% increased risk of birth defects, with bladder exstrophy being the fifth highest adjusted relative risk.<sup>34</sup> These findings support a multifactorial etiology with evidence for genetic predisposition. More recently, an epidemiologic survey of families with bladder exstrophy found no link between exstrophy and parental age, maternal reproductive history, or periconceptual maternal exposure to alcohol, drugs, chemical noxae, radiation, or infections. Periconceptual maternal exposure to smoking was noted to be significantly more common in patients with cloacal exstrophy.<sup>35</sup>

## Principles of Reconstruction

Current objectives for reconstruction in the treatment of exstrophy may be placed broadly in the categories seen in Table 59-1. Although these goals are straightforward and often interconnected, their successful achievement can be elusive. Many of the secondary goals address complications that can arise as a result or complication of surgical procedures used to treat exstrophy. Numerous operations have been devised for the treatment of bladder exstrophy in an effort

**Table 59-1** Goals of Reconstruction

Primary Goals	Secondary Goals
Preservation of kidney function	Minimization of urinary tract infections
Urinary continence	Adequate pelvic floor support
Low pressure urine storage reservoir	Minimization of the risk for malignancy associated with the urinary tract
Volitional voiding	Minimization of the risk for urinary calculi
Functionally and cosmetically acceptable external genitalia	Adequate abdominal wall fascia

**Table 59-2** Primary Pathophysiology of Bladder Exstrophy and Complications that Occur in Relation to its Management

Primary Pathophysiology (If Untreated)	Complications (Associated with Management of Exstrophy)
Malignancy (related to chronic exposure of the bladder plate)	Malignancy (related to the use of intestine in bladder reconstruction)
Pyelonephritis	Pyelonephritis
Kidney stones	Kidney and bladder stones
Total urinary incontinence	Stress or urge urinary incontinence
Chronic bladder irritation	Hydronephrosis
Pelvic floor insufficiency	Cystocele, uterine prolapse
Abnormal hip dynamics, back pain	Abnormal hip dynamics, back pain
Symphyseal diastasis, pelvic flattening	Urinary outlet obstruction
Abdominal wall defect	Absent umbilicus
Ventral and inguinal hernias	Incisional hernias
Severe penile shortening with dorsal chordee	Inadequate phallus in males with subsequent social and psychological sequelae

to achieve the goals above. The goals of surgery have expanded since the first operations were proposed and attempted in the 19th century. These objectives address the primary pathophysiology of exstrophy and the problems associated with this anomaly and its management (Table 59-2).

## Natural History and Early Attempts at Treatment

Exstrophy anomalies are not fatal. Some untreated patients with classic bladder exstrophy have lived into their eighth decade.<sup>36</sup> However, significant morbidity exists with these conditions if they are left untreated, including total urinary incontinence, bladder and kidney infections, skin breakdown, and tumor formation in the bladder plate. The surrounding skin around the exposed exstrophic bladder is often inflamed secondary to urine contact dermatitis, loss of skin integrity from constant wetness, and secondary infection. Untreated inguinal hernias can be life threatening, and organ prolapse is especially challenging to manage later in this patient group. These patients are often social pariahs as well because of odor and hygiene problems. In contrast, when these patients receive effective surgical and medical treatment, they can lead productive, healthy lives with minimal morbidity from their underlying urologic abnormality.

Early forms of treatment were largely directed at protecting the bladder plate and controlling urinary leakage.<sup>27</sup> The morbidity associated with untreated exstrophy led physicians to develop empirical operative approaches for this anomaly, such as urinary reconstructive or diversion procedures. Initial efforts were directed at partial reconstruction of the abdominal wall

to allow the application of a urinary receptacle to collect urine. Others performed urinary diversion through the creation of a ureterosigmoid fistula. These early results were poor. One patient died of peritonitis in the immediate postoperative period, and the other died of renal failure secondary to chronic pyelonephritis.<sup>27</sup> These early efforts were undertaken without an understanding of urinary tract and bladder physiology or how these operations would affect urine storage and emptying, kidney function, electrolyte homeostasis, the propensity for urinary tract infection, or urinary calculus formation.

## Current Operative Approaches

A wide range of operations has been devised and performed to repair bladder exstrophy. These procedures lump themselves into two groups: (1) urinary diversion and (2) anatomic reconstruction. Surgeon preference and experience, patient anatomy, previous surgical procedures, timing of reconstruction, availability of tertiary care facilities, and access to medical care and resources all play a role in which operative procedures are chosen for a particular patient. Even in the 21st century, no standard of care exists for this patient population. However, with the complexity of care and the rarity of this congenital defect, specialists with an interest in the exstrophy-epispadias complex usually manage these patients most effectively.

Early surgical treatment remains particularly problematic in many areas of the developing world owing to lack of a uniform health care infrastructure and resources. As a result, early diagnosis may not result in early operative correction in these regions. Management in this setting often includes delayed closure, which adds another level of challenge to achieve optimum outcomes.

### Urinary Diversion

Urinary diversion is not commonly used in the United States or most parts of Europe. This approach has generally been abandoned for an anatomically based approach. However, continent urinary diversion techniques can provide a more consistent degree of urinary continence with less surgical intervention than that achieved with functional reconstruction.<sup>37</sup> Reported rates of continence after primary reconstruction vary widely. Some urodynamic studies demonstrate low urine flow rates and poor contractility in patients after primary bladder reconstruction.<sup>38,39</sup>

Internal or incontinent urinary diversion avoids the complications associated with functional reconstruction, including urinary retention and subsequent kidney damage, and potential later dependence on clean intermittent catheterization (CIC) to empty the bladder. Advocates of early urinary diversion also cite a decreased risk of epididymitis and obstruction of the vas deferens by the creation of a receptacle with a suprapubic window at the level of the prostatic urethra. Diversion can also be combined with cosmetic and functional reconstructive operative procedures for the external genitalia.

Urinary diversion is also useful to achieve urinary continence in patients who have failed multiple attempts at functional reconstruction. Some also advocate primary urinary diversion for patients with bladder plates deemed too small to close. However, because we cannot accurately predict which bladder plates will increase significantly in size after primary closure, we do not use this as a criterion for primary diversion and do not divert the urine primarily in exstrophy patients.

Because of the difficulties encountered with functional bladder reconstruction in exstrophy, advocates of early urinary diversion argue that their approach achieves the primary goals of surgical intervention for bladder exstrophy with fewer operations and higher success rates than are achieved with bladder closure and urethral reconstruction. In fact, because of the dismal results associated with primary bladder reconstruction well into the 1970s, urinary diversion remained the treatment of choice for exstrophy in most of the world and still remains the treatment of choice in some regions today.

Given the successes with this approach, why abandon it? Long-term complications associated with ureterosigmoidostomy are significant and include hyperchloremic metabolic acidosis, chronic pyelonephritis, and a 250- to 300-fold increased risk of adenocarcinoma at the site of anastomosis.<sup>40</sup> Because of these complications, ureterosigmoidostomy was subsequently replaced by incontinent urinary diversions such as colonic and ileal conduits. A significant disadvantage to these forms of urinary diversion is the incontinent abdominal stoma associated with them. The popularization of CIC allowed the development of continent urinary diversions, which are now the preferred methods of nonorthotopic urinary diversion in areas of the world with access to medical supplies. Modifications to the ureterosigmoidostomy (described later) are currently used as well. Ultimately, any intestinal segment used for urinary storage confers a risk of bladder calculi, metabolic abnormalities, and malignancy that may be avoided with successful anatomic reconstruction.<sup>41,42</sup> As a consequence, although anatomic reconstruction may produce less consistent results, it has become the standard approach when possible.

## RECTAL RESERVOIRS

The Mainz II pouch and the Sigma pouch represent significant improvements to the ureterosigmoidostomy.<sup>43,44</sup> A rectal reservoir permits urinary continence without reliance on CIC. Renal preservation rates in children treated primarily with a urinary rectal reservoir (Mainz II pouch since 1991) approach 92%. Continence rates in school-age children approach 97% using this technique.<sup>37</sup> The Heitz-Boyer-Hovelacque procedure involves isolation of a rectal segment for ureteral implantation followed by posterior sagittal pull-through of the sigmoid colon to achieve both urinary and fecal continence. A small series using this procedure reported continence rates of 95% with acceptable complication rates.<sup>45</sup> Complications of this

form of diversion continue to include fecal-urinary incontinence in patients with impaired anorectal sphincter control. Metabolic electrolyte imbalances can be treated with complete and frequent emptying of the rectal reservoir, which reduces the contact time between urine and the absorptive rectal mucosa. Oral bicarbonate replacement is also important. However, a significant risk of malignancy remains with using a rectal urinary reservoir. Various modifications of the rectal reservoir to prevent admixture of feces and urine may decrease the incidence of adenocarcinoma if the risk is due to conversion of urinary nitrates into carcinogenic nitrites by fecal bacteria.<sup>46</sup> Long-term results are not yet available. Methods to construct urinary diversions can be seen in Table 59-3.

## Anatomic Reconstruction

The first efforts at anatomic reconstruction of the exstrophic bladder were unsuccessful but did set the stage for an anatomic approach. In 1881, Trendelenburg described an exstrophy closure emphasizing the importance of pubic reapproximation in front of the reconstructed bladder to achieve continence and prevent dehiscence.<sup>47</sup> However, because of discouraging results, anatomic reconstruction was largely replaced by urinary diversion in the early part of the 20th century, although functional reconstruction was not entirely abandoned. Successful attempts at reconstruction did occur during this time.<sup>48,49</sup> Other primary reconstructive efforts also showed promise.<sup>50,51</sup> However, several large series of patients who underwent single-stage reconstruction in the 1960s and 1970s reported continence rates of only 10% to 30%.<sup>52-57</sup> Renal damage was as high as 90% in these series, generally because of bladder outlet obstruction.<sup>52</sup>

Because of these complications and the low rate of urinary continence with single-stage approaches, reconstructive surgical efforts were subsequently directed toward planned staged bladder reconstruction, an approach pioneered and advocated in the 1970s and further refined to what is now known as

the modern staged repair of exstrophy (MSRE).<sup>48,58-60</sup> Recent advances in single-stage reconstruction for neonatal and older exstrophy patients have been advocated, and the complete primary repair for exstrophy (CPRE) has gained favor.<sup>61</sup>

All approaches aim to reconstruct and achieve anatomic and functional normalcy with minimal surgical morbidity. In the subsequent section, two currently popular surgical techniques, the CPRE and the MSRE, are detailed. Closure of the female with bladder exstrophy is somewhat similar in the CPRE and MSRE methods, with the end result being closure of the bladder, urethra, and abdominal wall. The difference is a more aggressive mobilization of the vagina and urethral plate into the pelvic diaphragm in the CPRE technique. In contrast, closure of the male with bladder exstrophy is quite different in the CPRE and MSRE. The CPRE closes and repositions the bladder and entire urethra at one stage. In contrast, the MSRE closes and repositions the bladder and posterior urethra at the first stage with the remainder of the urethra closed at a later date.

### PREOPERATIVE CARE

After delivery, to reduce trauma to the bladder plate, the umbilical cord should be ligated with silk suture rather than a plastic or metal clamp. A hydrated gel dressing may be used to protect the exposed bladder from superficial trauma. This type of dressing is easy to use, keeps the bladder plate from becoming desiccated, and stays in place to allow handling of the infant with minimal risk of trauma to the bladder. A plastic wrap is an acceptable alternative. Dressings should be replaced daily and the bladder should be irrigated with normal saline with each diaper change. A humidified air incubator may also minimize bladder injury.<sup>62</sup>

We routinely use intravenous antibiotics in the preoperative and postoperative period to decrease the risk for infection after reconstruction. We also perform preoperative ultrasonography to assess the kidneys and establish a baseline examination for later ultrasound studies. Preoperative spinal ultrasound examination should be considered if sacral dimpling or other signs of spina bifida occulta are noted on physical examination.

### OPERATIVE CONSIDERATIONS

Ideally, the primary exstrophy closure is performed in the neonatal period. If the bladder template is amenable, early exstrophy closure has several advantages. A prompt closure begins the road toward anatomic normalcy. Early closure also decreases bladder exposure, which can lead to such histologic changes as acute and chronic inflammation, squamous metaplasia, cystitis glandularis and cystitis cystica, and muscular fibrosis, which may adversely impact ultimate capacity and compliance.<sup>63</sup> Electron microscopy has shown that the neonatal exstrophy bladder is "immature" when compared with that of control neonates,<sup>64</sup> having fewer small nerve fibers,<sup>65</sup> less smooth muscle, and a three-fold increase in type III collagen content.<sup>66</sup> Although it is unclear whether these changes are a part of the

primary pathologic process or secondary to the lack of bladder cycling in utero, it is conceivable that prompt closure could also "mature" the bladder by restoring bladder cycling. Similarly, clinical data have verified the importance of immediate postnatal bladder exstrophy closure. Infants undergoing closure before 7 days of age required fewer bladder augmentations to achieve eventual continence.<sup>67</sup>

Bladder template assessment is subjective. Even a small bladder template, if distensible and contractile, can enlarge to a useful size once closed. However, some choose to defer immediate surgery and re-evaluate the bladder at 4 to 6 months of age with the neonate under anesthesia if the bladder template appears too small and stiff on initial assessment.<sup>68</sup> If at this date, the bladder continues to appear inadequate for primary closure, a nonrefluxing colon conduit may be used in combination with abdominal wall closure and epispadias repair. This can be converted later to a continent diversion or anastomosed to the rectosigmoid colon.

We routinely use general anesthesia. However, nitrous oxide should be avoided during primary closure because it may cause bowel distention, which decreases operative exposure during the operation and increases the risk of wound dehiscence. Some advocate the use of nasogastric tube drainage to decrease abdominal distention in the postoperative period, although we do not routinely use it postoperatively.<sup>69</sup> We also routinely place an epidural catheter to reduce the inhaled anesthetic requirement during the operation. Tunneling the catheter may reduce the risk for infection if it is left for prolonged periods after surgery.<sup>70</sup>

For patients older than 3 days, or neonates with a wide pubic diastasis, we perform anterior iliac osteotomies. In fact, we perform osteotomies in most patients unless the pelvis is very pliable. Robust neonates will often require osteotomy to optimize as low tension a closure as possible. Osteotomies assist closure and enhance anterior pelvic floor support, which may improve later urinary continence.<sup>58,71</sup>

Factors that appear to be important in the operative period include<sup>72,73</sup>:

- Use of osteotomies in selected cases and for neonatal closures more than 72 hours after birth to decrease the tension on the repair
- Ureteral stenting and bladder drainage catheters placed intraoperatively for use in the postoperative period to divert urine
- Avoidance of abdominal distention
- Use of intraoperative antibiotics

### Complete Primary Repair for Exstrophy

Complete primary reconstruction of the exstrophied bladder is best done in the neonatal period. Primary reconstruction in the neonatal period is technically easier than in an older child. If one considers that the stimulus for bladder development is dependent on bladder cycling, then early complete closure offers the advantage of "normal" bladder development and the potential for urinary continence. The bony pelvis

remains pliable in the neonatal period so that osteotomies may occasionally be avoided in some cases—usually if closure can be performed within the first 72 hours of life.

Clinical experience with patients with posterior urethral valves suggests that early restoration of nonobstructive emptying and filling of the bladder allows the bladder to regain some or all of its normal physiologic and developmental potential.<sup>74</sup> This implies that the bladder progresses through developmental milestones that occur in the first few months of life and that may be irreversibly lost if missed. Precedence for this form of organ development is found in the brain with the acquisition of language and visual perception. This is also true for skeletal and neuromuscular development. Finally, early primary bladder reconstruction creates a more normal appearance, which may foster improved bonding between the parents and their infant.

With the CPRE (or Mitchell operation),<sup>61</sup> the bladder, bladder neck, and urethra are moved posteriorly within the pelvis. This movement positions the proximal urethra within the pelvic diaphragm in an anatomically more normal position to maximize the effect of the pelvic muscles and support structures in the achievement of urinary continence. Posterior movement of the bladder neck and urethra also facilitates reapproximation of the pubic symphysis, which, in turn, helps prevent anterior migration of the urethra and bladder neck and provides a more anatomically normal muscular pelvic diaphragm.

Total penile disassembly reduces anterior tension on the urethra because it is separated from its attachments to the underlying corporeal bodies. These attachments otherwise pull the urethral plate anteriorly, preventing posterior placement of the proximal urethra and bladder neck in the pelvis. Tension reduction theoretically decreases the risk of bladder dehiscence and also temporarily reduces the dorsal tension on the corporeal bodies that may contribute to dorsal chordee in males. Combining the epispadias repair with primary closure allows for the most important aspect of primary closure—division of the intersymphyseal ligament or band located posterior to the urethra in these patients. Neonatal closure employing this technique optimizes

the chance for early bladder cycling and consequent normal bladder development. It may also obviate the need for a multiple-staged repair of the exstrophied bladder, including further bladder neck reconstruction (BNR), bladder augmentation, and penile reconstructive surgery. This operation or its principles are also useful in some reoperative repairs or delayed repairs for exstrophy.

### CPRE SURGICAL TECHNIQUE: BOYS

After standard preparation of the surgical field, transversely oriented traction sutures are placed into each of the hemiglans of the penis. The lines of dissection are marked (Fig. 59-2). Care is taken in marking these lines to exclude dysplastic tissue at the edges of the exstrophied bladder and bladder neck. This is particularly important at the bladder neck, where dysplastic tissue left in continuity may impair later bladder neck function. Following this, 3.5-Fr umbilical artery catheters are placed into both ureters and sutured in place with 5-0 chromic sutures. Bladder polyps are removed before beginning the dissection because these will act as space-occupying lesions after the bladder is reconstructed. Initial dissection begins superiorly and proceeds inferiorly to separate the bladder from the adjacent skin and fascia because it is usually easiest to identify tissue planes in this location. We use the tungsten fine-tip electrocautery during this dissection to reduce blood loss. The umbilical vessels may be ligated if necessary. We also incise the periumbilical skin circumferentially at this time. The umbilicus will be moved superiorly to a more anatomically normal location and will be used later as the location to exteriorize the suprapubic catheter.

**Penile/Urethral Dissection.** Traction sutures placed into each hemiglans of the penis aid in dissection at this point in the operation. The sutures will rotate to a parallel vertical orientation because the corporeal bodies will naturally rotate medially after they are separated from the urethral wedge (urethral plate plus underlying corpora spongiosa). We begin the penile dissection along the ventral aspect of the penis as a circumcising incision (Fig. 59-3A). This step precedes

**Figure 59-2.** In a male undergoing complete primary repair for bladder exstrophy, the outlines of the planes of dissection are seen in these drawings. **A**, Ventral view. **B**, Dorsal view. The ureteral stents are marked with arrows.

**Figure 59-3.** These two diagrams show early portions of the ventral subcoronal and corporeal dissection. **A**, Initiation of the subcoronal dissection is seen. This is typically the easiest plane to initiate dissection. **B**, Corporeal dissection proximally and dorsally is shown. Initiation of corporeal separation is easiest to establish proximally. Note the ureteral catheters (arrows), which have been introduced into the ureteral orifices.

dissection of the urethral wedge from the corporeal bodies because it is easier to identify the plane of dissection ventrally above Buck's fascia. Buck's fascia is deficient or absent around the corpora spongiosa. As the dissection progresses medially to separate the urethra from the corpora cavernosa, the plane shifts subtly from above Buck's fascia to just above the tunica albuginea. It is important to recognize this shift. Failure to adjust the plane of dissection will carry the dissection into the corpora spongiosa, which will result in excessive, difficult-to-control bleeding during the deep ventral dissection of the urethral wedge from the corporeal bodies.

Applying methylene blue or brilliant green to the urethra can help identify the plane between urothelium and squamous epithelium. We routinely inject surrounding tissues with 0.25% lidocaine and 1:200,000 U/mL epinephrine to improve hemostasis. Shallow incisions are made laterally along the dorsal aspect of the urethra to begin the dissection. Sharp dissection is required to develop the plane between the urethral wedge and the corporeal bodies. Careful dissection will preserve urethral width and length. This is particularly important because the urethra is often too short to reach the glans penis once the bladder has been located into the pelvis.

Careful lateral dissection of the penile shaft skin and dartos fascia from the corporeal bodies will avoid damaging the laterally located neurovascular bundles on the corpora of the epispadias penis. The lateral dissection on the penis should be superficial to Buck's fascia because of this lateral position of the neurovascular bundles.

**Complete Penile Disassembly and Deep Dissection.** Once a plane is established between the penis and the urethral wedge, the penis may be disassembled into three components: (1) the right and (2) left corporeal bodies with their respective hemiglans and (3) the urethral wedge (urothelium with underlying corpora spongiosa).<sup>75</sup> This is done primarily to provide exposure to the intersymphyseal band and to allow adequate proximal dissection. We have found the easiest plane of dissection to completely isolate the cor-

poral bodies to be proximal and ventral. The plane of dissection should be carried out at the level of the tunica albuginea on the corpora (see Fig. 59-3B). After a plane is established between the urethral wedge and the corporeal bodies, this dissection is carried distally to separate the three components from each other (Fig. 59-4A). Complete separation of the corporeal bodies increases exposure to the pelvic diaphragm for deep dissection. The corporeal bodies may be completely separated from each other because they exist on a separate blood supply. It is important to keep the underlying corpora spongiosa with the urethra. The blood supply to the urethra is based on this corporeal tissue, which should appear wedge-shaped after its dissection from the adjacent corpora cavernosa. The urethral/corpora spongiosa component will later be tubularized and placed ventral to the corporeal bodies. Paraexstrophy skin flaps should not be used with this technique because this maneuver will place the blood supply to the distal urethra at risk. Because the bladder and urethra are moved posteriorly in the pelvis as a unit (with a common proximal blood supply), division of the urethral wedge is counterintuitive to the intent of the repair. In some cases, a male patient will be left with a hypospadias that will require later surgical reconstruction. The urethra and corporeal bodies do not always have to be separated. Occasionally the urethra is long enough and the bladder mobile enough to preserve the connection between them while still effectively carrying out the deep pelvic dissection that is integral to this repair.

After separating the components distally, the urethral dissection is carried proximally to the bladder neck. Exposure to the pelvic diaphragm is optimized by complete separation of the urethra and corporeal bodies (see Fig. 59-4B). This creates the surgical exposure to perform the deep incision of the intersymphyseal band required to move the bladder and urethra posteriorly (Fig. 59-5). When dissecting the urethral wedge from the corporeal bodies medially, the dissection plane is on the tunica albuginea of the corpora cavernosa. This medial dissection should be carried down through the intersymphyseal band (the condensation of anterior pelvic fascia and ligaments).

**Figure 59-4.** A, Separation of corporeal bodies and urethra. B, Deep pelvic dissection. Note the division of the intersymphyseal band (*inset*) is critical to allowing placement of the bladder in the pelvis. Also note the tubularization of the neourethra over the urethral catheter (*solid arrow*) and the suprapubic tube in the still-open bladder (*dotted arrow*).

Deep incision of the intersymphyseal band posterior and lateral to each side of the urethral wedge is absolutely necessary to allow the bladder and bladder neck to achieve a posterior position in the pelvis. This dissection should be carried until the pelvic floor musculature becomes visible. Failure to adequately dissect the bladder and urethral wedge from these surrounding structures will prevent posterior movement of the bladder in the pelvis and create anterior tension along the urethral plate (see Fig. 59-5).

**Primary Closure.** Once the intersymphyseal band is adequately incised and the bladder and urethral wedge are adequately dissected from the surrounding tissues, bladder closure and urethral tubularization can be initiated. This portion of the repair is straightforward and anatomic (Fig. 59-6A). To provide urinary drainage,

a suprapubic tube is used. The bladder may be closed using a three-layer closure with monofilament absorbable suture. The urethra is tubularized using a two-layer running closure with monofilament and braided absorbable suture. Because of the previous deep dissection, we can position the tubularized urethra ventral to the corpora in a tension-free fashion. If the urethra cannot be positioned ventrally without creating tension, it is likely that a deeper incision is required into the intersymphyseal band and pelvic fascia.

The pubic symphysis is reapproximated using two No. 1 polydioxanone-interrupted sutures placed in a figure-of-eight fashion (see Fig. 59-6B). Knots are left anteriorly to prevent suture erosion into the bladder neck. Rectus fascia is reapproximated using an interrupted or running 2-0 polydioxanone suture. We also place interrupted 6-0 polydioxanone sutures along

**Figure 59-5.** Cross-sectional view of repair of bladder exstrophy in a male.

**Figure 59-6.** Once the intersymphyseal band is adequately incised and the bladder and urethral wedge are dissected from the surrounding tissues, bladder repair and urethral tubularization can be performed. **A,** The bladder is being closed in three layers using monofilament absorbable suture (*solid arrow*). The urethra has been tubularized using a two-layer running closure with monofilament and braided absorbable suture (*dotted arrow*). **B,** This schematic depicts closure of the pubic symphysis with two No. 1 polydioxanone interrupted sutures placed in a figure-of-eight fashion. The knots are placed anteriorly to prevent suture erosion into the neck of the bladder. The urethra (*dotted arrow*) has been placed ventral to the corpora.

the dorsal aspect of the corporeal bodies to reapproximate them. Penile skin coverage is provided using either a primary dorsal closure or reversed Byars flaps if needed. Skin covering the abdominal wall is reapproximated using a two-layer closure of absorbable monofilament suture.

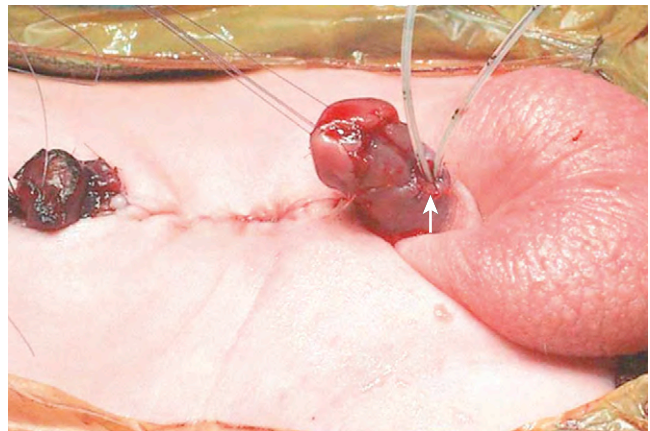

The corporeal bodies will rotate medially with closure. This rotation will assist in correcting the dorsal deflection and can be readily appreciated by observing the new vertical lie of the previously horizontally placed glans traction sutures. Occasionally, significant discrepancies in the dorsal and ventral lengths of the corpora will require dermal graft insertion to correct chordee.

If there is adequate urethral length, the urethra may be brought up to each hemiglans ventrally to create an orthotopic meatus. The glans is reconfigured using interrupted mattress sutures of polydioxanone suture followed by horizontal mattress sutures of 7-0 monofilament suture to reapproximate the glans epithelium. The neourethra is matured with 7-0 braided polyglactin suture similar to our standard hypospadias repair. When needed, glans tissue reduction may also be performed to create a conical-appearing glans and to eliminate the furrow between the glans halves. Tacking sutures are placed ventrally and dorsally to prevent penile shaft skin from riding over the corporeal bodies and “burying” the penis.

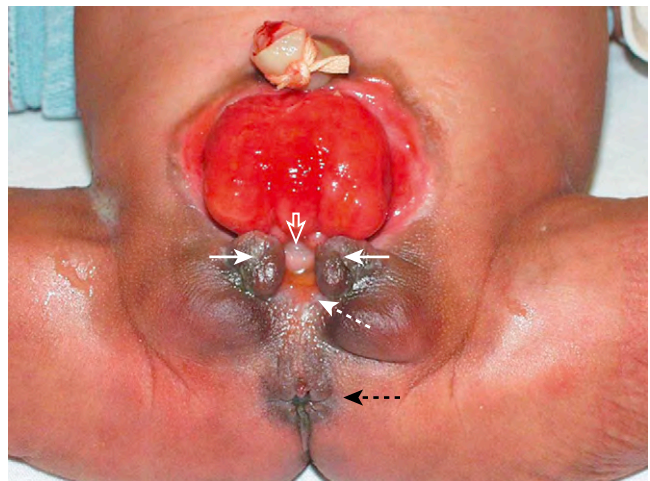

The urethra may lack enough length to reach the glans in about half the cases. In this situation, it is matured along the ventral aspect of the penis to create a hypospadias (*Fig. 59-7*). This can be corrected at a later date as a second-stage procedure. Redundant shaft skin may be left ventrally in these patients to assist in later penile reconstructive procedures.

#### THE PRIMARY REPAIR TECHNIQUE: GIRLS

The principles of this single-stage technique are similar in boys and girls (*Fig. 59-8*). After preoperative antibiotics are given, the patient is prepared and draped in a sterile field. We mark the planned lines of incision with the bladder neck, urethra, and vagina

**Figure 59-7.** If the urethra does not have adequate length to reach the glans (which occurs in about half of the cases), it is matured along the ventral aspect of the penis to create a hypospadias (*arrow*), as seen in this operative photograph. The hypospadias will be corrected at a later date.

**Figure 59-8.** Bladder exstrophy in a female infant. The epispatial urethra is marked with an *open white arrow*. The bifid clitoris is marked with *solid white arrows*, and the vagina is marked with a *dotted white arrow*. The anus is noted with a *dotted black arrow*.

**Figure 59-9.** In a female infant, the bladder neck, urethra, and vagina are mobilized as a unit. **A**, The lines of incision are seen. **B**, The dissection is carried down dividing the intersymphyseal band (arrows). Note the ureteral catheters in both drawings.

mobilized as a unit (Fig. 59-9). Again, we perform this dissection with the tungsten-tip electrocautery to minimize tissue damage while achieving hemostasis. The appropriate plane of dissection is found anteriorly along the medial aspect of the glans clitoris and proceeds posteriorly along the lateral aspect of the vaginal vault (Fig. 59-10A). The vagina is mobilized with the urethra and bladder neck. Dissection along the vaginal wall extends quite laterally. Placement of a hemostat in the vaginal vault will help with retraction to identify

the plane of dissection. The urethra and bladder neck should not be dissected from the anterior vaginal wall because this will compromise the blood supply to the urethra. During the posterior and lateral dissection, the intersymphyseal band will be encountered and should be deeply incised to allow the urethra and bladder neck to move posteriorly. The posterior limit of the dissection is reached when the pelvic floor musculature is exposed and the bladder, bladder neck, and urethra can move into the pelvis without tension.

**Figure 59-10.** **A**, The appropriate plane of dissection is found anteriorly along the medial aspect of the glans clitoris and proceeds posteriorly along the lateral aspect of the vaginal vault. The vagina is mobilized with the urethra and bladder neck (solid arrows). **B**, The bladder and urethra are closed in multiple layers, and the suprapubic tube (arrow) is brought out superiorly. Note the ureteral catheters (dotted arrows) in both drawings.

**Figure 59-11.** **A**, Pelvic positioning of the bladder and vagina and closure of the pubic symphysis with figure-of-eight No. 1 polydioxanone sutures. **B**, Repair of the vaginal introitus (solid arrow) is depicted. The labia majora are advanced posteriorly to the perineum at this time (dotted arrow).

After adequate dissection, the vagina, urethra, and bladder neck are moved posteriorly using a YV-plasty if the vagina is anteriorly located. The urethra is then tubularized using a two-layer closure of absorbable suture (see Fig. 59-10B). Before the urethral closure, we routinely place a suprapubic tube to provide postoperative urine drainage. The pubis symphysis is reapproximated using two figure-of-eight No. 1 polydioxanone sutures (Fig. 59-11A). Osteotomies may be necessary when a wide pubic diastasis prevents a low-tension reapproximation of the pubic symphysis or if the patient is older than 48 to 72 hours old. We use anterior iliac osteotomies in these situations. The rectus fascia can then be closed in the midline. We mature the neourethra with 5-0 polydioxanone sutures and reapproximate the bifid clitoris by denuding them medially so that they fuse together after suturing with 7-0 polydioxanone suture. The labia majora should be advanced posteriorly to the perineum at this time as well (see Fig. 59-11B). A Z-plasty aids in skin closure. A simplified mons plasty technique provides a satisfactory aesthetic result to the introital area and can be applied at the time of the primary repair.<sup>76</sup>

### Modern Staged Repair of Exstrophy

A staged approach for bladder exstrophy repair was developed in response to high reported rates of renal damage seen in single-stage approaches in the 1970s. The sequence for staged reconstruction initially consisted of bladder and posterior urethral closure at birth, BNR at 2 to 3 years of life, and epispadias repair later.<sup>77</sup> However, this order shifted when bladder capacity was noted to increase with the added resistance from early epispadias repair.<sup>78</sup> Currently, MSRE, as described by the Johns Hopkins group, consists of bladder and posterior urethral closure at birth or soon thereafter (stage 1), epispadias repair at 6 to 12 months of life (stage 2), and BNR when the bladder capacity is adequate and the child is showing interest in toilet training (usually

at 4 to 5 years of life) (stage 3).<sup>79</sup> Occasionally, epispadias repair and BNR ± ureteral reimplantation are combined.<sup>80,81</sup>

### MSRE STAGE 1: INITIAL EARLY BLADDER EXSTROPHY CLOSURE

In this first stage, the surgical objectives include (1) closure and repositioning of the bladder and urethra (posterior urethra in males and entire urethra in females) inside the pelvic ring and (2) approximation of the pelvic ring with closure of the abdominal wall. In male patients, at the end of stage 1, this closure technique ideally produces a result that mimics complete epispadias with incontinence and balanced posterior outlet resistance, which stimulates bladder growth while preserving renal function.

**Male MSRE Bladder and Posterior Urethral Closure Technique.** In stage 1 of the MSRE in the male child, ureteral catheters are inserted and secured. A traction suture is placed in the glans penis. The posterior urethra is developed by incising a 2-cm wide strip of mucosa from the distal trigone to below the distal verumontanum. Initial dissection begins at the umbilicus and is continued circumferentially, incising around the bladder plate. The two umbilical arteries are ligated and divided. The underlying detrusor muscle is mobilized from the rectus sheath to expose the peritoneum. The peritoneum is dissected from the dome of the bladder to allow bladder mobilization. Extraperitoneal dissection lateral to the bladder exposes the retroperitoneal space and caudally leads the dissection in the correct plane at the level of the bladder neck. At this level, the rectus fascia meets the pubis and the urogenital diaphragm fibers meet the posterior urethra/bladder neck. The urogenital diaphragm fibers and the intersymphyseal band must be completely taken down from the pubic subperiosteum bilaterally to the pelvic floor. Otherwise, the posterior urethra and bladder will not be recessed within the deep pelvis.

At this point, the posterior urethra is assessed. If the child has severe chordee and a short urethra that inhibits attempts at penile lengthening, an incision in the urethral plate may be necessary but only after extensive mobilization of the bladder and prostatic plate from the rectus fascia, the pubic bones, and the inferior ramus of the pubis. After aggressive division of the urogenital diaphragm fibers from the posterior urethra/bladder neck area, the prostatic urethra can be displaced posteriorly into the pelvis. Lack of urethral plate length can be managed by dividing the prostatic plate distal to the verumontanum in a "V"-shaped fashion. After corporeal mobilization and midline reapproximation, the penile urethral plate is fashioned from a lateral rotational flap generated after a single lateral incision in the paraexstrophy skin. Paraexstrophy skin flaps should be used with great caution because of the high complication rate associated with their use.<sup>53,82,83</sup>

The corporeal bodies are not sewn together at this time because this will be performed after the urethra has been transposed beneath the corpora at the time of epispadias closure. Adequacy of dissection can be assessed by compressing a urethral sound on the posterior urethra while manually approximating the pelvis.

After a silicone Malecot suprapubic tube has been placed, the umbilicus is excised and the bladder is closed in the midline in multiple layers with a running 3-0 polydioxanone suture. The posterior urethra is also closed onto the base of the penis, sizing it to accept a 12- to 14-Fr sound. It is important to perform a horizontal mattress closure of the pubic bones with long-lasting suture, planning for the knot to be placed on the anterior surface of the pubis. This technique prevents the suture or knot from eroding into the urethra or bladder neck. Once the suture is placed but not tied, three surgical personnel are used to reapproximate the pubis symphysis. One individual applies pressure over each greater trochanter to push the pubic rami to the midline. A second individual depresses the posterior urethra and bladder neck. The third individual ties the suture. If the rectus fascia is strong, a second suture is placed just above the symphysis. The abdominal wall, subcutaneous tissues, and skin are then closed in multiple layers with neoumbilical construction at or above the level of the iliac crests.

**Female MSRE Bladder and Posterior Urethral Closure Technique.** In stage 1 of the MSRE of the female child, the surgical technique of bladder, pelvic ring and abdominal wall closure are identical to that described for the male. However, the closure in the female differs from the male closure in that the female urethra is completely reconstructed at stage 1.<sup>1,84</sup> The urethral plate mucosal incision is 2 cm wide, traversing from the distal trigone to the vaginal orifice in the female. Paraexstrophy skin flaps are unnecessary in female exstrophy closure.<sup>85</sup> The medial aspect of each hemiclitoris is de-epithelialized to permit approximation of the two glans clitori and reconstruction of the mons. The bladder and female urethra are closed in a two-layer polyglactin closure, and the pubic bones,

abdominal wall, subcutaneous tissue, and skin are closed as outlined in the male. The mons plasty and genitoplasty are then performed.

**Postoperative Care of Stage 1 MSRE.** Adequate urethral caliber and minimal postvoid residuals are assessed before suprapubic tube removal at 4 weeks. The status of the upper urinary tracts is assessed before discharge and is followed by ultrasonography at 3 months and every 6 months to 1 year. Antibiotic prophylaxis for vesicoureteral reflux (VUR) is also used. Increasing hydronephrosis, worsening VUR, retained urine in the bladder, and recurrent urinary infections should prompt further evaluation for suture erosion or outlet obstruction. Between the ages of 1 to 3 years, yearly cystograms under anesthesia are performed to assess the degree of reflux and, more importantly, to assess the growth of the bladder (ideally, 60 to 85 mL by this age).

## MSRE STAGE 2: EPISPADIAS REPAIR

Epispadias repair is now typically performed at 6 to 12 months of age via the modified Cantwell-Ransley technique. The goals of epispadias repair include a straight penis and urethra, easy urethral catheterization, normal erectile function, and a cosmetically satisfactory phallus. These goals allow the patient to stand while voiding and to have intromission during intercourse.

**Preoperative Considerations.** Before performing the epispadias repair, some surgeons use topical or intramuscular testosterone to increase the size of the phallus and the phallic skin. Intramuscular testosterone enanthate in oil (2 mg/kg) can be administered at 5 and 2 weeks before epispadias closure. Penile lengthening can usually be achieved at this time by division of all remnants of the suspensory ligament and scar tissue as well as further release of the crura from the inferior pubic rami. In some situations, further urethral lengthening may require free skin grafts, buccal mucosal grafts, ureteral grafts, or pedicle skin flaps. These same maneuvers can be used to repair the scarred or stenosed posterior urethra.

### *The Modified Cantwell-Ransley Technique*

Cantwell first described mobilization of the urethra and moving it ventrally for epispadias repair. The technique has subsequently been modified.<sup>83,86</sup> A stay suture is first placed into the glans penis. A reverse meatal advancement and glanduloplasty (MAGPI), or IPGAM, procedure at the distal urethral plate allows advancement of the urethral meatus onto the glans. Incisions are then made on the lateral edges of the urethral plate and around the epispadias meatus. This plate is dissected from the corporeal bodies up to the level of the glans distally and to the prostatic urethra proximally. Glans wings should be developed distally as well. The corporeal bodies are then separated from each other to allow medial rotation. The urethra is then tubularized over a 6- or 8-Fr urethral catheter, using running 6-0 absorbable suture. The corporeal

bodies are rotated over the urethra and reapproximated using 5-0 absorbable suture in an interrupted fashion. Carnosotomies may be performed before reapproximating the corporeal bodies to help correct persistent chordee. These are performed at the point of maximal angulation. The neurovascular bundles may require mobilization to avoid injuring them if carnosotomies are performed. The glans wings are then closed over the urethra using interrupted 5-0 absorbable suture. Penile shaft skin can be trimmed and tailored to cover the penis using interrupted 5-0 or 6-0 absorbable sutures. Z-plasties at the level of the pubis may decrease the chance of a dorsal retractile scar at the base of the penis. Postoperative care includes bladder antispasmodics, broad-spectrum antibiotics, and removal of the urethral catheter at 2 weeks.

In the event of a significantly delayed primary closure or an initial bladder closure failure, a simultaneous closure of the exstrophy bladder and the epispadias can be performed.

### **Bladder Neck Reconstruction**

#### **PREOPERATIVE ASSESSMENT**

In incontinent children after CPRE or MSRE, a continence procedure is indicated when (1) the urethra is stricture free and capable of catheterization, if necessary; (2) under anesthesia, the bladder capacity has achieved a minimum volume of 60 to 85 mL; and (3) the child is mature enough to participate in the postoperative voiding program.<sup>87</sup> This is typically around age 4 to 5 years. Cystoscopy and gravity cystography provide information regarding bladder capacity and the status of any previous repairs. Advocates of staged reconstruction emphasize the importance of achieving adequate bladder capacity before performing BNR. A bladder capacity less than 60 mL under anesthesia or during urodynamic evaluation decreases the success of BNR. BNR requires adequate bladder capacity because some volume is lost during the procedure. Factors that increase the potential for the bladder to achieve adequate capacity before BNR include:

- Avoidance of urinary tract infections
- Complete bladder emptying with institution of CIC if bladder emptying is incomplete
- Epispadias repair
- Avoidance of bladder prolapse

Preoperative urodynamic evaluation should be considered because it allows detection of detrusor hyperactivity or atony as well as assessment of functional bladder capacity and leak-point pressures. However, the urethra of these patients may be difficult to catheterize. In these situations, a urodynamic catheter can be placed suprapubically at the time of the cystourethroscopic examination to be used later that day for the urodynamic evaluation.

Ureteroneocystostomy may be required at the time of BNR to correct VUR and to move the ureters from the lower bladder where BNR will occur. The Cohen technique is often employed. However, others have described a cephalotrigonal technique that is particularly applicable to exstrophy patients because of the angle

of ureteral entry into the bladder.<sup>88</sup> The Marshall-Marchetti-Krantz (MMK) bladder neck suspension or a bladder neck wrap using rectus muscle or fascia or gracilis may be combined with BNR as well. Osteotomies may also be necessary to stabilize the intersymphyseal bar and improve continence at the time of BNR.

The following section describes the most commonly employed BNR techniques, including the modified Young-Dees-Leadbetter and the Mitchell repairs.

#### **MSRE STAGE 3: MODIFIED YOUNG-DEES-LEADBETTER BNR**

The modified Young-Dees-Leadbetter (YDL) BNR technique<sup>89</sup> and the transtrigonal/cephalotrigonal bilateral ureteral reimplantation<sup>88</sup> are the surgical techniques employed in MSRE stage 3. The combined thoughts of several surgeons spanning an 82-year period have led to the modern YDL BNR.<sup>87</sup> To perform a modified YDL procedure,<sup>89</sup> the bladder neck is extensively dissected and a vertical cystotomy is made. Occasionally, a portion of the intersymphyseal band must be divided completely for good visualization. After transtrigonal/cephalotrigonal bilateral ureteral reimplantation, a strip of bladder mucosa 1.5 to 1.8 cm wide and 3.0 to 4.0 cm long is generated and the lateral bladder triangles are demucosalized. Use of an epinephrine-soaked sponge during this dissection aids in hemostasis and visualization. The bladder neck may be funneled further with small vertical incisions along the cut edge of the lateral bladder walls. The neourethra is tubularized over an 8-Fr stent using interrupted or running polyglycolic acid sutures (4-0 or 5-0). The two triangular regions of demucosalized detrusor muscle are then closed over the mucosal tube in a two-layer "vest over pants" double-breasted technique using 3-0 polyglycolic acid sutures. This reinforces the neobladder neck, decreases the risk of fistula, and augments the outlet resistance.<sup>90</sup> The sutures in the third layer are not cut because they are used in the MMK bladder neck suspension.<sup>87</sup>

Some surgeons recommend avoidance of a urethral catheter in the postoperative period because of concerns that it may adversely affect later urinary continence. Urinary drainage is achieved by the use of bilateral ureteral catheters and suprapubic tube drainage. Ureteral stents are removed at 2 to 3 weeks, and voiding trials are begun in the third week. The urethra is calibrated with a soft 8-Fr catheter, and voiding trials are begun with the suprapubic tube in place after the urine has been sterilized. If no urine is passed, cystoscopy and urethral stenting may be required for a short period of time. A bladder readjustment period may span several months before day and, subsequently night, continence is achieved.

#### **BNR: THE MITCHELL REPAIR**

This repair employs a modification of the Leadbetter procedure technique described previously.<sup>89</sup> In this modification, a full-thickness transverse incision is made in the anterior urethra and is extended cephalad. After cross-trigonal ureteral reimplantation, the urethral strip is tubularized in two layers using polyglycolate or

monocryl suture (4-0 or 5-0) over an 8- or 10-Fr urethral catheter depending on the size of the patient. The bladder may be closed in continuity with the urethral closure. This procedure effectively narrows and lengthens the urethra. It also moves fibrotic tissue at the level of the original bladder neck away from the new bladder neck. After the closure, dissection around the new bladder neck may be performed if a combined bladder neck wrap or sling will also be created.

Postoperatively, urine is drained through a combination of ureteral stents, a suprapubic tube, and a 6-Fr urethral catheter. The urethral catheter is removed 7 to 10 days after the operation. Ureteral stents are removed at 10 to 14 days after surgery. The suprapubic tube remains for 3 weeks. Voiding trials are performed with measurement of postvoid residual urine volumes to assess for urinary retention before removing the suprapubic tube. As with any BNR procedure (without augmentation), several months of adjustment will be required before the patient develops adequate bladder awareness, capacity, and control to achieve prolonged intervals of urinary continence.

Occasionally, trigonal tubularization must be combined with bladder augmentation because of small bladder capacity as most BNRs decrease bladder capacity because a portion of the bladder is used to create the continence mechanism.<sup>91</sup> Stomach offers the best potential to preserve spontaneous volitional voiding in this group but places these children at risk of hematuria-dysuria syndrome, which can be especially troubling in the presence of persistent urinary incontinence and normal sensory innervation.<sup>92</sup> Other intestinal segments may also be used depending on surgeon preference. If augmentation is required, appendicovesicostomy or another form of the Mitrofanoff operation can be simultaneously performed if the urethra is difficult to negotiate because of the likelihood that the patient will require intermittent catheterization to empty the bladder after BNR.

## Results

### *Exstrophy Results*

Complications can occur with any form of exstrophy closure. The most commonly reported complication is urethrocutaneous fistula formation (at the penopubic angle dorsally) in males. These fistulas will often close spontaneously. They may initially be managed conservatively by providing urinary diversion via catheter drainage. If the fistula does not close after conservative management, the bladder and urethra should be examined cystoscopically for the possibility of obstruction at the bladder neck or urethra.

If a child develops chronic bladder and kidney infections after exstrophy closure, he or she should be evaluated for possible outlet obstruction. We routinely maintain our patients on suppressive antibiotic therapy because of the high incidence of VUR in this population.

In the long term, patients are also concerned with fertility. For men, the vas deferens and ejaculatory ducts are normal at birth. However, fertility may be

compromised as a consequence of surgery they may have had in the region of the bladder neck and posterior urethra. Most men can experience orgasm but some cannot effectively ejaculate. Intracytoplasmic sperm injection can be useful in this setting. Women with bladder exstrophy can become pregnant but are prone to develop uterine prolapse, especially after pregnancy. This is thought to be due to further stress and damage to the already abnormal pelvic musculature.

### *Epispadias Results*

Outcomes reveal urethrocutaneous fistula rates ranging from 5.5% to 42%. Complications seem more common in those patients who undergo correction as part of an exstrophy closure versus isolated epispadias.<sup>93</sup> Other complications include atrophy of the corpora cavernosa and urethra. These complications can occur if the blood supply to the corporeal bodies or urethral wedge is damaged during dissection or closure.<sup>94</sup> Similar complications have been described after the initial stage of a staged reconstruction as well as after the use of the complete penile disassembly technique.<sup>95</sup> In experienced hands, such complications are unusual and underscore the importance of involving surgeons experienced in the surgical management of these patients.

### *BNR Results*

After BNR, surgical success is defined as a dry interval of more than 2 to 3 hours and spontaneous voiding without catheterization. YDL BNR and its variants have yielded surgical success with urinary continence rates of 30% to 80% or more for patients with bladder exstrophy.<sup>89,96-98</sup> Many factors influence the outcome of surgery. For instance, an initial failed bladder closure or prior failed BNR reduces the chance to achieve subsequent urinary continence.<sup>99</sup> A preoperative bladder capacity of more than 85 mL portends a greater continence rate after YDL BNR.<sup>100</sup> Use of osteotomies to provide a tension-free anastomosis and patient immobilization through the use of spica casting or Bryant's traction in the postoperative period increases the success of bladder closure and subsequent continence. Delayed bladder closure increases the likelihood for the eventual need for bladder augmentation due to inadequate bladder capacity that, in turn, reduces the chance for volitional voiding.

Long-term studies have reported that 8 of 13 patients with initially successful bladder closures and BNR required further surgery in their second decade of life because of poorly compliant, low-capacity bladders that caused urinary incontinence.<sup>101</sup> Surgeons who care for these patients must be committed to the long-term follow-up of this complex group of patients because late complications may develop.

### *Adjunctive Aspects of the Repair*

Inguinal hernias are commonly associated with exstrophy in both male and female patients.<sup>102,103</sup> The majority of these are indirect hernias. They arise as a

consequence of enlarged internal and external inguinal rings combined with compromised fascial support and lack of obliquity of the inguinal canal.<sup>104</sup> In a review of patients from the Hospital for Sick Children in Toronto, 56% of classic male exstrophy patients and 15% of classic female exstrophy patients developed inguinal hernias over a 10-year period.<sup>62</sup> The authors recommended that these hernias should be repaired at the time of primary bladder closure to prevent incarceration that could affect up to 50% of these patients in the first 2 years of life. Reinforcement of the transversalis and internal oblique fascia during hernia repair decreases the later development of direct inguinal hernias. Umbilical hernias, as a contiguous defect with the bladder plate, also uniformly occur with exstrophy and are corrected at the time of the primary repair.

Because of the high incidence of VUR, we use low-dose suppressive antibiotic therapy for all neonates after bladder closure. This is continued until either the VUR is corrected or resolves spontaneously. Some surgeons perform neoureterocystotomies at the time of initial closure. The results of this approach have not been reported.

## Osteotomies

Approximation of the open pelvic ring eases abdominal wall closure and diminishes the rate of bladder and abdominal wall dehiscence.<sup>72,105</sup> This allows the construction of an intrapelvic urethra and reapproximates the pelvic floor musculature, likely contributing to long-term continence.<sup>58,105</sup> Therefore, pelvic ring reapproximation is useful at initial bladder closure and at later stages of reconstruction if satisfactory reapproximation was not achieved initially. However, beyond this age or at this time, if the pelvis is not sufficiently malleable, osteotomies are performed at the time of closure.

Osteotomies offer several advantages to the anatomic approach to exstrophy closure, including (1) optimizing pubic symphysis apposition; (2) diminishing tension on the fascial closure; (3) optimizing anatomic placement of the bladder, bladder neck, and urethra in the pelvis; (4) improving the reapproximation of the corporal and clitoral bodies; and (5) possibly decreasing the chance for later uterine prolapse because the anterior closure brings the pelvic diaphragm into a more normal anatomic position that offers better support.

The need for osteotomy is typically assessed under general anesthesia. Indications for osteotomy include patients more than 72 hours old, neonates with a wide pubic diastasis, neonates with cloacal exstrophy, and patients who have had a previously failed closure. Osteotomies are usually performed at the same setting as bladder closure to help secure the closure.

Several operative approaches can be used for osteotomies. Posterior iliac osteotomies are performed with the patient in the prone position, after which the patient is then repositioned for the bladder closure. However, complications involving increased blood loss and occasional malunion of the ilium have led to using other approaches. Anterior iliac osteotomies offer the advantage of a single position (supine) and sterile field preparation. Compared with posterior iliac osteotomies,

an anterior approach also has been shown to result in less blood loss and better apposition and mobility of the pubic rami. Anterior approaches include an anterior diagonal approach or a combination of bilateral combined anterior innominate and vertical iliac osteotomies, which have had excellent initial and long-term results compared with anterior iliac osteotomies alone in some series.<sup>71,106</sup> Both osteotomies can be performed through the same anterior skin incision on each side with minimal blood loss and 4% complication rate.<sup>107,108</sup> The use of a diagonal mid-iliac osteotomy performed through the same incision as the exstrophy closure has also been described.<sup>109</sup> Division of the superior pubic ramus has also been performed. However, it is not as effective as the other methods described but can be used in the neonatal period.<sup>110,111</sup>

To avoid osteotomies, a technique has been developed that secures the pubic symphyseal closure with deeply placed polyglactin sutures through the bone followed by placement of a miniature metal plate that may be removed later. Initial results are promising.<sup>112</sup> Use of radical soft tissue mobilization for exstrophy (the Kelly technique) also may allow the surgeon to avoid the more routine use of osteotomies seen with the CPRE and MSRE techniques for exstrophy closure.

The patient must be immobilized to decrease lateral stresses on the closure after the primary reconstructive procedure. Choice of immobilization techniques remains controversial with a variety of options. Current approaches include (1) Bryant's traction, (2) use of an external fixator, (3) spica casting, and (4) mummy or mermaid wrapping. Likely, the most important variable with these techniques is familiarity of the user because they all have learning curves associated with them that increase the complication rates of those not familiar with their use. We prefer to use a spica cast for 3 weeks to prevent external hip rotation and optimize pubic apposition (Fig. 59-12). Modified Buck's traction has been used by many groups with success. A posterior lightweight splint can be used in neonates when the child is out of traction to maintain hip adduction. We have stopped using Buck's traction because spica casts are easier for the families to manage at home. External fixation devices have also been used successfully.<sup>106</sup> Fixator pins for these devices should be cleaned several times a day to reduce the chance for infection. Internal fixation may be necessary in older patients. Femoral nerve palsy is a possible complication with fixation that must be monitored and can be reduced with gradual tightening of the fixator. The osteotomies are secured by intrafragmentary pins, external fixation (4 weeks for neonates; 6 to 8 weeks for older patients), and light Buck's traction for 2 to 4 weeks.

## CLOACAL EXSTROPHY

Although cloacal exstrophy has been recognized for several hundred years, in 1965 Spencer reported the first successful repair and survival of an infant with this anomaly.<sup>113</sup> Mortality rates for infants with cloacal exstrophy remained high for years after this initial

**Figure 59-12.** In order to immobilize the patient to decrease lateral stresses on the closure after the primary reconstructive procedure, a number of immobilization techniques are possible. This photograph shows a spica cast that was applied to prevent external hip rotation and optimize pubic apposition in the early postoperative period. Note the suprapubic bladder catheter (arrow).

success because affected infants routinely died of malnutrition and sepsis. With continuing improvement in total parenteral nutrition and neonatal management, mortality rates currently are less than 10%.<sup>114</sup> Issues of quality of life are now paramount in this patient group.

The bladder plate associated with cloacal exstrophy is divided in half by the hindgut plate, which represents the deformation in the development of the colon that occurs with cloacal exstrophy. Ileum enters and intussuscepts into the middle of the hindgut, creating the “trunk of an elephant’s face” appearance with appendiceal appendages located laterally to give the impression of “tusks on the face of the elephant” (Fig. 59-13).<sup>115</sup>

With cloacal exstrophy, the bladder neck (internal urethral sphincter) and external urethral sphincter are not fully developed owing to the failed development of the bladder and urethral remnant located on the anterior and dorsal surfaces of the body wall and penis, respectively. However, because the innervation to these structures may be intact, anatomic closure

theoretically offers the possibility of achieving urinary continence. The urethral plate is characteristically short as well.

## Associated Anomalies

### *Kidneys and Upper Urinary Tract*

Renal anomalies are much more common with cloacal exstrophy than with bladder exstrophy. They include anomalies of location such as pelvic kidneys or crossed fused ectopia. Horseshoe kidneys, renal agenesis, and ureteropelvic junction obstruction may occur as well.

### *Genitalia*

In cloacal exstrophy, the penis is often separated into two hemiphalluses due to the wide pubic diastasis. This can make subsequent reconstructive efforts technically more challenging if a male phenotype is preserved. Cryptorchidism is the rule with cloacal exstrophy.

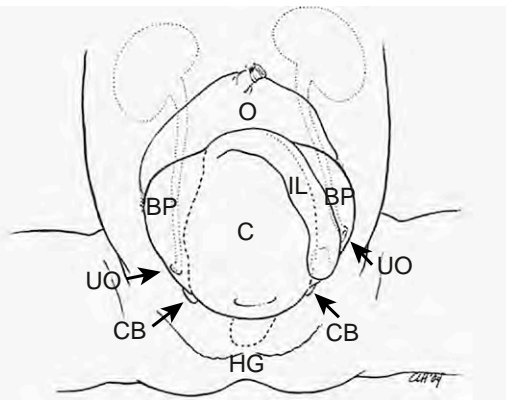

For girls, in addition to the genital pathology described previously with bladder exstrophy, uterus didelphys and other fusion anomalies of the müllerian duct structures are seen in up to two thirds of cloacal exstrophy patients. Vaginal agenesis occurs in a third of these girls as well.

### *Anorectal and Intestinal Abnormalities*

Associated intestinal abnormalities specific to cloacal exstrophy include imperforate anus, foreshortening of the midgut, bowel duplication, malrotation, intestinal atresia, and Meckel’s diverticulum. These are in addition to the exstrophy of the hindgut, ileal intussusception, and exposed appendices that are considered part of the primary pathology of cloacal exstrophy.

### *Skeletal Abnormalities*

In addition to the features seen with bladder exstrophy, patients with cloacal exstrophy can have other skeletal abnormalities. Skeletal anomalies are seen in as many as half of patients with cloacal exstrophy.

**Figure 59-13.** Photograph and schematic drawing of a neonate with cloacal exstrophy. O, omphalocele; IL, ileum; BP, bladder plate; C, colon plate; HG, hindgut; CB, corporeal body; UO, ureteral orifice.

Anomalies include congenital hip dislocation, talipes equinovarus, and a variety of limb deficiencies.<sup>116</sup>

### **Fascial Abnormalities**

The fascial anomalies associated with cloacal exstrophy include those described previously for bladder exstrophy. In addition, an omphalocele is often associated.<sup>117,118</sup> This omphalocele can be closed during the initial bladder closure if it is small. If the omphalocele is large, it may require closure as a primary procedure with the reapproximated bladder halves acting as a silo to decompress the increased intra-abdominal pressure. Alternatively, the omphalocele can be treated with antiseptic paint to promote skin overgrowth. Our preference is to proceed with staged surgical correction of the omphalocele and primary reconstruction of the bladder at a later date. In our opinion, the degree of increased intra-abdominal pressure after omphalocele closure determines whether we can proceed with primary bladder closure at the same time as the omphalocele repair or whether these operations should be staged. Aggressive one-stage closure of a cloacal exstrophy can lead to organ ischemia from the increased intra-abdominal pressure. Rupture of an omphalocele clearly requires immediate attention and would take precedence over other considerations. Fortunately, this occurs rarely.

### **Neurologic Abnormalities**

Neurologic involvement of the lower spinal cord in the cloacal exstrophy population is reported to occur in 50% to 100% of patients.<sup>117,119,120</sup> Most patients have lumbar or sacral cord involvement, but thoracic level myelodysplasia has been reported as well.<sup>117</sup> Management of cloacal exstrophy in these situations must be coordinated with the closure of the neural tube defect.

## **Operative Correction**

### **Perioperative Management**

Cloacal exstrophy patients are best cared for by a team of experienced physicians, including a pediatric urologist, surgeon, orthopedist, gastroenterologist, endocrinologist, and neurosurgeon. Given that many infants are diagnosed prenatally by ultrasonography, this multisystem care can often be coordinated before the infant's birth. Advances in neonatal care, intravenous nutrition, and the surgical management of these children have markedly reduced the mortality and morbidity of this disease. Nonetheless, the management of these children remains challenging.

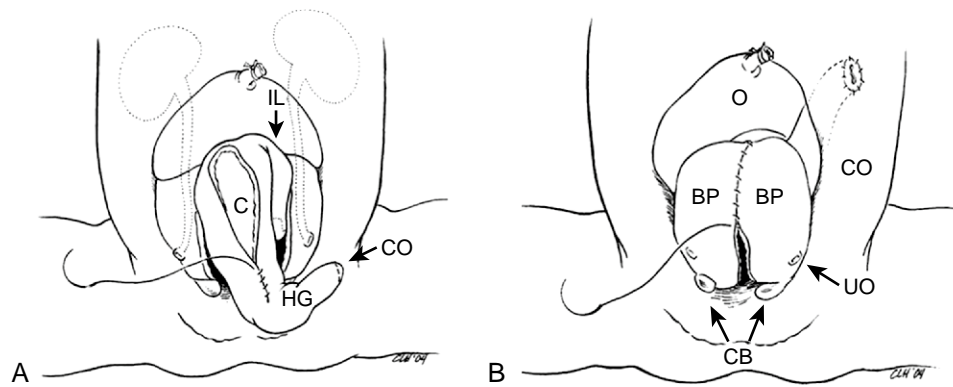

In the neonatal period, the bladder and hindgut plate should be covered (with Saran Wrap or Vigilon [Bard Medical Division, Covington, GA]) to protect these structures. The umbilical cord should be ligated with a silk suture to prevent an umbilical clamp from abrading the bladder or hindgut plate. Antibiotic prophylaxis should be given because of the high incidence of renal abnormalities.

Preoperative studies include ultrasonography, abdominal radiographs, and karyotyping. Ultrasound examination allows the evaluation of the upper urinary tracts, internal genital structures, and spinal cord. Because the genital anomalies associated with cloacal exstrophy may make it difficult to accurately identify the gender of the neonate, karyotyping is indicated to define the chromosomal gender in situations in which the gender is unclear.

### **Considerations for Closure**

Each cloacal exstrophy patient is unique and requires an individualized surgical plan. Because of the broad spectrum of this problem, a flexible treatment strategy is important. In general this would incorporate the following components: (1) closure of the omphalocele with reapproximation of the posterior bladder halves, tubularization of the cecum, and incorporation of the hindgut into the gastrointestinal tract (functionally this creates the anatomy of classic bladder exstrophy) and (2) repair of the exstrophic bladder and genitalia. If the neonate's condition is stable, the initial reconstructive procedures should be performed within the first 48 hours of life, thus taking advantage of the pliable bony pelvis for possible closure of the entire defect. However, spina bifida is present in many children and may need attention, delaying the ventral abdominal wall closure. In addition, the omphalocele, seen in most (88%) infants,<sup>121</sup> may require immediate care to prevent rupture. The size of the omphalocele, the size of the hindgut plate and bladder plates, the extent of the pubic diastasis, and the extent of co-morbidities largely dictate the timing and staging of closure. A large omphalocele containing liver may preclude any attempt at complete closure. If the large omphalocele cannot be closed because of increased abdominal pressure or tension, a Silastic silo or biosynthetic materials can be used to cover the abdominal contents.

In the past an ileostomy was routinely performed, but the metabolic consequences can be significant. Currently, management decisions focus around the use of the exstrophic cecal plate and the terminal blind-ending hindgut. Options for the cecal plate include retaining it in the bladder closure as a bladder augmentation versus separating it and reconstructing it for the fecal stream (Fig. 59-14A). To improve bowel length and water resorption, current recommendations are to tubularize the cecal plate, making the terminal ileum, cecum, and the blind-ending hindgut segment all in continuity for the fecal stream. The hindgut segment can be anastomosed either in an isoperistaltic or anti-peristaltic fashion and exteriorized as a colostomy. In some cases, there are hindgut duplications. No segment of bowel should be discarded unless absolutely unusable, because it might be usable in the future for reconstruction of the bowel, bladder, or vagina. Similarly, appendiceal segments should be preserved for possible use in later reconstruction of the urinary tract. Because of altered innervation to the pelvis, only a few patients with cloacal exstrophy are candidates

**Figure 59-14.** A, Depiction of removal and tubularization of the cecal plate. B, Reapproximation of the bladder plates. IL, ileum; HG, hindgut; CO, colostomy site; C, colon; BP, bladder plate; UO, ureteral orifice; CB, corporeal body; O, omphalocele.

for an anal pull-through procedure. These are infants with an anal fistula and preserved innervation.

### Operative Repair

Ureteral catheters are inserted in the ureteral orifices and secured with 5-0 chromic suture. The omphalocele repair is begun with the initial dissection beginning superiorly. The umbilical vessels are ligated and the bladder plates separated from the adjacent skin as described in the CPRE and MSRE techniques. The medial cecal hindgut plate is separated from the paired bladder plates and is tubularized. After the hindgut has been reconstructed, the bladder halves are reapproximated in the midline (see Fig. 59-14B). If found, inguinal hernias should be repaired. Primary bladder closure may be performed at this time if the intra-abdominal pressure remains low after omphalocele closure. This can be determined clinically by assessing ventilatory effort. A one-stage closure of cloacal exstrophy (closure of the omphalocele, cecal plate tubularization, creation of a colostomy, bladder and urethral closure, reconstruction of the external genitalia, and osteotomies) should be performed *only* under optimal anatomic conditions.

The decision to proceed with one-stage closure versus staged reconstruction spanning a period of months must be weighed carefully. After forced closure, increased abdominal pressure may result in organ ischemia, excessive tension to the midline closure, or compromised lower extremity blood flow. The importance of including surgeons experienced in the care of these patients cannot be overemphasized. Thus, the reconstruction can be staged by converting the cloacal exstrophy into a classic bladder exstrophy. A colostomy is then created with the previously described caveats in mind.

If staging is required, once the infant has recovered sufficiently to tolerate another surgical procedure, the remaining steps of reconstruction of the bladder, bladder neck, and genitalia using the CPRE technique<sup>122</sup> (Fig. 59-15) or MSRE technique are performed as previously described. Deep pelvic diaphragm dissection with division of the intersymphyseal band is crucial for appropriate posterior

positioning of the bladder and urethra. After the bladder and urethra are positioned within the pelvis, reconstruction of the bladder, genitalia, abdomen, and pelvis is anatomic.

Osteotomies are almost always necessary to assist in closure and posterior positioning of the urinary tract, given that the pubic diastasis is usually more severe than in classic bladder exstrophy. Before incision, the need for osteotomies is assessed under anesthesia by watching for ischemia of the lower extremities and external genitalia during pubic reapproximation. The Hopkins group recommends bilateral combined anterior innominate and vertical iliac osteotomies with gradual approximation of the bones over 1 to 2 weeks via the external fixator and interfragmentary pins.<sup>123,124</sup> The Seattle group prefers iliac osteotomies. Other authors prefer to avoid the use of osteotomies because they believe that osteotomies make the abdominal closure more difficult.<sup>125</sup> This has not been our experience. Fewer wound dehiscences and ventral abdominal wall hernias have been noted with the use of osteotomies.<sup>124</sup>

**Figure 59-15.** Diagram showing use of the complete primary repair of exstrophy technique for bladder reconstruction. B, bladder; CC, corpora cavernosa; U, urethra; C, colostomy.

Late procedures may be required on the urinary tract to achieve continence, including BNR, bladder neck closure, bladder augmentation with stomach, ileum, or hindgut, and creation of a continent catheterizable stoma.<sup>117,126-129</sup> Given nearly all of these children will be dependent on CIC to achieve dryness, surgical reconstruction must be individualized to meet the needs of their limitations.

### Genital Reconstruction and Gender of Rearing

Gender assignment for patients with cloacal exstrophy is currently under scrutiny both by the medical profession and lay public. Traditionally, male patients underwent gender conversion in infancy because of concerns that the small, paired male hemiphalluses in these patients were inadequate for reconstruction. This approach was supported by anecdotal data of unsatisfied patients after reconstruction of the male phallus.<sup>117</sup> These observations, in conjunction with the prevailing notion that humans were gender neutral at birth and could undergo sex conversion safely in infancy, have recently come into question.<sup>130</sup> Gender identity now appears to be a much more complex issue than previously thought.

Currently, we reconstruct males with cloacal exstrophy as males whenever technically possible. Many gender-reassigned individuals will later identify themselves in a male gender role in adolescence and adulthood.<sup>130</sup> Technically, however, reconstruction of

external male genitalia in the cloacal exstrophy population can be quite difficult. The wide pubic diastasis and small phallic size add to the technical complexity because these findings make it more difficult to bring the two phallic halves together. In some cases, if one phallic half is diminutive, the small one can be removed and the reconstruction performed using only the larger phallic half.

Female genital reconstruction is complex as well. In genetic females, complete müllerian and vaginal duplication often leads to attempted midline reapproximation. However, if one system appears more substantial, excision of the lesser unit may be prudent. In genetic males raised female, neovaginal reconstruction is typically delayed and may require use of hindgut segment or perineal skin.

### Gastrointestinal Reconstruction

Short gut syndrome is usually present in patients with cloacal exstrophy at birth, even in those with a normal bowel length. The effects of malabsorption and fluid loss from the short bowel length appear to be clinically most significant early in life.<sup>131</sup> Many such children require parenteral nutritional support in early infancy.<sup>132,133</sup> Because of this, we share the belief that the hindgut should be constructed and placed in continuity with the intestine during initial reconstruction. This may improve nutrition and also preserves intestinal tissue that can be used in later reconstruction of the urinary tract or the vagina, if needed.

# HYPOSPADIAS

J. Patrick Murphy, MD

**H**ypospadias is a developmental anomaly characterized by a urethral meatus that opens onto the ventral surface of the penis, proximal to the end of the glans. The meatus may be located anywhere along the shaft of the penis, from the glans to the perineum.

Chordee, which is ventral curvature of the penis, has an inconsistent association with hypospadias. The degree of chordee is ultimately more significant in the surgical treatment of hypospadias than is the initial location of the meatus. A subcoronal hypospadias with little or no chordee is much less complicated to repair than is one with significant chordee and insufficient ventral skin. For this reason, when discussing the degrees of hypospadias, it is more appropriate to use the clinically relevant and common classification system that refers to the meatal location after the chordee has been released (Table 60-1).<sup>1</sup>

Normal phallic development occurs in weeks 7 to 14 of gestation. By 6 weeks of gestation, the genital tubercle is formed anterior to the urogenital sinus. In the next week, two genital folds form caudad to the tubercle and a urethral plate forms between them. Under the influence of testosterone from the fetal testes, which begins to be produced at about 8 weeks of gestation, the inner genital folds fuse medially to form

a tube that communicates with the urogenital sinus and runs distally to end at the base of the glans. The formation of the penile urethra is thus generally completed by the end of the first trimester.<sup>2</sup>

Classically, the glanular urethra is thought to form as an ectodermal ingrowth on the glans. This ingrowth deepens to meet the distal urethra that has formed from the closure of the endodermal genital folds. The capacious junction of these two structures is the fossa navicularis.<sup>3</sup> Recently, this theory has been challenged by the endodermal ingrowth theory. It suggests that the entire urethra forms from the urogenital sinus, which is endoderm. This endoderm differentiates into stratified squamous epithelium.<sup>4</sup> The formation of the glanular urethra is the last step in the formation of the completed urethra. This sequence probably accounts for the predominance of glanular and coronal hypospadias.

Dorsal to the developing urethra, mesenchymal tissue forms the paired corporeal bodies. These are the major erectile tissue components and are invested by the tunica albuginea. Mesenchyme also forms Buck's fascia, the dartos fascia, and corpus spongiosum.

The corpus spongiosum is the supportive erectile tissue that normally surrounds the urethra and communicates with the erectile tissue of the glans. Buck's fascia is the deep layer of fascia that surrounds the corporeal bodies and invests the spongiosum. The dorsal neurovascular bundles are deep to this layer. Superficial to this layer is the dartos fascia, which is the loose subcutaneous layer that contains the superficial veins and lymphatics. These structures form subsequent to completion of the urethra by medial fusion of the outer genital folds, proceeding from the proximal to the distal aspect of the penis. This development accounts for how a fully formed urethra can have a poorly formed spongiosum with thin overlying skin and ventral tethering, despite the meatus being located at the tip of the glans. Finally, the prepuce is formed, originating at the coronal sulcus. It gradually encloses the glans circumferentially.

Arrested development of the urethra may leave the meatus located anywhere along the ventral surface of the penis. Typically, this would lead to foreshortening of the ventral aspect of the penis distal to the meatus and to failure of the prepuce to form circumferentially.

**Table 60-1** Hypospadias Classification According to Meatal Location after Release of Chordee

**Anterior (65%-70% of cases)**

Glanular  
Coronal  
Distal penile shaft

**Middle (10%-15% of cases)**

Middle penile shaft

**Posterior (20% of cases)**

Proximal penile shaft  
Penoscrotal  
Scrotal  
Perineal

However, in the megameatus form of hypospadias, the prepuce may form normally.

## HISTORICAL PERSPECTIVES

The first description of hypospadias and its surgical correction was reported in the 1st and 2nd centuries by the Alexandrian surgeons Heliiodorus and Antyllus. They described the defect of hypospadias and its relation to problems with urination and ineffective coitus. They further described a surgical treatment consisting of amputation of the glans distal to the hypospadiac meatus.<sup>5,6</sup>

Little progress was made in the surgical treatment of hypospadias until the 19th century, when two Americans, Mettauer and Bush, described techniques using a trocar to establish a channel from the meatus to the glans. Dieffenbach also described a similar technique in the 1830s. None of these methods was very successful.<sup>5</sup>

In 1874, Theophile Anger reported the successful repair of a penoscrotal hypospadias using the technique described in 1869 by Thiersch for the repair of epispadias in which lateral skin flaps were tubularized to form the neourethra. Anger's report initiated the modern era of hypospadias surgery characterized by the use of local skin flaps.<sup>7,8</sup> Duplay soon described his two-stage technique.<sup>6</sup> In the first stage, the chordee was released; in the second stage, a ventral midline strip of skin was covered by closure of the lateral penile skin flaps in the midline. Duplay did not believe that it was necessary to form the urethral tube completely because he thought that epithelialization would occur even if an incomplete tube were buried under the lateral skin flaps. Browne used this concept in his well-known "buried strip" technique, which was widely used in the early 1950s.<sup>9</sup> In the late 1800s, various other surgeons reported on penile, scrotal, and preputial flap techniques for multistage procedures. Several of them used the technique of burying the penis in the scrotum to obtain skin coverage, similar to the technique described by Cecil and Cuip in the late 1950s.<sup>10</sup> In 1913, Edmonds was the first to describe the transfer of preputial skin to the ventrum of the penis at the time of release of chordee. At a second stage, the Duplay tube was created to complete the urethral closure. Byars popularized this two-stage technique in the early 1950s.<sup>11</sup> Smith further improved on the procedure by denuding the epithelium of one of the lateral skin flaps to give a "pants-over-vest" closure and thus reduce the risk of fistula formation.<sup>12</sup> Belt devised another preputial transfer, two-stage procedure that was popularized by Fuqua in the 1960s.<sup>13</sup>

Nove-Josserand, in 1897, was the first to report the use of a free, split-thickness skin graft in an attempt to repair hypospadias.<sup>14</sup> Over the next 20 years, various other tissues were used as free grafts, including saphenous vein, ureter, and appendix. With none of these procedures was consistent success attained. McCormack used a free, full-thickness skin graft in a two-stage repair.<sup>15</sup> In 1941, Humby described a one-stage

technique using the full thickness of the foreskin.<sup>16</sup> Devine and Horton later popularized this free preputial graft technique with very good results.<sup>17</sup>

In 1947, Memmelaar reported the use of bladder mucosa as a free graft technique in a one-stage repair.<sup>18</sup> Marshall and Spellman, in 1955, used bladder mucosa in a two-stage technique.<sup>19</sup> Urologists in China also experienced success with a primary repair using bladder mucosa. This technique was developed independently during the period of scientific and cultural isolation in China.<sup>20</sup> Buccal mucosa from the lip was used for urethral reconstruction in 1941 by Humby<sup>16</sup> and has recently gained renewed attention as a free graft technique.<sup>21</sup>

Improved techniques in preputial and meatal-based vascularized flaps since the 1970s to 1980s have greatly advanced hypospadias repair. Through the contributions of surgeons such as Mathieu, Barcat,<sup>1</sup> Mustarde,<sup>22</sup> Broadbent,<sup>23</sup> Hodgson,<sup>24</sup> Horton and Devine,<sup>17</sup> Standoli,<sup>25</sup> and Duckett,<sup>26</sup> the single-stage repair of even the most severe forms of hypospadias has become commonplace.

## CLINICAL ASPECTS

### Incidence

The incidence of hypospadias has been estimated to be between 0.8 and 8.2 per 1000 live male births.<sup>27</sup> The wide variation probably represents some geographic and racial differences, but of more significance is the exclusion of the more minor degrees of hypospadias in some reports. If all degrees of hypospadias, even the most minor, are included, then the incidence is probably 1 in 125 live male births.<sup>28</sup> With the most quoted figure of 1 per 250 live male births, it can be assumed that more than 6000 boys are born with hypospadias each year in the United States.<sup>29</sup>

### Etiology

A defect in the androgen stimulation of the developing penis, which precludes complete formation of the urethra and its surrounding structures, is the ultimate cause of hypospadias. This defect can occur from deficient androgen production by the testes and placenta, from failure of testosterone to convert to dihydrotestosterone by the 5 $\alpha$ -reductase enzyme, or from deficient androgen receptors in the penis. Various disorders of sexual differentiation can cause deficiencies at any point along the androgen-stimulation axis. These are discussed in Chapter 63.

The origin of hypospadias not associated with disorders of sexual differentiation is unclear. An endocrine cause has been implicated by some reports that show a diminished response to human chorionic gonadotropin in some patients with hypospadias, suggesting delayed maturation of the hypothalamic/pituitary axis.<sup>30,31</sup> Other reports have shown an increased incidence of hypospadias in monozygotic twins, suggesting an insufficient amount of human chorionic gonadotropin production by the single placenta to accommodate the two male fetuses.<sup>32</sup>

Environmental causes also have been implicated. A higher incidence of hypospadias has been noted in winter conceptions.<sup>32</sup> A weak association between hypospadias and the maternal ingestion of progestin-like agents has been noted.<sup>33,34</sup> No association has been found between hypospadias and oral contraceptive use before or during early pregnancy.<sup>35</sup>

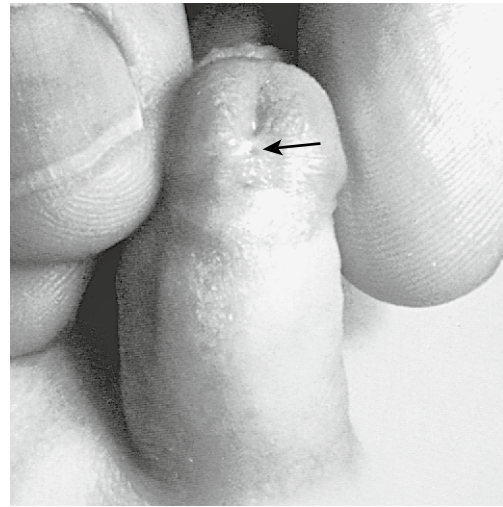

Genetic factors in the etiology of hypospadias are indicated by the higher incidence of the anomaly in first-degree relatives of hypospadiac patients.<sup>27,34,36</sup> In one study that evaluated 307 families, the risk of occurrence of hypospadias in a second male sibling was 12%. If the index child and his father were affected, the risk for a second sibling increased to 26%. If the index child and a second-degree relative were affected, rather than the father, the risk of the sibling being affected was only 19%.<sup>36</sup> This pattern suggests a multifactorial mode of inheritance, with these families having a higher than average number of influential genes for creation of the anomaly.<sup>36</sup> A combination of the endocrine, environmental, and genetic factors ultimately determines the potential for developing the hypospadias complex in any one individual.<sup>31</sup>

### Anatomy of the Defect

The clinical significance of the hypospadias anomaly is related to several factors. The abnormal location of the meatus and the tendency toward meatal stenosis result in a ventrally deflected and splayed stream. This fact makes the stream difficult to control and often makes it difficult for the patient to void while standing. The ventral curvature associated with chordee can lead to painful erections, especially with severe chordee. Impaired copulation and thus inadequate insemination is a further consequence of significant chordee. In addition, the unusual cosmetic appearance associated with the hooded foreskin, flattened glans, and ventral skin deficiency frequently has an adverse effect on the psychosexual development of the adolescent with hypospadias.<sup>37-41</sup> All of these factors are evidence that early surgical correction should be offered to all boys with hypospadias, regardless of the severity of the defect.

The distal form of hypospadias is the most common (see Table 60-1). Frequently, little or no associated chordee is present (Fig. 60-1). The size of the meatus and the quality of the surrounding supportive tissue as well as the configuration of the glans are variable and ultimately determine the surgical procedure. Well-formed, mobile perimeatal skin and a deep ventral glans groove may allow local perimeatal flaps to create the urethra (Fig. 60-2). In contrast, atrophic and immobile skin around the meatus may require tissue transfer from the prepuce to form the neourethra.

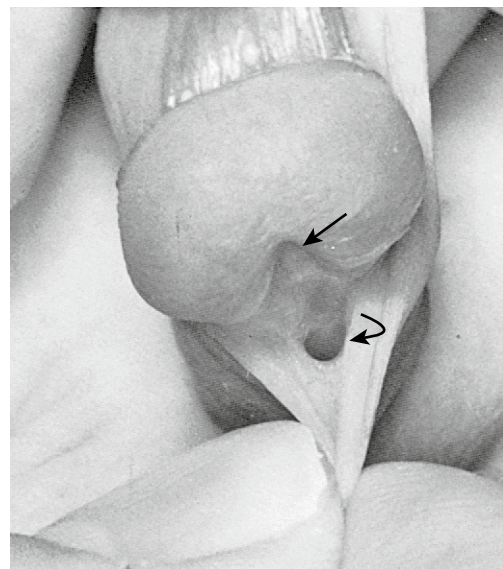

An unusual variant of the distal hypospadias is the large wide-mouthed meatus with a circumferential foreskin (the megameatus/intact prepuce variant) (Fig. 60-3).<sup>42</sup> Owing to the intact prepuce, this variant is often not identified until a circumcision has been done. If clinicians discover hypospadias during circumcision, they should stop and preserve the foreskin, even if the dorsal slit has been created.

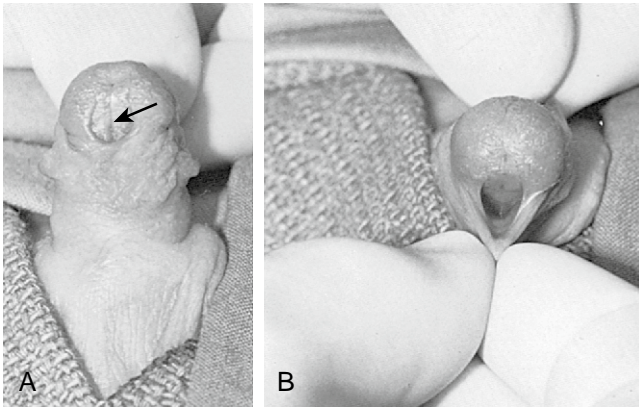

**Figure 60-1.** Distal hypospadias with a stenotic meatus (arrow) located on the glans with no chordee. This patient is a good candidate for a meatal advancement and glanuloplasty (MAGPI) procedure or a tubularized incised urethral plate (TIP) operation.

At times, the distally located meatus may be associated with significant chordee, sometimes of a severe degree (Fig. 60-4). The release of the chordee places the meatus in a much more proximal location, requiring more complicated transfers of tissue to bridge the gap between the proximal meatus and the tip of the glans.

When the meatus is located on the penile shaft, the character of the urethral plate (midline ventral shaft skin distal to the meatus) is important in determining what type of repair is possible. A well-developed and elastic urethral plate suggests minimal, if any, distal ventral curvature (Fig. 60-5). However, a thin atrophic urethral plate heralds a significant chordee. The proximal

**Figure 60-2.** Patulous, subcoronal meatus (curved arrow) with mobile perimeatal skin and deep ventral glans groove (straight arrow). This is a good variant for a meatal-based flap procedure, glans approximation (GAP), or tubularized incised urethral plate (TIP) repair.

**Figure 60-3.** A, Previously circumcised penis with megameatus (arrow) and intact circumferential prepuce. B, Large wide-mouthed meatus in the same penis as shown in A.

supportive tissue of the urethra also is important. If there is a lack of spongiosum proximal to the hypospadiac meatus, this portion of the native urethra is not substantial enough to use in the repair (Fig. 60-6). Therefore, the neourethra must be constructed from the point of adequate spongiosum.

The position of the meatus at the penoscrotal, scrotal, or perineal location is usually associated with severe chordee, which requires chordee release with an extensive urethroplasty (Fig. 60-7). This type is usually more predictable in the preoperative period as to the choice of repair than are some of the more distal types previously discussed.

**Figure 60-4.** Scrotal hypospadias with severe chordee and marked penoscrotal transposition is seen in this infant.

**Figure 60-5.** Midshaft hypospadias with elastic, well-developed urethral plate distal to the meatus (arrow). No significant chordee is present. This is a good variant for an onlay island flap procedure or possibly a tubularized incised urethral plate operation.

Other anatomic elements of the anomaly that are important to consider include penile torsion, glans tilt, penoscrotal transposition, and chordee without hypospadias. These are discussed more completely later.

### Associated Anomalies

Inguinal hernia and undescended testes are the most common anomalies associated with hypospadias. They occur from 7% to 13% of the time, with a greater incidence when the meatus is more proximal.<sup>43-45</sup> An enlarged prostatic utricle also is more common in posterior hypospadias, with an incidence of about 11%.<sup>44</sup> Infection is the most common complication of a utricle, but surgical excision is rarely necessary.<sup>46</sup> Several reports have emphasized significantly high numbers of upper urinary tract anomalies associated with hypospadias,<sup>47-50</sup> suggesting that routine upper tract screening is necessary. However, when the association is studied selectively, it can be shown that the types of hypospadias that are at risk for surgically significant upper tract anomalies are the penoscrotal and perineal forms and those associated with other organ system abnormalities.<sup>43,45</sup> When one, two, or three other organ system anomalies occur, the incidence of significant upper tract anomalies is 7%, 13%, and 37%, respectively. Associated myelomeningocele and imperforate anus carry a 33% and 46% incidence, respectively, of upper urinary tract malformations. In isolated posterior hypospadias, the incidence of associated upper tract anomalies is 5%.<sup>45</sup>

In middle and distal hypospadias, when not associated with other organ system anomalies, the incidence is similar to that in the general population.<sup>43,45,51</sup> Therefore, it is recommended that screening for upper

**Figure 60-6.** Midshaft hypospadias with a lack of spongiosum support proximal to the meatus. The urethra should be opened back to an area of good spongiosum support at the penoscrotal position.

urinary tract anomalies by voiding cystourethrogram and renal ultrasonography be done in patients with penoscrotal and perineal forms of hypospadias and in those with anomalies associated with at least one additional organ system. Screening should be done in patients with other known indications, such as a history of urinary tract infection, upper or lower tract obstructive symptoms, and hematuria, and in those boys having a strong family history of urinary tract abnormalities.<sup>52</sup>

Disorders of sexual differentiation are also potentially associated with hypospadias. This association is rare in the routine forms of hypospadias. Failure of testicular descent, micropenis, penoscrotal transposition (see Fig. 60-4), or bifid scrotum (see Fig. 60-7) when associated with hypospadias are all signs of potential disorders of sexual differentiation and warrant evaluation with karyotype screening.<sup>27,53,54</sup>

## TREATMENT

The advent of safe anesthesia, fine suture material, delicate instruments, and good optical magnification has allowed virtually all types of hypospadias to be repaired in infancy. Generally, the repair is done on an outpatient basis. To deny a child the benefit of repair because the defect is “too mild” or the risk of complication is “too high” is inappropriate. The chance to make the phallus as normal as possible should be offered to all children, regardless of the severity of the defects.

## Age at Repair

The technical advances over the past few decades have made it possible to repair hypospadias in the first 6 months of life in most patients.<sup>55-57</sup> Some surgeons have suggested delaying repair until after the child is age 2 years.<sup>52,58-60</sup> However, most surgeons who deal routinely with hypospadias prefer to perform the repair when the patient is 6 to 12 months old.<sup>53,54,56,57,61,62</sup> One study compared the emotional, psychosexual, cognitive, and surgical risks for hypospadias. The “optimal window” recommended for repair was age 6 to 15 months (Fig. 60-8).<sup>63</sup> Unless other health or social problems require delay, we believe the ideal time to complete penile reconstruction in the pediatric patient is about age 6 months.<sup>64</sup> The anesthetic risk is low and, at this age, postoperative care is much easier for the parents than it is when the child is a toddler.

## Objectives of Repair

The objectives of hypospadias correction are divided into the following categories:

1. Complete straightening of the penis
2. Locating the meatus at the tip of the glans
3. Forming a symmetric, conically shaped glans
4. Constructing a neourethra uniform in caliber
5. Completing a satisfactory cosmetic skin coverage

If these objectives can all be attained, the ultimate goal of forming a “normal” penis for the child with hypospadias can be accomplished.

## Straightening

Curvature of the penis is difficult to judge, at times, in the preoperative period. Artificial erection, by injecting physiologic saline in the corpora at the time of

**Figure 60-7.** Perineal/scrotal hypospadias (arrow) with severe chordee and a bifid scrotum.

**Figure 60-8.** Evaluation of the risk for hypospadias repair from birth to age 7 years. Optimal window is 6 to 15 months of age. (From Schultz JR, Klyklyo WM, Wacksman J: Timing of elective hypospadias repair in children. *Pediatrics* 71:342-351, 1983.)

operation, allows determination of the exact degree of curvature.<sup>65</sup> This curvature may be caused only by ventral skin or subcutaneous tissue tethering, which is corrected with the release of the skin and dartos layer.<sup>66,67</sup> Infrequently, the curvature may be secondary to true fibrous chordee, which requires division of the urethral plate and excision of the fibrous tissue down to the tunica albuginea.

Sometimes, even after extensive ventral dissection of chordee tissue, a repeated artificial erection still reveals the presence of significant ventral curvature. This finding is usually secondary to the uncommon problem of corporal body disproportion, which is caused by a true deficiency of ventral corporal development. This problem can be treated by making a releasing incision in the ventral tunica albuginea and inserting either a dermal or a tunica vaginalis patch to expand the deficient ventral surface.<sup>68,69</sup> Others have suggested the use of small intestinal submucosa as an off-the-shelf substitute for the autologous grafts.<sup>70</sup> Another technique is to excise wedges of tunica albuginea dorsally with transverse closure to shorten this dorsal surface and straighten the penis.<sup>71,72</sup> Other surgeons have had success with dorsal plication without excision of tunica albuginea.<sup>73,74</sup> Anatomic studies suggest that this plication should be done in the midline dorsally.<sup>75</sup> Still others advocate corporal rotation dorsally with or without penile disassembly to correct severe chordee.<sup>76,77</sup>

Axial rotation of the penis, or penile torsion, is another aspect of penis straightening that must be managed. This problem can generally be corrected by releasing the dartos layer as far proximal as possible on the penile shaft. This allows the ventral shaft to rotate back to the midline and corrects the torsion. Chordee or torsion can also occur without hypospadias. The management of these boys encompasses the entire spectrum of techniques as when hypospadias is involved (Fig. 60-9).<sup>78,79</sup>

### Locating the Meatus

Locating the meatus at the tip of the glans has not always been standard in hypospadias repair. Historically, the risk of complications was thought to be too great to recommend procedures that would locate the meatus beyond the subcoronal area. Multistage repairs popular in the 1950s and 1960s were designed to attain only a subcoronal location of the meatus. Surgical techniques since then have improved sufficiently so that glans-channeling and glans-splitting techniques are used with minimal complications, making the distal tip meatus possible.

In glanular and subcoronal variants, the configuration of the meatus is the factor for determining what technique is used to move the meatus distally on the glans. Meatoplasty with or without dorsal advancement, distal urethral mobilization and tubularization, or meatal-based flaps are the methods selected in most cases of distal hypospadias.<sup>80,81</sup> In the more proximal forms, creating the neourethra with local vascularized skin flaps or free grafts allows placement of the urethra at the end of the penis. Alternatively, glans channeling or glans splitting allows placement of the meatus at the tip of the glans.<sup>1,17,22,26,82,83</sup>

### Glans Shape

Creation of a symmetric, conically shaped glans is the objective of the glansplasty component of the repair. Approximating the lateral glanular tissue in the midline ventrally over a meatoplasty or meatal advancement corrects the flattened glans appearance to the more anatomically normal, conically shaped glans. Similarly, approximation of well-developed glans wings to the midline over a neourethra in a split glans restores the glans to its normal conical shape.

**Figure 60-9.** **A**, Chordee without hypospadias. The meatus is located at the tip of the glans with marked ventral curvature. **B**, Fibrous ventral tissue is all released. The urethra is mobilized, but curvature persists, indicating corporeal body disproportion. This requires a ventral patch or dorsal plication (see text).

### Urethral Construction

Formation of the neourethra can be accomplished with local skin flaps, various types of free grafts, or vascularized pedicle flaps. Local skin flaps may be formed from in situ skin or dorsal skin transferred to the ventrum in a previous stage. In either case, it is important to avoid making these flaps too narrow or thin because their vascular supply may be compromised. The hypospadiac urethral plate has been shown on histologic studies to consist of epithelium covering well-vascularized connective tissue without fibrosis.<sup>84</sup> This finding supports the clinical findings that urethral plate preservation is helpful for successful urethroplasty. Free grafts depend on an adequately vascularized bed for survival. Therefore, they should not be placed in a scarred channel. Well-vascularized subcutaneous tissue and skin must cover them to allow adequate neovascularization and survival of the graft.<sup>17</sup>

Mobilized vascularized flaps of prepuce have a more reliable blood supply than do free grafts. Therefore, if they are available, these flaps are the choice of most surgeons.<sup>24,26,83,85</sup> They may be used as patches onto a strip of native urethral plate to complete the urethra, or they may be tubularized and used as bridges over the gap between a proximal native urethra and the end of the glans.<sup>26,86</sup> A watertight closure of the well-vascularized neourethra is formed, with care being taken to make it uniform in caliber and of appropriate size for the age of the child. This closure helps avoid stricture and the formation of saccules, diverticula, and fistulas.

### Cosmesis

Creating cosmetically appealing, well-vascularized skin coverage of the penile shaft after urethroplasty can sometimes be challenging. Transfer of vascularized dorsal preputial skin to the ventrum can be accomplished in several ways.

Buttonholes of the dorsal skin allow the penis to come through this defect, draping the distal prepuce

over the ventral surface of the penis.<sup>19</sup> This maneuver has the advantage of transferring well-vascularized skin over the repair, but it is not as appealing cosmetically.

A more satisfactory method of transferring skin to the ventrum is by splitting the dorsal skin in the midline longitudinally and advancing the flaps around on either side to meet in the ventral midline. This technique allows a midline ventral closure, which simulates the median raphe. Moreover, it allows a subcoronal closure to the preputial skin circumferentially, which simulates the suture lines of a standard circumcision.<sup>87,88</sup> Another adjunct is to advance lateral flaps of inner preputial skin from each side to the ventral midline of the penis at the time of glansplasty or closure of glans wings.<sup>89</sup> Approximating these flaps in the midline gives the appearance of an intact circumferential preputial collar, further enhancing the potential for an anatomically normal skin closure (see Fig. 60-14).

Some patients, particularly those in European countries, prefer the appearance of a noncircumcised penis. In distal repairs, reconstruction of the prepuce for a noncircumcised appearance can be accomplished in certain cases.<sup>90</sup> Correction of the more significant degrees of penoscrotal transposition is often necessary to avoid the feminizing appearance. In select cases, this step can be done at the time of the original repair. However, when using vascularized pedicle flaps for the repair, it is usually safer to correct significant penoscrotal transposition with rotational flaps at a later time.<sup>91-94</sup>

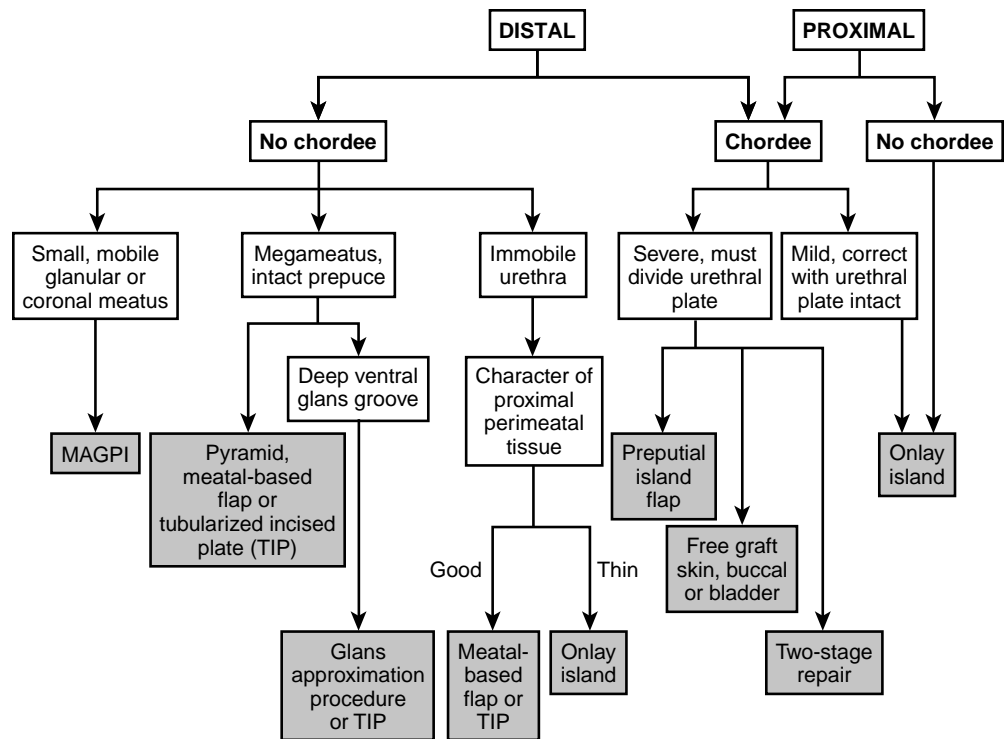

### Surgical Procedures

Because of the wide variation in the anatomic presentation of hypospadias, no single urethroplasty is applicable for every patient. At times, a final decision regarding the degree of curvature and the ultimate location of the meatus cannot be made until the operation has started and an artificial erection is performed. The surgeon who repairs hypospadias must be adaptable and experienced to deal with all variants of the defect. Versatility and experience with all options of surgical treatment are the keys to successful management. By recognizing the sometimes subtle nuances of meatal variation, glans configuration, and curvature character, the experienced surgeon can make the best choice as to the type of repair to use (Fig. 60-10).

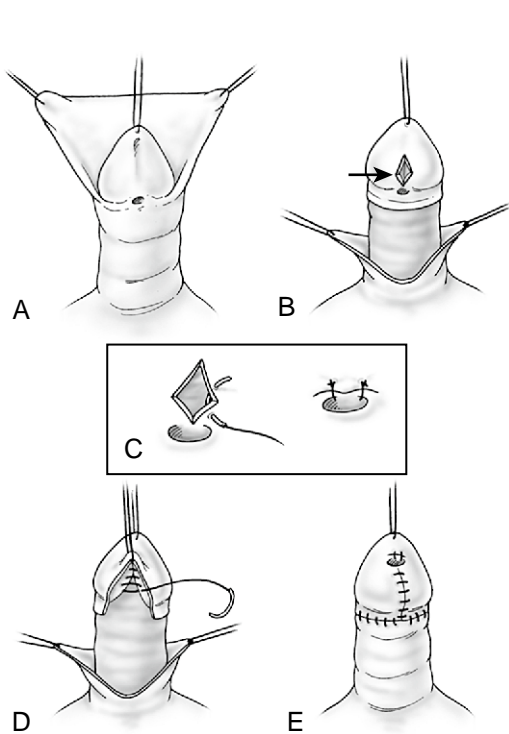

### Anterior Variants

Some glanular variants are amenable to the meatal advancement and glansplasty (MAGPI) type of repair (Fig. 60-11).<sup>95</sup> A stenotic meatus with good mobility of the urethra and a fairly shallow ventral glanular groove are the anatomic characteristics best suited for the MAGPI. A wide-mouthed meatus is not amenable to the MAGPI repair. The meatal-based flap repair may be used effectively in this situation, assuming no chordee is present and mobile, well-vascularized skin exists proximal to the meatus (Fig. 60-12).<sup>96,97</sup> This repair works well when there is a moderately deep ventral groove, allowing the urethra to be placed deep in the glans and a conically shaped glans to be created after

**Figure 60-10.** Flow diagram for types of repair in variants of hypospadias. MAGPI, meatal advancement and glansplasty. TIP, tubularized incised plate urethroplasty.

**Figure 60-11.** Meatal advancement and glansplasty. **A**, Circumferential subcoronal incision to deglove the penile shaft skin. **B**, Longitudinal incision through the ventral groove of glans (arrow). **C**, Transverse closure of glans groove incision to advance dorsal urethral plate and to open stenotic meatus. **D**, Glans tissue approximated ventrally in the midline to restore conical configuration to glans. **E**, Completion of the skin closure.

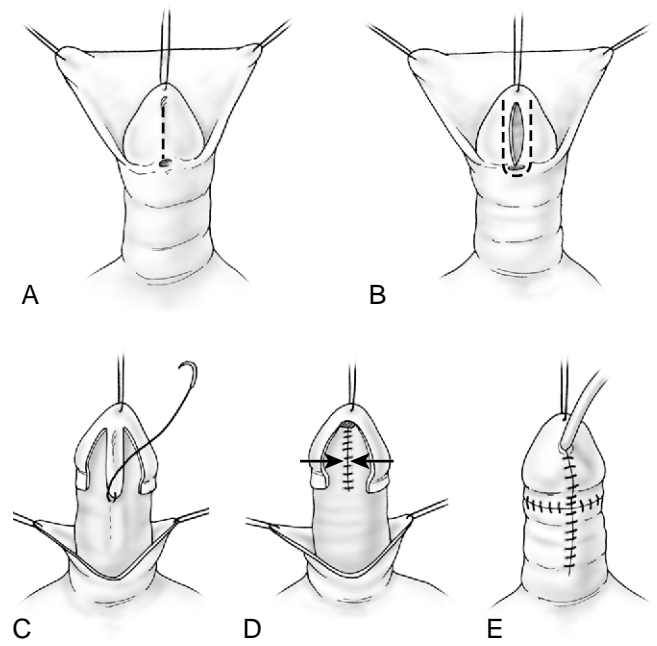

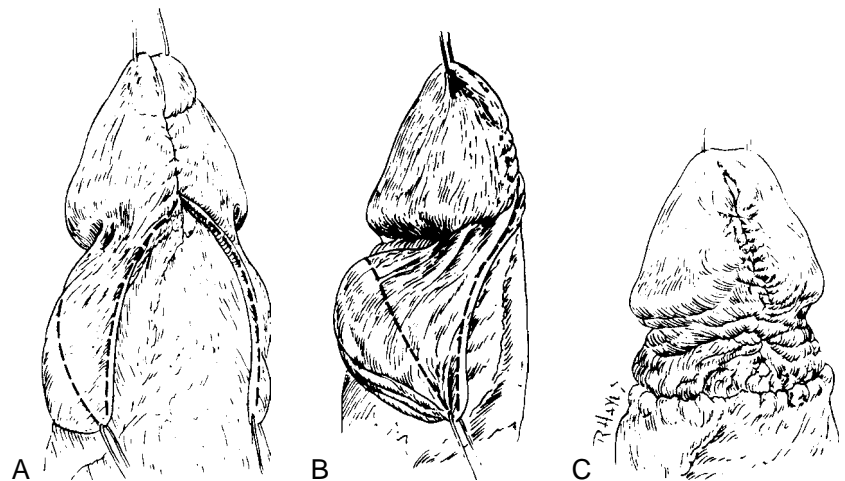

**Figure 60-12.** Meatal-based flap repair. **A**, Parallel incisions along ventral groove distal to the meatus and formation of meatal-based flap proximal to meatus. **B**, Glans wings developed on either side of the urethral plate (arrow) to close over the neourethra later. Meatal-based flap is mobilized distally maintaining good vascular and tissue support. **C**, Flap is anastomosed to bilateral edges of the urethral plate to form neourethra. **D**, Glans wings are closed over the neourethra in the midline, giving conical glans configuration. Penile shaft is covered with dorsal foreskin advanced ventrally.

**Figure 60-13.** Glans approximation procedure. **A**, Deep ventral groove and patulous, coronal meatus with outline of proposed incision. **B**, Skin is excised along previously marked "U"-shaped line. **C**, De-epithelialized glans with the urethral plate intact. **D**, Two-layer closure of the glanular urethra with glans skin still open. (From Zaontz MR: The GAP [glans approximation procedure] for glandular/coronal hypospadias. *J Urol* 141:359-361, 1989.)

closure of the glans wings. The glans approximation procedure is sometimes useful when a wide-mouthed proximal glanular meatus exists with a very deep groove (Figs. 60-13 and 60-14).<sup>98</sup> The pyramid procedure is well suited for the fish-mouth type of meatus seen in the megameatus/intact prepuce variant.<sup>42</sup> These repairs give a very good cosmetic result when done in the proper situation.

**Figure 60-14.** **A**, Glanular skin approximated and lateral wings of inner preputial skin outlined. **B**, Lateral view of outline for preputial collar. **C**, Lateral preputial wings closed in midline to give circumferential preputial collar. (From Zaontz MR: The GAP [glans approximation procedure] for glanular/coronal hypospadias. *J Urol* 141:359-361, 1989.)

**Figure 60-15.** Tubularized incised urethral plate (TIP) technique. **A**, Urethral plate is incised longitudinally. **B**, Glans incisions are made longitudinally, wide enough to leave two strips of epithelium for 10-Fr size neourethra. **C**, Neourethra is tubularized in the midline with multiple layers and dartos flap to reinforce. **D**, Glans wings are closed in the midline. **E**, Skin closure is completed and the urethral stent is in place (optional).

The tubularized incised plate urethroplasty (TIP) is a modification of the Thiersch-Duplay tubularization, which involves a deep longitudinal incision of the urethral plate in the midline (Fig. 60-15). This allows the lateral skin flaps to be mobilized and closed in the midline without tension. This procedure also allows the wide-mouthed meatus variant with a flat, shallow ventral groove to be repaired without the need for additional flaps.<sup>99</sup> The TIP urethroplasty has gained wide acceptance in recent years. Its durability and long-term success have been demonstrated even in some of the more proximal variants.<sup>100-102</sup>

**Figure 60-16.** Onlay island flap repair. **A**, Outline of incisions along the well-developed urethral plate with no chordee. **B**, Mobilization of glans wings and shaft skin with urethral plate intact distal to meatus. Outline of inner preputial island flap that will be transposed ventrally for onlay completion of neourethra. **C**, Island flap transposed ventrally on pedicle. The first part of the anastomosis is completed. **D**, Remainder of anastomosis to complete neourethra to tip of glans. **E**, Glans wings are approximated over the neourethra in the ventral midline. The penile shaft is covered with the ventral advancement of dorsal foreskin.

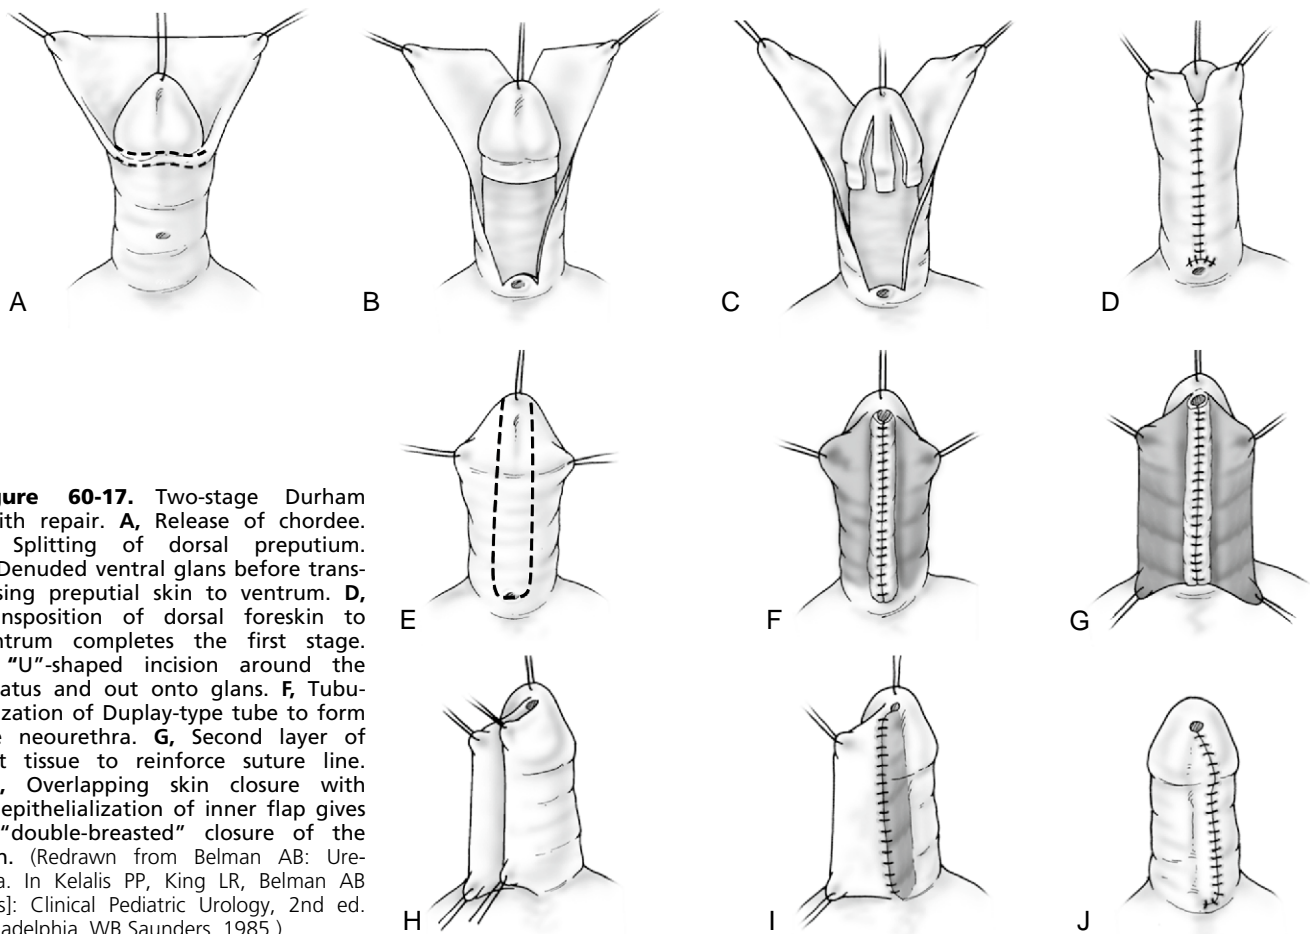

**Middle Variants**

The amount of ventral curvature generally dictates the type of repair in middle- and distal-shaft hypospadias. When no significant chordee is present, the TIP repair or the meatal-based flap can sometimes be performed. Another technique is the onlay island flap repair (Fig. 60-16).<sup>86</sup> This procedure involves mobilizing an inner preputial flap on its pedicle and rotating it ventrally to lay on the well-developed ventral urethral plate to complete the tubularization of the neourethra. This technique is applicable to many forms of penile shaft hypospadias.

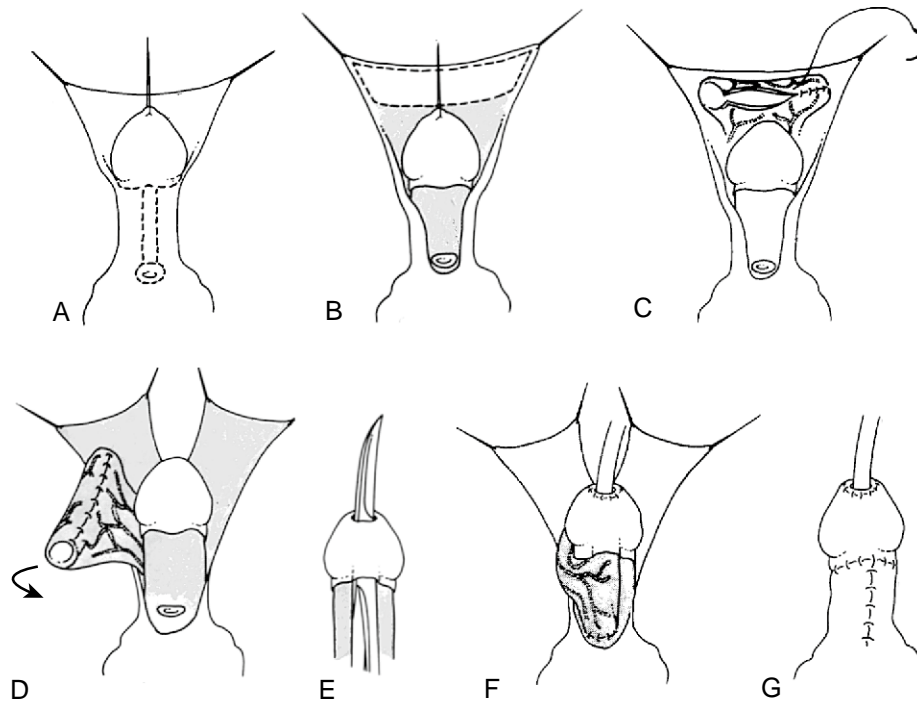

In milder degrees of chordee, the curvature can be corrected without dividing the urethral plate by taking down tethering bands lateral to the urethral plate or by dorsal plication techniques.<sup>74,75</sup> This allows the onlay island flap technique to be used instead of the tubularized pedicle flap or free graft, which have a higher incidence of complications.<sup>54</sup> If significant chordee is present, division of the urethral plate may be necessary. This moves the meatus more proximal and requires treatment as described for proximal variants.

**Proximal Variants**

Many of the scrotal and perineal forms of hypospadias are associated with significant chordee, which requires division of the urethral plate and results in a gap to be

**Figure 60-17.** Two-stage Durham Smith repair. **A**, Release of chordee. **B**, Splitting of dorsal preputium. **C**, Denuded ventral glans before transposing preputial skin to ventrum. **D**, Transposition of dorsal foreskin to ventrum completes the first stage. **E**, “U”-shaped incision around the meatus and out onto glans. **F**, Tubularization of Duplay-type tube to form the neourethra. **G**, Second layer of soft tissue to reinforce suture line. **H-J**, Overlapping skin closure with de-epithelialization of inner flap gives a “double-breasted” closure of the skin. (Redrawn from Belman AB: Urethra. In Kelalis PP, King LR, Belman AB [eds]: Clinical Pediatric Urology, 2nd ed. Philadelphia, WB Saunders, 1985.)

**Figure 60-18.** Transverse preputial island flap tube repair. **A and B,** Release of chordee and degloving of penile shaft skin. **B,** Outline of inner preputial island flap. **C,** Tubularization of inner preputial island flap. **D,** Transposition of the tubularized island flap to the ventrum, maintaining pedicle blood supply. **E,** Creation of a channel through glans tissue with sharp incisional and excisional technique. **F,** Island tube anastomosed to proximal native urethra, brought through glans channel and anastomosed to epithelium at tip of glans. **G,** Penile shaft covered with dorsal foreskin advanced ventrally. Skin closure is completed.

bridged between the proximal native urethra and the tip of the glans. This can be done with staged procedures in which coverage of the ventral penile shaft is attained by rotation of dorsal flaps to the ventrum, with later tubularization to form the neourethra (Fig. 60-17).

Another method is the tubularized free graft anastomosed to the native urethra proximally and extended to the end of the glans by a tunneling or splitting technique. The most commonly used free grafts are full-thickness skin, bladder mucosa, or buccal mucosa. Preputial skin is much preferred to extragenital skin.<sup>17,103</sup> If genital skin is not available, buccal mucosa may be the next best tissue.<sup>21,104,105</sup> Vascularized flaps are a more physiologically sound alternative to free grafts. The transverse inner preputial island flap that is tubularized and transposed ventrally to form the neourethra is the preferred type of vascularized flap<sup>106</sup> (Fig. 60-18). In contrast to free grafts, it provides good preputial skin with a reliable blood supply that does not rely on neovascularization for healing of the neourethra. Occasionally, the length of the prepuce alone may not be adequate to bridge the defect to a very proximal meatus. In this case, the shiny non-hair-bearing skin around the meatus can be tubularized (Fig. 60-19), moving the proximal urethra to the penoscrotal junction. The preputial vascularized tube graft can then be used to bridge the remaining distance to the end of the penis.<sup>53</sup>

In some cases, the penile shaft may be deficient enough to cause concern about ventral coverage after formation of the neourethra. The double-face island flap can solve this problem.<sup>24</sup> This technique leaves some

of the outer preputial skin attached to the pedicle after tubularizing the inner preputial layer. This outer prepuce is transferred to the ventrum with the pedicle and supplies the skin coverage of the ventral shaft. However, the complications associated with the double-face island flap are numerous, and it has few advocates.<sup>55</sup>

**Figure 60-19.** Outline of non-hair-bearing skin distal to scrotal meatus (arrow) that will be tubularized to move the meatus to the penoscrotal junction. Island flap tube will complete the repair to the end of the glans.

I prefer the transverse island flap in a one-stage procedure in most cases of proximal hypospadias with chordee.<sup>106</sup> In the rare case in which the skin deficiency is so severe that a vascularized pedicle cannot be used or in which the chordee is so severe that a dermal or tunica vaginalis graft is required to correct disproportion, a two-stage repair may be better.<sup>107-109</sup>

## Technical Perspectives

### Optical Magnification

Most surgeons agree that optical magnification is indispensable in hypospadias surgery. Standard operating loupes, ranging from 2.5× power to 4.5×, are generally thought to be ideal for the magnification needed for this type of surgery. Some workers advocate the use of the operating microscope and suggest an improved result with this technique.<sup>110</sup> Most surgeons have not believed that this degree of magnification is necessary for obtaining excellent results. The microscope may be overly cumbersome for the small improvement in visualization it may provide.<sup>111</sup>

### Sutures and Instruments

Fine absorbable suture is chosen by most surgeons to close the neourethra. Polyglycolic or polyglactin material is probably the most common suture choice. However, some surgeons prefer the longer-lasting polydioxanone suture.<sup>110</sup> Permanent sutures of nylon or polypropylene, in a continuous stitch that is pulled out 10 to 14 days after surgery, are recommended by some.<sup>12,56</sup>

The type of optical magnification also determines the size of the suture. Generally, 6-0 or 7-0 suture is preferred. With the microscope, 8-0 or 9-0 may be used. Skin closure is usually accomplished with either fine chromic (6-0 or 7-0) or plain catgut suture. Small suture-sinus tracts may occur along these suture lines as they dissolve. I have used a subcuticular closure with either 6-0 chromic or polydioxanone for the past 10 years and have mostly eliminated the problem of these suture-sinus tracts.

The delicate instruments of ophthalmologic surgery are well designed for the precise tissue handling required in hypospadias repair. Small, single-toothed forceps or fine skin hooks allow tissue handling with minimal trauma. Standard microscopic tools are necessary for those who prefer the microscope over loupe magnification.

### Urinary Diversion

The goal of the surgeon in any urinary diversion procedure in hypospadias repair is to protect the neourethra from the urinary stream for the initial healing phase. In theory, this diversion should decrease the complication rate, particularly fistula formation. The more traditional perineal urethrostomy and suprapubic cystostomy are uncomfortable and cumbersome to manage in the postoperative period. Small indwelling 6- or

**Figure 60-20.** Occlusive dressing of transparent adhesive material in sandwich fashion on the abdominal wall, with a 6-Fr soft polymeric silicone (Silastic) indwelling tube inserted for urinary diversion.

8-Fr polymeric silicone (Silastic) tubes left through the repair and just into the bladder allow drainage of the urine into the diaper in infants (Fig. 60-20).<sup>111</sup> This technique greatly facilitates the outpatient care of these patients. These stents are well tolerated by the babies. Problems with the stents becoming plugged or dislodged are uncommon.

Some surgeons favor a stent that traverses the repair but is not indwelling in the bladder.<sup>110</sup> The patient is allowed to void, but the stent protects the repair. I prefer the indwelling stent, used for 5 to 14 days, depending on the complexity of the repair. In older children who would not tolerate wearing a diaper, a 6- or 8-Fr Foley catheter may be used in the simpler distal repairs and a suprapubic cystostomy is used in the more complex repairs. Suprapubic drainage should be used in complex reoperations or in any repairs requiring a free graft. Studies have suggested that no diversion is required for simpler distal procedures, such as MAGPI, meatal-based flap, or distal Duplay tubes. Simple small fistula repairs can be accomplished without diversion.<sup>112,113</sup>

### Dressings

Hypospadias dressings should apply enough gentle pressure on the penis to help with hemostasis and to decrease edema formation, without compromising the vascularity of the repair. Various dressings accomplish this purpose. A silicon-foam dressing, which can be placed around the penis in a liquid state that transforms to solid later, leaves a soft, mildly compressive dressing that is waterproof.<sup>114</sup> This dressing can be removed without difficulty several days after operation. Other dressings include transparent adhesive dressings wrapped around the penis or fixed to the abdominal wall in a sandwich-like fashion (see Fig. 60-20).<sup>68</sup> A DuoDerm (ConvaTec, Skillman, NJ) dressing can be applied around the penis as an alternative, before using a transparent adhesive dressing.<sup>110</sup> Two prospective studies have shown that the type of dressing

does not influence healing or complication rates.<sup>115,116</sup> I have continued to use a transparent dressing against the abdominal wall for the hemostatic effect in the first 12 postoperative hours.

### **Analgnesia**

Postoperative pain is generally controlled with oral analgesics. Bladder spasms caused by indwelling catheters can be managed with propantheline bromide and opium suppositories or by oral oxybutynin. A dorsal penile nerve block performed intraoperatively with bupivacaine can help control postoperative pain.<sup>117</sup>

A caudal block is my preferred method for postoperative pain control. In most cases, the patients are comfortable for the entire day and evening of surgery and are easily cared for at home with only oral analgesia.<sup>118</sup>

### **Complications**

The type and incidence of complications vary with the particular form of repair. Attention to detail and meticulous technique are imperative to keep the incidence of all complications to a minimum. The following is a discussion of some of the general complications that can occur with all repairs.

#### **Bleeding**

Intraoperative bleeding can, at times, be troublesome. However, with the judicious use of the point tip cautery, it can be generally be kept to a minimum. Tourniquets or cutaneous infiltrations with dilute concentrations of epinephrine can be helpful, but they should not replace careful technique. Postoperative bleeding is generally prevented by mildly compressive dressings. Subcutaneous hematomas may occur but generally do not need to be drained.

#### **Infection**

Wound infection is a rare problem in hypospadias repair, especially in the prepubertal patient. As long as good viability of tissue is maintained, infection should be a minor problem. Perioperative antibiotic prophylaxis is favored by some surgeons.<sup>119</sup> This is probably a reasonable precaution in an extensive repair, especially in the postpubertal patient. Urinary suppression with oral antibiotics is recommended with indwelling catheters that are open to drainage in the diaper.<sup>68,120,121</sup>

#### **Devitalized Skin Flaps**

If sloughing of the skin coverage occurs, it is usually on the ventral surface of the penis where dorsal skin has been transposed. When the devascularized skin is over a well-vascularized bed of tissue, such as with a pedicle flap, primary healing generally occurs without sequelae. If the slough is over poorly vascularized tissue, such as a free graft, the result can be the

breakdown of the repair. Careful attention to transposing well-vascularized tissue for coverage of the neourethra in all repairs is critical to avoid this problem.

### **Fistulas**

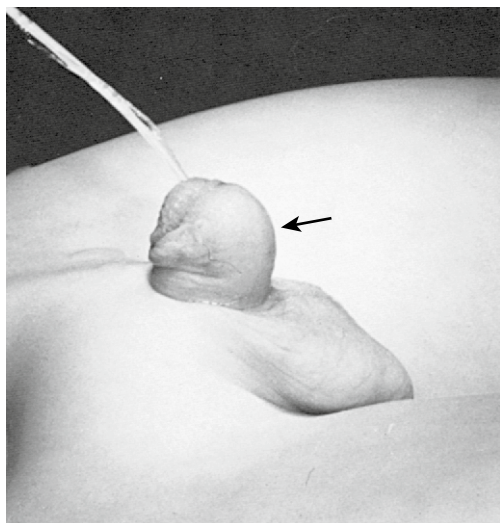

A urethrocutaneous fistula is the most commonly reported complication of hypospadias surgery. It results from failure of healing at some point along the neourethral suture line and can range in size from pinpoint to large enough for all voided urine to exit at this site. Fistulas also may be associated with stenosis or distal stricture. Occasionally, small fistulas seen in the early postoperative period may close spontaneously. Surgical closure should be postponed until complete tissue healing has occurred, which requires at least 6 months.<sup>122,123</sup> A small fistula may be closed by local excision of the fistula tract followed by closure of the urethral epithelium with fine absorbable suture. Approximating several layers of well-vascularized subcutaneous tissue over this closure is important to prevent recurrence. Urinary diversion is usually not necessary in small fistula repairs. Larger fistulas may require more complicated closures, with mobilization of tissue flaps or advancement of skin flaps to ensure an adequate amount of well-vascularized tissue for a multilayered closure.<sup>122-124</sup> Urinary diversion is often necessary with more complicated closures.

### **Strictures**

Narrowing of the neourethra may occur anywhere along its course. However, the most common sites of stricture formation are at the meatus and at the proximal anastomosis. Most cases of meatal narrowing can be managed as an office procedure by gentle dilation in the first few postoperative weeks. Occasionally, meatotomy or meatoplasty is needed, especially when associated with a proximal fistula or neourethral diverticulum. More proximal strictures can generally be treated with dilation or a visual internal urethrotomy.<sup>125</sup> However, open urethroplasty may sometimes be required, with excision of the stricture and primary urethral anastomosis or patch graft urethroplasty.<sup>122,123,126</sup>

### **Diverticulum**

Saccular dilation of the neourethra may result from distal stenosis causing progressive dilation, contained urinary extravasation from the breakdown of the repair, or initial creation of an oversized segment of the neourethra. Classic bulging of the urethra ventrally with voiding is evident with significant diverticulum formation (Fig. 60-21). Urinary stasis with chronic inflammation is common. Obstruction can result from kinking of the urethra when the diverticulum distends with voiding. Repair requires excision of the redundant neourethra with primary closure to restore a uniform caliber to the urethra.<sup>127</sup> Special attention should be paid to any narrowing of the neourethra distally, just as in fistula repair.

**Figure 60-21.** A neourethral diverticulum is seen to be bulging ventrally with voiding (arrow).

### Retrusive Meatus

Retraction of the meatus from its original position at the tip of the glans to a proximal glanular or subcoronal position can occur with any repair. A retrusive meatus is caused by the failure of the glansplasty closure or the breakdown of devascularized distal neourethra. Retraction is a common problem when the MAGPI procedure is used in patients whose meatus is too proximal or when too much tension is placed on the glansplasty closure.<sup>128</sup> Correction can usually be accomplished by a repeat glansplasty or a meatal-based flap procedure.<sup>122,128</sup>

### Persistent Chordee

Residual ventral curvature after hypospadias repair can be a troublesome problem. It is usually related to inadequate release of chordee at the original procedure. Increased ventral curvature occurring as the penis grows is at least a theoretical possibility. The artificial erection has made this complication much less common. Treatment of the problem is similar to the treatment of chordee without hypospadias. Degloving of the penis and takedown of any ventral tethering tissue is accomplished by using the artificial erection technique to guide dissection. Dorsal plication, ventral excision with patching, and division of the urethra may all be necessary.<sup>123,129</sup>

### Recurrent Multiple Complications

Patients with recurrent multiple complications generally have experienced multiple failed repairs that have resulted in a combination of severe complications. Extensive fibrosis of the urethra with fistulas, strictures, diverticula, and residual chordee may be present. The successful outcome of further repair depends on thorough evaluation of each complication and the use of all the techniques available to the surgeon experienced in hypospadias repair. If tissue is available, vascularized flaps or staging procedures are preferable to free grafts in a scarred phallus.<sup>130</sup> If a free graft must be used, it is important to obtain the most vascularized bed possible in which to place the graft. Buccal mucosa is probably the best tissue for a free graft in this type of situation.<sup>21,54,123</sup> In patients with severe scarring and ventral skin loss, a split-thickness skin graft may be used for ventral coverage. This tissue may then be tubularized at a second stage.<sup>131</sup>

### Sexual Function

Long-term results of hypospadias repair with regard to erectile function, ejaculation, and fertility are not available for the children who have undergone repairs at a younger age over the past decade. Historically, sexual difficulties after hypospadias repair have been reported. These were thought to be secondary to psychosexual factors related to surgery in childhood rather than to anatomic problems.<sup>36,41</sup> Fertility has been assessed by semen analysis in patients after hypospadias repair.<sup>38</sup> Higher rates of oligospermia are reported. These lower sperm counts generally occur in patients with associated anomalies such as cryptorchidism, chromosome abnormalities, varicoceles, or torsion. In a patient with an anatomically successful hypospadias repair and no associated anomalies that might affect fertility, a high potential for fertility and an adequate sexual function are expected.<sup>132</sup> Only close observation of pediatric patients into their adulthood after hypospadias repair early in life will reveal the true incidence of sexual dysfunction and fertility problems.

### Results

A summary of the incidence of certain complications for commonly used procedures is seen in [Table 60-2](#). Also, a personal series of mine is included that represents those patients who underwent operation over a 20-year period (1987 to 2007) with a minimum follow-up of 6 postoperative months.

# CIRCUMCISION

Stephen C. Raynor, MD

Circumcision is the removal of the prepuce or foreskin and is one of the most frequently performed surgical procedures in the world. Indications for circumcision include the treatment of disease, perceived benefits of prophylactic circumcision, and social or religious concerns. There is a wide variability in the rate of circumcision among different populations. A lack of consensus regarding the function of the foreskin as well as often strident debate concerning the benefits of circumcision have led to much controversy as to the appropriateness of the procedure.

## EMBRYOLOGY

The development of the prepuce begins during the third month of gestation as a fold of skin at the base of the glans. With growth, this skin extends distally, with the dorsal portion growing at a more rapid rate than the ventral component. The proper development of the prepuce is dependent on the presence of androgen and androgen receptors. The closure of the ventral portion of the prepuce is completed by the fifth month of gestation after closure of the glanular urethra. Keratinization of the glans and inner epithelial surface of the prepuce then follows. Initially, the inner surface of the prepuce and the epithelium of the glans are fused. Lacunae then begin to form between the two surfaces, resulting in an eventual complete separation. This process of separation is a gradual one and typically remains incomplete at birth.<sup>1</sup>

As a result of this incomplete keratinization, the foreskin can be completely retracted in less than 5% of neonates. The adherence between the glans and prepuce may not allow visualization of the meatus in about half of neonates. The natural separation of the two surfaces continues with growth of the child. Separation of the prepuce from the glans progresses with growth. A completely retractable foreskin is present in 60% of boys aged 11 to 15 years.<sup>2</sup> All foreskins should be retractable by age 17.<sup>3</sup> Until this natural process of separation is complete, there is usually no need for forceful retraction of the foreskin and cleaning of the glans.

## HISTORY AND INCIDENCE

Circumcision has been practiced since ancient times. Evidence of circumcision has been found in the study of ancient Egypt, with the identification of circumcised mummies as well as the depiction of circumcision in bas relief on an ancient tomb.<sup>1,4</sup> Columbus found the New World natives to be circumcised.<sup>1</sup> Circumcision may also have developed as a mark of defilement or slavery.<sup>4</sup>

A common rationale given for the decision to proceed with circumcision is religious beliefs. The Bible declares circumcision to be the sign of the covenant between God and the people of Israel.<sup>5</sup> In the Muslim faith, circumcision is recommended but not obligatory.<sup>6</sup> There is a high rate of circumcision in Jewish and Muslim populations, and circumcision is quite common in the United States. Areas of Africa, Australian aborigines, and people of the Near East also practice ritual circumcision.<sup>7,8</sup> In contrast, routine circumcision is rarely performed in Europe, China, the Far East, and Central and South America.<sup>7</sup> This wide variation in incidence is probably reflective of religious and cultural differences, as well as strong disagreement regarding the value of routine neonatal circumcision.

## THE PREPUCE

The prepuce is the anatomic covering of the glans. Contributing to the debate concerning the appropriateness of routine circumcision is a lack of clear understanding of the function of the prepuce. The prepuce is a specialized junctional mucocutaneous tissue that provides adequate skin and mucosa to cover the entire penis during erection. The somatosensory innervation is by the dorsal nerve of the penis and branches of the perineal nerve. Autonomic innervation is from the pelvic plexus. There are encapsulated somatosensory receptors, both mechanoreceptors and nociceptors in the prepuce. This innervation of the prepuce differs from the glans, which is primarily innervated by free nerve endings and has primarily protopathic sensitivity. As a result

of these differences, the inner mucosa of the prepuce is believed to be a part of the normal complement of the penile erogenous tissue.<sup>9</sup>

## MEDICAL INDICATIONS

The inability to retract the foreskin of a neonate is a result of the incomplete keratinization of the glans and is not pathologic. Phimosis is the inability to retract the foreskin due to narrowing of its opening. True phimosis is associated with a white, scarred preputial orifice, which is uncommon before 5 years of age. It is most common just before puberty and is an indication for circumcision.<sup>10</sup> Balanitis xerotica obliterans is a ring-like distal sclerosis of the prepuce with whitish discoloration or plaque formation that may involve the prepuce, glans, or urethral meatus and is an indication for circumcision.<sup>11</sup> Paraphimosis occurs when the foreskin has been retracted behind the corona but is able to be brought back over the glans with great difficulty or not at all. This is also an indication for circumcision, although ardent opponents of circumcision would offer preputial stretching, preputial plasty, or topical corticosteroid creams as alternative therapy.<sup>12-15</sup> Balanitis is an infection of the glans, and posthitis is an infection of the prepuce. Recurrent infection with scarring of the prepuce is an accepted indication for circumcision.<sup>8,16</sup>

## ROUTINE NEONATAL CIRCUMCISION

The appropriateness of routine circumcision of healthy male neonates is an emotional and contentious issue. Confounding the argument is the lack of a clear understanding as to the precise function of the prepuce.<sup>17</sup> Opponents of circumcision have represented the procedure as a symbol of the "therapeutic state"<sup>18</sup> and as a mutilating procedure<sup>19</sup> and have questioned the legality of routine neonatal circumcision.<sup>20</sup> Circumcision is done on the eighth day in the Jewish faith, traditionally performed by a mohel, a member of the Jewish faith trained in ritual circumcision. In Islamic countries, circumcision is considered traditional but not obligatory, with a wide variability in age at time of circumcision.<sup>6,21</sup> Proponents for routine neonatal circumcision generally cite three advantages: the prevention of urinary tract infections (UTIs) in infants, the prevention of sexually transmitted disease, and the prevention of penile cancer.

As rates of circumcision diminished in the United States, reports appeared demonstrating an increased rate of UTIs in uncircumcised male infants. An initial report of infant UTIs showed a male predominance in infants younger than 3 months of age, with a disproportionate number of these being uncircumcised.<sup>22</sup> A subsequent large retrospective analysis of infants of families in the armed services suggested that uncircumcised infants have a 12-fold increased risk for UTI as compared with circumcised infants.<sup>23-25</sup> A 10-fold increase in the cost of managing UTIs in uncircumcised

infants as compared with circumcised infants was also shown.<sup>26</sup>

The increased incidence of infection is believed to be secondary to adherence of pathogenic bacteria to the prepuce.<sup>27</sup> It has also been suggested that there is an increased risk of UTIs in uncircumcised young adults.<sup>28</sup> Proponents of circumcision point out that the 10% incidence of concurrent bacteremias and the long-term sequelae of renal scarring are factors to be considered in the circumcision debate.<sup>29</sup> Critics have been quick to note that these studies have been retrospective analyses and therefore are subject to significant bias.<sup>30,31</sup> Others have suggested that colonization of the prepuce by nonmaternal uropathic bacteria could be prevented by strict rooming-in with the mother.<sup>32</sup>

There have been many studies examining the relationship between circumcision status and sexually transmitted diseases (STDs). Studies have shown that patients who are not circumcised have an increased risk of chancroid, syphilis, gonorrhea, candidiasis, genital warts, and genital herpes.<sup>33-36</sup> However, other studies have found little support for or have refuted these findings altogether.<sup>37,38</sup> There is also evidence that circumcision is associated with a decreased risk of cervical cancer in women with high-risk sexual partners as a result of the reduced risk of human papillomavirus infection in the male partner.<sup>35</sup> It is possible that the protective effect of circumcision against STDs may differ between developed and developing nations with poor hygiene.<sup>38</sup> Possible mechanisms for differing rates of STDs in relation to circumcision status include a more easily traumatized mucosa and epithelium of the uncircumcised phallus, the environment of the foreskin being more conducive to certain infectious agents, or nonspecific balanitis in uncircumcised men predisposing to certain STDs. Behavior and sexual practice still represent the greatest risk factors in the transmission of STDs.<sup>35</sup>

Epidemiologic studies of human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS) have raised another argument for prophylactic circumcision. There has been a substantial amount of evidence linking uncircumcised men with an increased risk of HIV infection. This increased risk of HIV infection is independent of the increased risk of genital ulcers in uncircumcised men.<sup>39</sup> In Africa, there are regional differences in the rate of circumcision. As the HIV/AIDS epidemic has emerged on the continent, an increased rate of HIV/AIDS has been observed in areas with low circumcision rates.<sup>40</sup> An analysis of 30 epidemiologic studies from Africa concluded that there was enough evidence that circumcision was associated with reduced HIV infection rates to consider male circumcision as a viable strategy to reduce HIV transmission.<sup>32</sup> Three randomized trials in Africa showed an estimated 50% to 60% reduction in the relative risk of HIV infection with circumcision.<sup>41,42</sup> A similar association between circumcision status and HIV has been noted in the United States, with uncircumcised homosexual men having a twofold increase in the risk of HIV infection.<sup>43</sup> If a male partner is uncircumcised,

there appears to be an increased risk of transmission of HIV to heterosexual contacts.<sup>44</sup>

Another reason espoused for routine circumcision is as a protective measure against invasive penile cancer. The lack of circumcision has been strongly associated with invasive penile cancer in multiple case series.<sup>39</sup> The etiology of penile cancer is unknown, but there appears to be an association with human papillomavirus (HPV).<sup>45</sup> The incidence of penile cancer in the United States is approximately one case per 100,000, with nearly all cases occurring in uncircumcised men.<sup>31,46</sup> This protective effect against penile cancer is diminished or lost when circumcision is done after the neonatal period.<sup>8,46,47</sup> Other factors associated with invasive penile cancer include smoking, a history of genital warts, penile rash or tears, multiple sexual partners, and poor penile hygiene.<sup>39,47</sup> Critics of circumcision cite equally low rates of penile cancer in developed countries with low circumcision rates. These epidemiologic data, combined with the extremely low incidence of penile cancer and the probable viral etiology, have led some authors to conclude that the impact of routine neonatal circumcision against penile cancer does not justify its widespread practice.<sup>30,45</sup>

There are many strong feelings but no definitive answer to the question of the appropriateness of routine neonatal circumcision. Taken together, studies do not provide conclusive evidence for or against it. Males not circumcised at birth have between a 2% and 10% likelihood of needing circumcision in the future.<sup>15,19</sup> A longitudinal study comparing circumcised with uncircumcised males showed a higher risk of penile problems in infancy in the circumcised group.<sup>48</sup> However, there was a higher rate of problems in the uncircumcised group after infancy. By 8 years of age, the uncircumcised group had experienced 1.5 times the rate of penile problems.

The most recent circumcision policy statement from the American Academy of Pediatrics in 1999 acknowledges the potential medical benefits of neonatal male circumcision, but does not recommend it as a routine procedure.<sup>39</sup> Its interpretation of the data, as well as this recommendation, has been questioned.<sup>49</sup> On their review of the data, the Canadian Pediatric Society stated that the risks and benefits of routine neonatal circumcision were evenly balanced and concluded that routine neonatal circumcision was not recommended.<sup>45</sup> In the United States, the decision regarding neonatal circumcision seems to be based more on social as opposed to medical reasons.<sup>50</sup>

## SURGICAL TECHNIQUE

Circumcision has been practiced for centuries and there have been numerous techniques developed. Common to all methods, the goal is removal of an adequate amount of the prepuce to uncover the glans, treat or prevent phimosis, and eliminate the possibility of paraphimosis. Whichever method is chosen, the surgeon must be familiar with and adept at the

procedure with a resultant low complication rate. Informed consent should always be obtained before any circumcision.<sup>51</sup>

## Neonatal Circumcision

Circumcision represents the most frequently performed male operation in the United States, with close to 64% of male neonates circumcised in 1995.<sup>39</sup> Neonatal circumcision is most frequently performed with a circumcision device. These various devices may be a shield, which is used in the traditional Jewish circumcision, a Mogen clamp, a Gomco clamp, or a Plastibell.<sup>7</sup> Before the procedure, the penis should be inspected for any contraindication to circumcision. Contraindications to circumcision in the neonate include a short or small phallus, hypospadias, chordee with no hypospadias, hooded prepuce, dorsal penile cutaneous hump, penile curvature or torsion, penoscrotal fusion, or large hernias or hydroceles that engulf the penis.<sup>52</sup>

There is general agreement as to the need for adequate analgesia when performing neonatal circumcision. Studies have shown that infants circumcised without analgesia have a stronger pain response to vaccination at 4 and 6 months of age as compared with those who received analgesics.<sup>53</sup> Effective relief of circumcision pain has been found with acetaminophen, topical lidocaine-procaine cream, and local nerve blocks.<sup>54-57</sup> One study showed a subcutaneous ring block with 1% lidocaine without epinephrine to be the most effective pain relief.<sup>39</sup> Sucrose on a pacifier can also provide added pain control.<sup>58</sup>

Even though many circumcisions are performed outside the operating room, antisepsis is critical because infection is a serious potential complication. In performing a Gomco circumcision, the field is sterilely prepped and then the adhesions between the glans and inner surface of the prepuce are bluntly separated. The extent of foreskin to be excised is then marked, either with a marking pen or with a crush of the dorsal prepuce done with a straight mosquito clamp. A dorsal slit allows the appropriate-sized bell to be placed over the glans, inside the prepuce (Fig. 61-1). The bell and foreskin are then brought through the opening in the base of the clamp, placed in the yoke, which is tightened, followed by excision of the foreskin distal to the base of the clamp. Electrocautery must never be used to excise the foreskin because transmission of the electrical current to the shaft of the penis will occur. The bell is then released and removed, taking care not to disrupt the weld between the shaft skin and the remnant of the inner surface of the prepuce.

A Plastibell differs from the Gomco clamp in that the distal foreskin is strangulated, with a resulting slough of that tissue. After sterile prep and dorsal slit, the appropriate-sized Plastibell is placed over the glans inside the prepuce (Fig. 61-2). A string is then tied around the prepuce and positioned in a groove in the bell. The excess foreskin is trimmed and the handle is broken off the bell. The foreskin remnant and bell are expected to slough off in 7 to 12 days.

**Figure 61-1.** The Gomco technique. **A**, A short dorsal slit has been performed to allow an appropriate sized bell to be placed over the glans and inside the prepuce. **B**, Next, the prepuce to be excised along with the bell have been brought through the opening in the base of the clamp and placed in the yoke. **C**, The yoke has then been tightened to coapt the skin edges. After waiting for 5 to 7 minutes, the excess prepuce is excised. Electrocautery must never be used to excise the foreskin because transmission of electrical current to the shaft of the penis will occur. **D**, The bell has been released, and the circumcision is completed.

## Freehand Circumcision

In older patients, circumcision is usually performed in the operating room. Circumcision devices seem to be less adequate for the older patient, and sleeve resection of the foreskin is preferable. As shown in [Figure 61-3](#), after prepping the operative field, any remaining adhesions between the glans and foreskin are bluntly lysed.

After marking the subcoronal sulcus, the foreskin is incised along the base of the glans with the foreskin in its normal position. Less skin is excised from the ventral surface. Dissection is carried down to Buck's fascia. The prepuce is then retracted and an incision made in the subcoronal sulcus, leaving a generous cuff of subcoronal skin. Injury to the urethra must be avoided. The collar of foreskin that has been isolated is then

**Figure 61-2.** Similar to the Gomco technique, in the Plastibell technique, adhesions between the glans and inner surface of the prepuce are bluntly separated. **A**, An appropriate-size Plastibell has been selected. **B**, The Plastibell is placed over the glans inside the prepuce. **C**, A string is then tied around the prepuce and positioned in the groove of the bell. The excess foreskin is trimmed and the handle is broken off the bell. The foreskin remnant and bell are expected to slough in 1 to 2 weeks.

**Figure 61-3.** A, For a freehand circumcision, the initial incision is made in the shaft skin, leaving more skin ventrally. B, A second incision is then made in the subcoronal sulcus, leaving a generous cuff. The *inset* shows the amount of foreskin to be excised. The isolated foreskin (C) is then excised (D), and the shaft skin is sutured to the subcoronal skin (E).

excised, and electrocautery is used to obtain meticulous hemostasis. The shaft skin is then approximated to the subcoronal skin using absorbable sutures.

## COMPLICATIONS

When performed by experienced surgeons under sterile conditions, circumcision has a low complication rate of between 2% and 10%.<sup>45</sup> Bleeding is the most frequent complication and is generally minor. Infection is the second most common complication and is generally minor. Although adhesions between the

foreskin remnant and the glans are common, many of these will resolve with time.<sup>59</sup> However, serious problems can result, including necrotizing fasciitis, sepsis, Fournier's gangrene, and meningitis.<sup>8</sup> There can be excision of too much or too little of the foreskin, with resultant postoperative phimosis or concealed penis. Revision of the circumcision may sometimes be necessary later in childhood.<sup>60</sup> Other complications include skin bridges, inclusion cysts, iatrogenic hypospadias or epispadias, partial amputation of the glans, and the catastrophic loss of the penis when electrocautery is used with a metal circumcision device.

# PRUNE-BELLY SYNDROME

Romano T. DeMarco, MD

In 1839, Frohlich first reported a neonate born with congenital absence of his abdominal musculature.<sup>1</sup> Years later, Parker described the accompanying genitourinary tract abnormalities of hydroureteronephrosis, megacystis, and undescended testes associated with deficiency of the abdominal wall musculature.<sup>2</sup> In 1901, Osler described a child with this condition, likening the abdomen to that of a prune, and coined the term prune-belly syndrome (PBS) (Fig. 62-1).<sup>3</sup> Subsequently in 1950, Eagle and Barrett published an exhaustive review of the syndrome and detailed the characteristic features and constellation of anomalies found in affected children.<sup>4</sup> These features include congenital absence or deficiency of the abdominal wall musculature and urinary tract abnormalities including a large hypotonic bladder (megacystis), dilated ureters, dilated prostatic urethra, and bilateral undescended testes. Also associated with this syndrome are renal, cardiac, pulmonary, gastrointestinal, and orthopedic anomalies (Table 62-1).<sup>5</sup>

Other names that have been used to describe this syndrome include Eagle-Barrett, triad, and abdominal musculature deficiency syndromes.<sup>5,6</sup> The use of these monikers has been encouraged by some to lessen the potential psychological impact to the affected child and family.<sup>7</sup> However, the designation prune-belly syndrome is still the most widely accepted term to describe the child with classic findings.

## INCIDENCE

The incidence of prune-belly syndrome is estimated to be 1 in 30,000 to 1 in 50,000 live births.<sup>8,9</sup> The current incidence may be less, as the Malformations Surveillance Program at Brigham and Women's Hospital led to elective termination of 31% of children diagnosed prenatally with prune-belly syndrome from 1974 to 1994.<sup>10</sup> Children with incomplete forms of the condition may present with typical abdominal wall changes but no urologic or testicular manifestations. Also, children may present with classic bladder and ureteral features with little to no involvement of the abdominal musculature.<sup>11,12</sup> The female patient

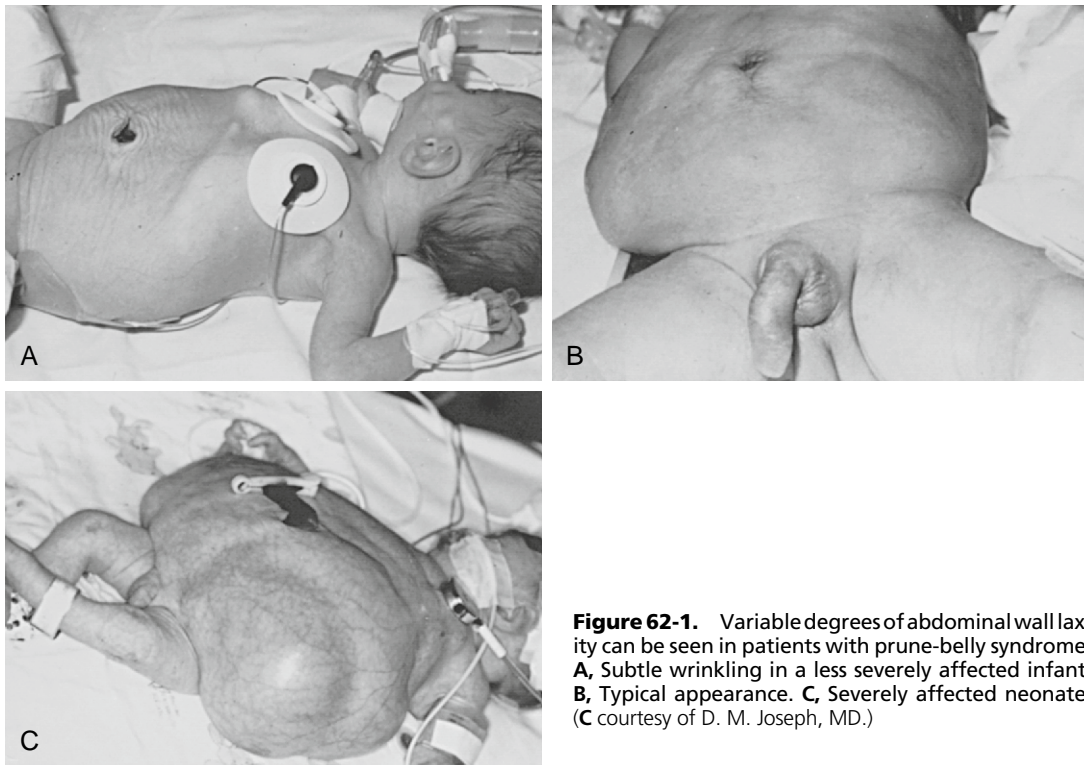

with characteristic abdominal wall and urologic findings is also considered to have an incomplete form of the condition and appears to make up less than 5% of reported cases.<sup>11,13,14</sup>

## GENETICS

Although population-based studies provide a hint that gene factors may play a role in the etiology of prune-belly syndrome, no specific gene defect for the disorder has been identified. Recent work studying a consanguineous union of parents with two male offspring found to have prune-belly syndrome and three with posterior urethral valves point to two loci, 1q and 11p, as the likely causative gene(s).<sup>15</sup> Whereas previous studies suggested that the genetic mechanism involved in the phenotypic presentation of prune-belly syndrome was potentially an X-linked recessive mutation,<sup>16,17</sup> an X-linked inheritance is not supported by this recent report.<sup>15</sup> Sporadic cases have also been associated with other chromosomal abnormalities, including Turner's syndrome and trisomies 13 and 18.<sup>18-20</sup> Multiple familial cases have also been published, including twins found to have deficiency of the abdominal wall musculature.<sup>21,22</sup> However, no specific genetic abnormalities have been noted in these reports. In one study, maternal cocaine use was found to be associated.<sup>23</sup> Therefore, spontaneous genetic mutations or a combination of genetics and environment likely play a significant role in the phenotypic expression of prune-belly syndrome.

## EMBRYOLOGY

A variety of hypotheses have been proposed to explain the common constellation of findings seen in prune-belly syndrome.<sup>24</sup> Although there is no consensus of opinion about the etiology of prune-belly syndrome, the most widely accepted specific mechanism for development of this condition is bladder obstruction.<sup>25</sup> According to this theory, urethral obstruction occurring early in development leads to

**Figure 62-1.** Variable degrees of abdominal wall laxity can be seen in patients with prune-belly syndrome. **A,** Subtle wrinkling in a less severely affected infant. **B,** Typical appearance. **C,** Severely affected neonate. (C courtesy of D. M. Joseph, MD.)

massive distention of the bladder and ureters. This obstruction may be anatomic,<sup>26</sup> but others have proposed a functional etiology, potentially related to hypoplasia of the prostate.<sup>27</sup> Whatever the source of the urethral obstruction, subsequent bladder distention leads to the abdominal wall muscle and skin changes. The high-grade urethral obstruction and secondary bladder changes can then lead to renal dysplasia and potentially oligohydramnios and bronchopulmonary dysplasia seen in many children with prune-belly syndrome. To tie in all the characteristic findings of prune-belly syndrome with this theory, the massively distended bladder prevents the normal descent of the testes, which leads to their intra-abdominal position.

The other most commonly accepted hypothesis involves a primary mesenchymal defect occurring early in embryogenesis. This defect leads to incomplete differentiation or failure of migration of the lateral mesoderm. This failure of migration is thought to lead to the characteristic myopathy and abdominal wall appearance.<sup>28</sup> Although this mesenchymal defect can account for the abdominal wall findings, the weakness in this theory is that it cannot explain the urinary tract and testicular abnormalities. To account for the classic triad of anomalies, researchers proposed that a primary defect of the intermediate and lateral plate mesoderm in prune-belly syndrome would also affect embryogenesis of the mesonephric and paramesonephric ducts.<sup>29</sup> This mesodermal error may also explain the posterior urethral abnormalities occasionally seen in this condition.

**Table 62-1**

**Commonly Associated Anomalies in Prune-Belly Syndrome**

**Cardiac**

Patent ductus arteriosus  
Ventricular septal defect  
Atrial septal defect  
Tetralogy of Fallot

**Gastrointestinal**

Intestinal malrotation  
Intestinal atresia  
Omphalocele  
Imperforate anus  
Hepatobiliary anomalies  
Hirschsprung's disease

**Orthopedic**

Congenital hip dislocation  
Scoliosis  
Pectus excavatum and carinatum  
Varus deformities of feet  
Severe leg maldevelopment

**Pulmonary**

Hypoplasia  
Pneumothorax  
Pneumomediastinum  
Lobar atelectasis

**Miscellaneous**

Splenic torsion  
Adrenal cystic dysplasia

## CLINICAL FEATURES

### Genitourinary Anomalies

#### Bladder

The bladder is usually very large and irregular with a patent urachus found in approximately 25% of patients.<sup>4,30</sup> The bladder wall is typically smooth, with an increased ratio of collagen to muscle fibers.<sup>31</sup> In some patients with severe muscle loss, the bladder will bulge and give the impression of a pseudodiverticulum most commonly seen at the dome of the bladder (Fig. 62-2).<sup>7</sup> The trigone is typically enlarged with displaced ureteral orifices laterally and superiorly, which likely contributes to the high incidence of vesicoureteral reflux.<sup>5,7</sup> The bladder neck is usually poorly defined and opens widely into a dilated prostatic urethra. Patients with prune-belly syndrome typically have a very large capacity, compliant bladder, with delay in first sensation to void.<sup>32</sup> The ability to empty the bladder is variable and thought to be due to relative outlet resistance. Many patients will void efficiently, but these patients must be followed closely because their ability to empty the bladder well can deteriorate.<sup>33</sup>

#### Ureters

The ureters are typically dilated and tortuous. The degree of ureteral pathology is variable and can be segmental. However, the proximal ureter is usually less dilated and appears to have more normal smooth muscle than the distal ureter.<sup>34,35</sup> Collagen fibers and connective tissue have been found to be abundant

**Figure 62-2.** A large bladder and pseudodiverticulum (arrow) at the dome of the bladder is often seen in children with prune-belly syndrome.

between muscle bundles containing few muscle cells,<sup>36</sup> particularly refluxing ureters.<sup>37</sup> Vesicoureteral reflux is found in 75% of patients with prune-belly syndrome (Fig. 62-3).<sup>38</sup> Obstruction, either at the ureteropelvic or ureterovesical junction, is rare.<sup>11,39</sup>

These large and dilated ureters have ineffective peristalsis. The propulsion of urine is hindered owing to poor contractile properties of the ureter. The decreased ureteral myofibrils, separated by patches of collagen, ineffectively transmit urine, leading to upper tract stasis.<sup>40</sup>

#### Kidneys

Renal abnormalities span a large spectrum in children with prune-belly syndrome. Children can present with severe dysplasia or have completely normal kidneys. Patients can have significant laterality of the dysplasia, with one kidney severely affected and the other kidney normal.<sup>39</sup> Whereas both antenatal bladder outlet obstruction and abnormal ureteral bud-metanephric blastema interaction have been implicated in the genesis of the dysplasia,<sup>41</sup> the exact mechanism is uncertain.

Hydronephrosis is typically seen. The degree of hydronephrosis can be quite variable with preservation of the calyceal morphology in the presence of severe ureteral and renal pelvic distention.<sup>38</sup> Although primary or secondary ureteropelvic junction obstruction can occur in children with prune-belly syndrome, nonobstructive hydronephrosis is usually seen<sup>42</sup> without significant correlation between the degree of hydroureteronephrosis and parenchymal injury.

#### Posterior Urethra, Prostate, and Accessory Sex Organs

The posterior urethra is extremely dilated in children with prune-belly syndrome (Fig. 62-4). This dilation is thought to be due to generalized hypoplasia of the prostate epithelium with replacement of the normal smooth muscle anteriorly with connective tissue. While obstructive lesions are rare findings in the distal posterior urethra,<sup>40,43</sup> several investigators have described valve-like obstructive tissue in the posterior urethra.<sup>44</sup>

The loss of smooth muscle support alters the configuration of the prostate gland, leading to its widened appearance.<sup>25</sup> An abnormal epithelial-mesenchymal interaction has been proposed as the cause of this anomaly.<sup>45</sup> This lack of normal prostatic parenchyma is thought to play a role in ejaculatory failure.<sup>44</sup>

Retrograde ejaculation is also commonly seen in patients with prune-belly syndrome and is thought to be related to bladder neck incompetency. The vas and seminal vesicles are typically affected. Atresia of these structures is common. Conversely, some patients present with dilation of both of these structures.<sup>29</sup>

#### Anterior Urethra

Typically, the anterior urethra is normal. However, atresia of the bulbar or membranous urethra has been reported, occurring in 18% of patients in one review.<sup>46</sup>

**Figure 62-3.** Variable degrees of dilation and dysmorphism of the upper urinary tract are seen in prune-belly syndrome. **A**, Dysmorphic renal pelvis with mild ureteral dilation. **B**, Calyceal clubbing and a tortuous “wandering” ureter. **C**, Dysmorphic pelvis with exaggerated dilation of the distal ureteral spindle. **D**, Bizarre appearance of the collecting system as well as the bladder.

In babies with urethral atresia, urachal patency, spontaneous bladder rupture with either cutaneous, vaginal, or rectal fistula formation, or in utero vesicoamniotic shunt placement are necessary for survival.

PBS is also associated with two variations of megalourethra.<sup>47</sup> The scaphoid megalourethra is the most common and less severe form. The scaphoid variety is associated with a deficiency of the spongiosum with preservation of the normal glans and corporeal bodies (Fig. 62-5). The fusiform type has a deficiency of not only the

spongiosum but also of the corpus cavernosum.<sup>48</sup> With voiding, the entire phallus dilates in patients with the fusiform variety, whereas those children with the scaphoid form have dilation of **only the anterior urethra**.

### Testes

Bilateral intra-abdominal testes are the most typical findings in children with prune-belly syndrome. The testes are commonly found near the ureterovesical

**Figure 62-4.** Posterior urethral dilation (*asterisk*) is often found in children with prune-belly syndrome. This dilation is similar to that seen in boys with posterior urethral valves.

junction but can be located in more proximal locations as well.<sup>5,7</sup> Infants with prune-belly syndrome have been reported to have essentially normal testicular histology as compared with age-matched controls.<sup>7</sup> Other series have documented present but diminished spermatogonia with Leydig cell hyperplasia in comparison with normal controls.<sup>49</sup> This suggests that the histologic findings are caused by more than the cryptorchid state. Azoospermia is the rule in adult patients with prune-belly syndrome, with no reported cases of a natural paternity.<sup>50</sup>

## Extragenitourinary Anomalies

### Abdominal Wall

The most characteristic clinical finding in neonates with prune-belly syndrome is the wrinkled and floppy appearance to the abdominal wall and bulging flanks associated with crisscrossed and creased skin. Older patients have a more potbelly appearance once the amount of cutaneous abdominal adipose tissue increases. The degree of the “pruned” appearance can vary significantly from patient to patient as can the degree of the deficiency of the abdominal wall musculature. While rarely completely absent,<sup>39</sup> the medial and inferior aspect of the abdominal wall is most severely involved, with normal or near-normal musculature in the periphery of the abdominal wall.<sup>51,52</sup> The most affected individual muscle is the transversus abdominis, followed in decreasing frequency by the rectus abdominis inferior to the umbilicus, internal oblique,

external oblique, and superior aspect of the rectus.<sup>11,39</sup> While the innervation of the abdominal muscle appears unaffected, light and electron microscopy have demonstrated multiple abnormalities of the abdominal wall muscle. These abnormalities include variations in or decreased muscle fiber size, excessive collagen accumulation, and myofilamentous disarray and loss.<sup>53</sup>

### Cardiac Anomalies

Cardiac anomalies occur in approximately 10% of patients with prune-belly syndrome. The most common cardiac findings include patent ductus arteriosus, atrial and ventricular septal defects, and tetralogy of Fallot.<sup>54</sup>

### Pulmonary Anomalies

Pulmonary abnormalities are common and typically related to the degree of renal dysplasia and associated oligohydramnios. Because of the high likelihood of having pulmonary hypoplasia, neonates exhibiting pulmonary distress should be presumed to have hypoplasia and hyaline membrane disease.<sup>11</sup> Additionally, these children are at increased risk for both pneumonia and spontaneous pneumothorax not necessarily related to the degree of hypoplasia.<sup>55</sup> Older patients may be found to have significant restrictive lung disease thought to be related to musculoskeletal abnormalities rather than parenchymal lung disease.<sup>56</sup>

### Gastrointestinal Anomalies

The most common gastrointestinal anomaly is intestinal malrotation.<sup>39,52</sup> The risk for malrotation is thought to be due to an incomplete rotation of the

**Figure 62-5.** Gross appearance of scaphoid megalourethra in a child with prune-belly syndrome.

midgut leading to a wide mesentery, allowing for increased bowel mobility.<sup>13</sup> Other intestinal abnormalities associated with prune-belly syndrome include persistent cloaca,<sup>13</sup> gastroschisis,<sup>21</sup> imperforate anus,<sup>57</sup> colonic atresia,<sup>52</sup> and volvulus.<sup>52</sup> Additionally, reports of splenic torsion and biliary tract abnormalities occurring in children with prune-belly syndrome have been published.<sup>58,59</sup> Chronic constipation can be a lifelong issue and is secondary to the inability to generate significant intra-abdominal pressure owing to the lax abdominal wall. An acquired megacolon is sometimes encountered.<sup>60</sup>

### Orthopedic Anomalies

Musculoskeletal abnormalities are common, occurring in approximately 50% of children with prune-belly syndrome.<sup>61,62</sup> Abnormalities of the hip joint, most commonly subluxation or dislocation, are frequently reported.<sup>61</sup> The most common orthopedic deformity is clubfoot, with an incidence of at least 25%. About 50% of patients have bilateral disease.<sup>62</sup> Other findings include congenital scoliosis, talipes equinovarus, and pectus excavatum.<sup>60,62</sup> The specific mechanisms leading to the orthopedic issues are unknown. Green and colleagues proposed that because of the unilaterality of most of the orthopedic deformities, oligohydramnios is the likely cause.<sup>63</sup> Others have attributed a distended bladder or a common mesenchymal error as the cause of these anomalies.

## CLINICAL PRESENTATION

### Antenatal Diagnosis and Management

Antenatally, a fetus with prune-belly syndrome behaves similarly to a fetus with posterior urethral valves or other causes of bladder outlet obstruction. The typical antenatal ultrasound findings include bilateral hydronephrosis, a distended bladder, and an irregular abdominal wall circumference.<sup>64</sup> These findings are not specific for this condition, and other diagnostic possibilities should also be considered. Reports of antenatal diagnosis as early as 11 to 14 weeks have been described.<sup>65,66</sup> However, the more classic findings are seen early in the third trimester.

In-utero intervention has been proposed by several authors in patients with prune-belly syndrome who have met certain criteria with no appreciable benefit.<sup>67,68</sup> At this time it would be the rare patient who is considered a candidate for antenatal therapy. Most pregnancies are carried to term, with rare instances of dystocia or worsening oligohydramnios leading to early delivery.<sup>69</sup> Pregnancy termination is typically considered only in those fetuses with early and severe oligohydramnios and evidence of significant renal dysplasia.

**Table 62-2** Classification System for Prune-Belly Syndrome

#### Category 1

Pulmonary hypoplasia and/or pneumothorax  
Oligohydramnios  
Renal dysplasia  
Urethral atresia  
Clubfeet

#### Category 2

Typical physical features  
Renal dysplasia common but less severe than category 1  
No pulmonary hypoplasia  
Can progress to renal failure

#### Category 3

Incomplete or mild physical features  
No renal dysplasia  
No pulmonary dysplasia  
Stable renal function

## Postnatal Diagnosis

### Neonatal Presentation

The appearance of a neonate with a wrinkled abdominal wall usually suggests the diagnosis of prune-belly syndrome. Another easily appreciated finding includes bilateral nonpalpable testes. Children with more significant oligohydramnios may present with some element of Potter's features, limb abnormalities, and pulmonary/chest anomalies.

### Neonatal Evaluation

The initial management entails a rapid and complete evaluation of all organ systems. To help guide clinicians regarding the prognosis of children with prune-belly syndrome, a classification system has been described (Table 62-2) with three categories.<sup>70</sup> Category 1 patients have the worst prognosis. Although this classification system can be a helpful prognostic aid, prune-belly syndrome is a condition with a wide spectrum of severity.

The initial concern in a child born with prune-belly syndrome is that of the pulmonary and cardiac systems. Thorough initial assessment of these systems is essential and includes the physical examination, a chest radiograph, and an appropriate laboratory evaluation. Directed and further care for the cardiac and respiratory systems is determined by the neonatology, cardiology, and pulmonary consultants.

On physical examination, particular attention should be paid to whether the kidneys and bladder are palpable. Initial assessment of renal function should be used as a baseline, but initial postnatal creatinine levels are most reflective of the mother. The electrolyte and creatinine trend over the early postnatal period is more predictive of long-term renal function. A nadir creatinine concentration of greater than 0.7 mg/dL in

a term infant is a poor prognostic sign that has been noted by several groups.<sup>55,71,72</sup>

Once the neonate is stable, renal and bladder ultrasonography is recommended to assess the renal parenchyma and degree of upper and lower tract dilation. Voiding cystourethrography is performed to assess bladder emptying and the bladder outlet in addition to evaluating for vesicoureteral reflux. Any instrumentation of the urinary tract should be undertaken with strict attention to sterile technique. Prophylactic or perioperative antibiotics are recommended to decrease the possibility of bacterial inoculation and urinary tract infection. Nuclear renography is typically performed at 4 to 6 weeks of age to assess renal function and drainage. Earlier examinations would not account for neonatal physiologic transitioning and have less sensitivity for assessing obstruction.

## MANAGEMENT

Controversy exists regarding which treatment approach is best for the child with prune-belly syndrome. Aggressive surgical management of the urinary tract has been advocated by some and historically was performed in the neonatal period.<sup>40</sup> This approach usually entails ureteral reimplantation with ureteral tailoring and reduction cystoplasty with the hope of eliminating obstruction and eliminating reflux to help prevent pyelonephritis and further renal loss. Now, even those surgeons who strongly agree with early reconstruction recommend waiting until the child is at least several months old to allow for improved pulmonary function.<sup>40</sup>

An alternative approach centers on limited surgical intervention. This treatment plan involves close surveillance with aggressive medical management. Surgical intervention is reserved for those young children with recurrent or persistent infection or proven obstruction. Advocates of this approach cite previous experience demonstrating that some patients can be maintained infection free and without worsening of their bladder dynamics and renal function using this approach.<sup>73,74</sup> Additionally, those advocating for a more minimalistic approach point to the fact that surgery has not been proved to slow progression of renal dysfunction. In many children with severe renal dysplasia, no approach will alter the ultimate renal outcome. Most pediatric urologists currently seem to favor the limited surgical approach, particularly within the first year of life, with intervention reserved for infection or obstruction. Elective lower urinary tract reconstruction is more controversial for the older stable child.

The goal of either management approach is to keep the child infection free. Acquired renal scarring secondary to pyelonephritis can occur often in children with PBS.<sup>39</sup> Antibiotic prophylaxis is recommended in all neonates, even those without reflux. Particular attention to urinary stasis, either at the bladder level or more proximally, is required. The combination of infection and stasis/obstruction can lead to worsening renal function and both factors need to be addressed aggressively.

## Surgical Management

The surgical management of the patient with prune-belly syndrome focuses on addressing three main systems: the urinary tract, the undescended testes, and the abdominal wall.

### Cutaneous Vesicostomy

Urinary diversion may be a necessary temporary procedure in the setting of a neonate with bladder outlet obstruction. The Blocksom technique, as modified by Duckett, is the recommended method with attention paid to creating a capacious stoma.<sup>75</sup> If a large diverticulum is encountered during creation of the vesicostomy, it can be excised.

### Supravesical Diversion

In rare situations of either upper or lower ureteral obstruction or stasis, a proximal diversion is required. A cutaneous pyelostomy is the recommended form of diversion because it provides the best form of upper tract drainage. Percutaneous nephrostomy tubes may be placed as a temporary form of drainage and then used as a gauge to determine if a pyelostomy would be beneficial.

### Internal Urethrotomy

Internal urethrotomy should be considered in the older child with increased bladder outlet resistance that is clinically manifesting as poor bladder emptying and a large postvoid residual. The procedure involves an incision through the distal prostatic urethra with careful avoidance of the urinary sphincter. Reports have demonstrated an improvement in urinary flow rates, overall radiographic appearance, and lower post-void residual urine.<sup>32,73</sup>

### Anterior Urethral Reconstruction

Megalourethra is best treated with penile degloving, excision of the redundant urethra, and urethral tailoring and reconstruction. Urethral atresia is commonly treated in the neonatal period with a temporary cutaneous vesicostomy. Achieving a functional urethra usually requires a formal urethroplasty involving complex skin flaps and/or grafts. Progressive dilation of the hypoplastic urethra has been reported as an alternative in select patients.<sup>76</sup>

### Reduction Cystoplasty

Poor bladder contractility and incomplete emptying is common in the child with prune-belly syndrome. Several authors reported methods to reduce the bladder size and create a more normal, spherical bladder in hopes of improving bladder emptying. These approaches range from excision of the urachal diverticulum to more complex reconstructive surgeries involving detrusor plication or the creation of overlapping bladder flaps. Although early postoperative results seemed to be

encouraging, long-term results have noted recurrence of the large bladder capacity and poor bladder emptying.<sup>77</sup> Currently, reduction cystoplasty is performed at the time of ureteral reconstruction to aid with the lower urinary tract reconstruction and is rarely performed as a primary procedure or to facilitate bladder emptying. Better options to improve bladder emptying include clean intermittent catheterization through the urethra or via a continent catheterizable channel.<sup>78</sup>

### Ureteral Surgery

Ureteral tailoring and reimplantation is usually undertaken in those children with recurrent UTIs. As previously noted, routine and early postnatal ureteral reconstruction has generally been abandoned. The severity of the reflux and ureteral distention are not the sole indications for ureteral reconstruction. When performed, meticulous ureteral dissection is required. In most cases, the distal, redundant, and ectatic ureter is discarded and common ureteral tailoring techniques are used to decrease the size of the ureter. Reimplantation into a prune-belly syndrome bladder can be very difficult. Fixation of the large, floppy bladder with a psoas hitch may be required to prevent “J”-hooking and possible postoperative ureterovesical obstruction.

### Orchiopexy

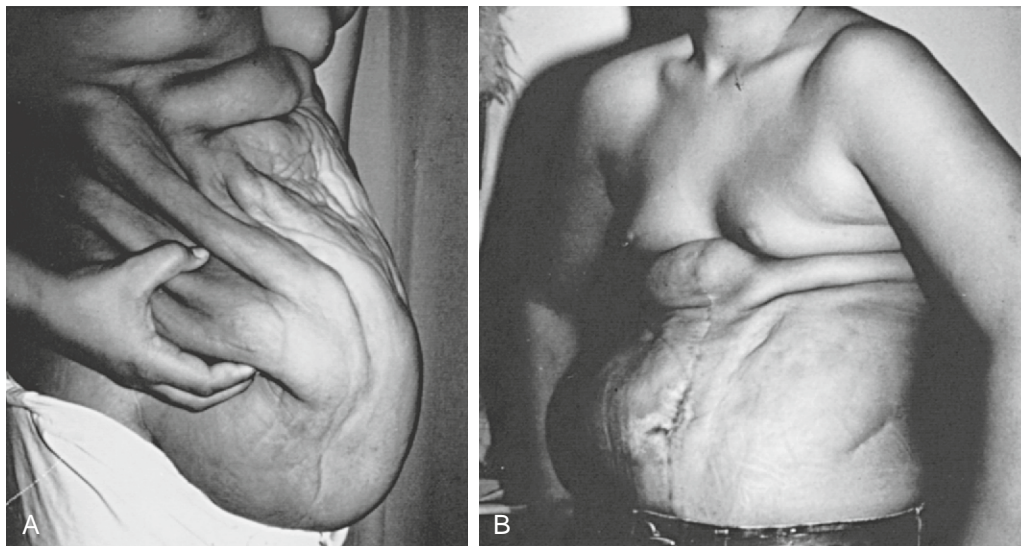

The timing of orchiopexy is dependent on the child’s overall health and clinical status and the need for scrotal positioning of the undescended testes at a young age. In the healthy child, bilateral orchiopexy is typically performed via a transabdominal approach at about 6 months of age. Those infants requiring temporary or reconstructive surgery earlier usually have the orchiopexies performed as a conjunctive procedure. The flaccid abdomen allows for excellent exposure, and ligation of the internal spermatic vessels is usually

not required for children younger than 2 years of age.<sup>79</sup> In older children or those with high intra-abdominal testes, a primary or staged Fowler-Stephens approach is best. With the recent advancements in laparoscopy, a minimally invasive procedure shows promise, particularly in older children and those who do not need other operations.<sup>80,81</sup>

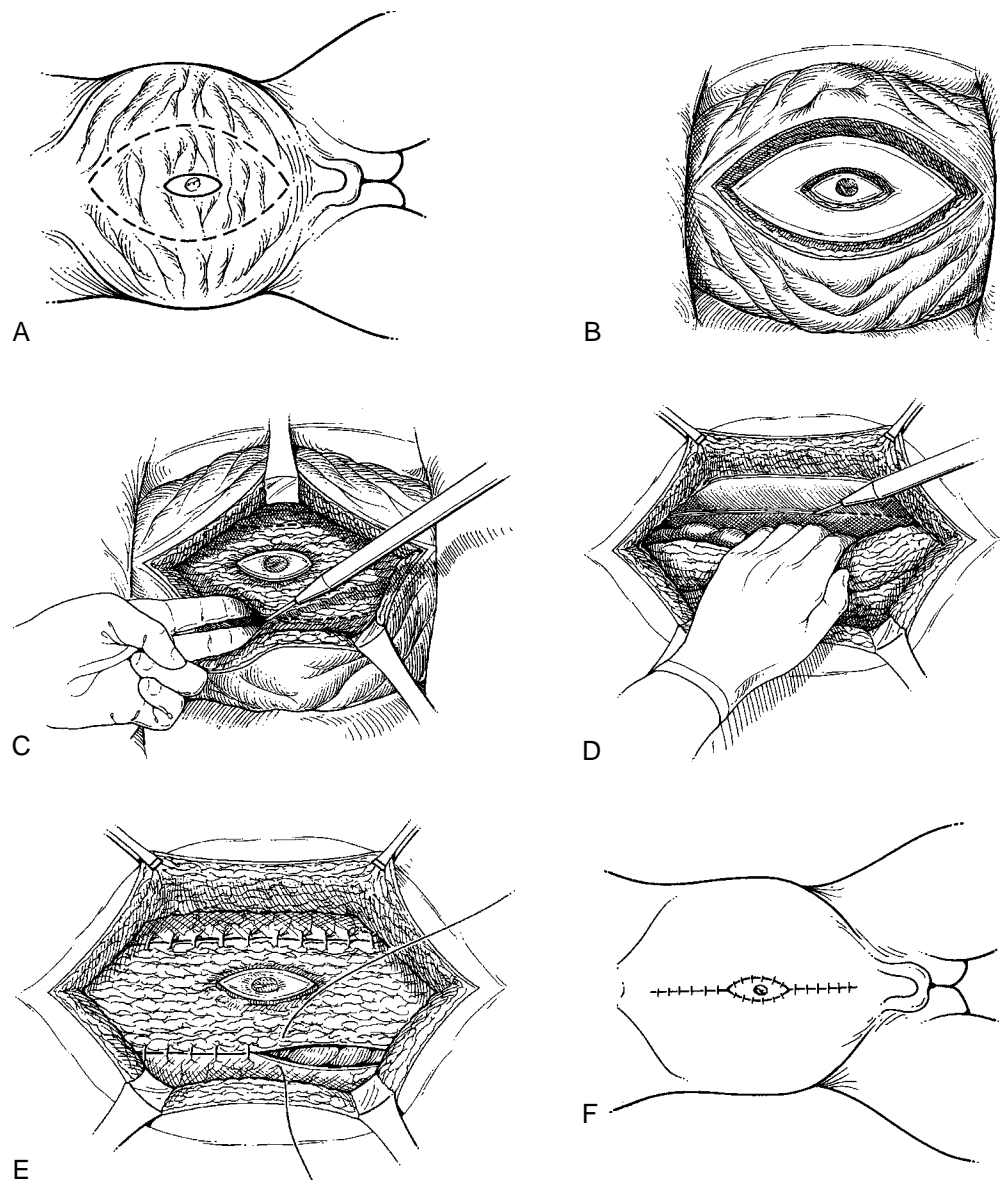

### Abdominoplasty

The management of the abdominal wall in children with prune-belly syndrome is determined by the severity of the condition. In children with very mild degrees of deformity, observation is usually the rule, with some having spontaneous improvement in their appearance. In those with more significant degrees of abdominal wall laxity, abdominoplasty is usually recommended, because the cosmetic and psychological benefits are believed to outweigh the risks of the surgery. Improvement in pulmonary, bladder, and bowel function after abdominoplasty may be improved but is not well substantiated.<sup>60,82</sup> The timing of abdominoplasty is dictated by the child’s general health and need for future reconstructive surgery. Children as young as 6 months have undergone abdominal wall reconstruction at the same setting as orchiopexy or bladder reconstruction.

Several methods with modifications have been described for abdominal wall reconstruction. Popular techniques today include those described by Monfort<sup>83</sup> and Ehrlich.<sup>84</sup> The Ehrlich technique utilizes a transabdominal approach through a vertical midline incision with preservation of the umbilicus on a vascular pedicle via the inferior epigastric artery.<sup>84</sup> The skin and subcutaneous tissues are then elevated off the underlying fascia and muscle followed by a pants-over-vest buttressing of the more normal lateral fascia and abdominal muscle. The excess abdominal skin is then removed, and the skin is reapproximated longitudinally in the midline (Fig. 62-6).

**Figure 62-6.** The Ehrlich technique was used in this patient. The preoperative appearance of the abdominal wall is seen on the left (A) and the postoperative view is on the right (B).

**Figure 62-7.** The Monfort abdominoplasty is depicted. **A,** Skin incisions circumscribe the umbilicus and define areas of adjacent abdominal wall redundancy to be removed. **B,** Excision of skin (epidermis and dermis alone) by using electrocautery. **C,** Abdominal wall central plate is incised at the lateral borders of the rectus muscle on either side, creating a central musculofascial plate. **D,** The parietal peritoneum overlying the lateral abdominal wall musculature is scored with electrocautery. **E,** Edges of the central plate are sutured along the scored line. **F,** Excess skin is removed, and the midline approximation envelops the previously isolated umbilicus.

Monfort's technique also employs a vertical incision. However, his modification uses an elliptically oriented incision as a means of excising the redundant skin (Fig. 62-7). The incision usually extends from the tip of the xiphoid down to the pubis. A second elliptical incision is then made around the umbilicus for its preservation. Similar to the Ehrlich technique, the skin is dissected off the fascia and muscle laterally to at least the anterior axillary line. However, the Monfort procedure includes making vertical relaxing fascial incisions lateral to the superior epigastric arteries, allowing mobilization of the lateral fascial flaps over a central fascial bridge. Durable functional results have been reported with this technique.<sup>85,86</sup> Recently, other authors have described alternative techniques for abdominal wall reconstruction, which include extraperitoneal dissection, fascial folding, or laparoscopic-assisted approaches.<sup>87,88</sup>

## RENAL TRANSPLANT

Close follow-up and monitoring of renal function is essential in patients with prune-belly syndrome. Approximately 30% of patients presenting with renal insufficiency will develop chronic renal failure during childhood or in their adolescent years. In those requiring renal transplantation, both cadaver and living-related donor kidneys transplanted in the patient with prune-belly syndrome have equal long-term function as compared with well-matched controls.<sup>89,90</sup> In young children, peritoneal dialysis can be used temporarily until the child is of adequate size to accept a transplant.

# DISORDERS OF SEXUAL DIFFERENTIATION

John M. Gatti, MD

Disorders of sexual differentiation (DSD) resulting in what have previously been referred to as intersex disorders are among the most fascinating conditions confronting the pediatric urologist and surgeon. Our understanding of these conditions and their causes continues to evolve, but many questions remain. Even with a better understanding of the underlying etiology of these different conditions, optimal gender assignment and the timing of surgical reconstruction continue to be controversial.

## NORMAL GENDER AND SEXUAL DIFFERENTIATION

An understanding of these conditions builds on a working knowledge of normal sexual differentiation. The most commonly accepted paradigm, described by Jost,<sup>1</sup> involves a stepwise process to gender and sexual development. The primary determinant is the chromosomal gender, which is established at fertilization when the sperm provides an X or Y chromosome to the ovum's X chromosome. Chromosomal gender determines gonadal gender, with XX resulting in ovarian development and XY resulting in testicular formation. Finally, the gonadal function determines the phenotypic gender, including internal and external physical and psychological features. Although this paradigm is a helpful cascade to explain gender development, as the actual genes and locations have been elucidated, the simple Y = male, No Y = female equations are not always valid.

## Chromosomal Determination

The chromosomal gender determination is based on the Y chromosome. In the 1950s, research characterizing the male phenotype of Klinefelter's syndrome with a 47,XXY karyotype, and a female phenotype of Turner's syndrome with a 45,XO karyotype, discovered that the presence of the Y chromosome causes male gonadal development and the lack of a Y chromosome results in ovarian formation.<sup>2,3</sup> This was irrespective of a complete X chromosomal content. The theorized

gene that was responsible for male gonadal development was termed the *testis-determining factor (TDF)*.

## Gonadal Development

The location of *TDF* was further elucidated with molecular techniques by studying individuals with chromosomes discordant with their phenotype: 46,XY females with a deletion of the *TDF* region and 46,XX males with Y chromosomal and *TDF* genetic material, presumably through gene translocation or other means. *TDF* was cloned and, based on genome mapping, its location was isolated to the short arm of the Y chromosome near the centromere at the distal aspect of the Y-unique region.<sup>4</sup> *TDF* was found to be a 35-kilobase pair sequence on the 11.3 subband of the gender-determining region of the Y chromosome (*SRY*). Interestingly, *SRY* appears to be expressed by the somatic cells from the urogenital ridge and not from germ cells.

The *SOX9* gene, located on the long arm of chromosome 17, has been identified as an additional gender-determining gene. It has been noted that a translocation involving the *SOX9* gene results in campomelic dysplasia, characterized by skeletal abnormalities and associated with 46,XY gender reversal. The *SRY* gene is thought to regulate the *SOX9* gene. Despite the presence of a functional *SRY* gene in this syndrome, a female phenotype develops in the majority of chromosomal males.<sup>5,6</sup>

In addition to the *TDF* and *SOX9* genes, other genes are also involved in gonadal development. The Wilms' tumor gene (*WT1*) appears to play a key role not only in renal development but also in testicular development. It is theorized that *WT1* regulates the interaction between the mesonephric ducts and germ cells, with early alteration of gene function resulting in testicular agenesis and later dysfunction resulting in aberrant testicular development (streak gonad or dysgerminomas). This tumor suppressor gene has been implicated in Denys-Drash syndrome involving testicular (mixed gonadal dysgenesis) and renal (Wilms' tumor) abnormalities.<sup>7,8</sup>

Fushi-Tarzu factor-1 (FTZ-F1) exerts its effect on gonadal development through its regulation of steroidogenic factor-1 (SF-1). The *SFI* gene is involved

with steroid hormone production and the production of müllerian-inhibiting substance (MIS) by the Sertoli cells of the testis that causes regression of the müllerian ductal system. Although FTZ-1 and SF-1 are also expressed in ovarian tissues, the timing and intensity of their effect are critical for normal gonadal development.<sup>7,9</sup>

Finally, the lack of an *SRY* gene alone does not impart normal female phenotypic and gonadal development, based on studies of 46,XY females with intact *SRY* regions. The *DAX1* gene, located on the short arm of the X chromosome, appears to be essential for the development of the ovary. The *DAX1* gene product appears to compete with the *SRY* gene product for a steroidogenic regulatory protein (StAR). Also, a dosage-sensitive element is important. Normally, the single *SRY* gene has a greater impact than a single *DAX1* gene and causes upregulation of StAR. In those chromosomal abnormalities in which more than one *DAX1* gene is present, however, downregulation of StAR occurs, testicular development is inhibited, and ovarian formation is promoted. As in the case of Turner's syndrome, however, these primordial ovaries develop into streak gonads. Likely, other genes are also important for normal ovarian development.<sup>10-12</sup>

## Phenotype Development

Development of the internal ductal structures is dependent on hormone secretion by the developing gonads (Table 63-1). In the absence of functioning testicular tissue, the female internal müllerian duct structures develop. The presence of a functioning testis results in male internal wolffian duct development. This differentiation is mediated by the production of testosterone from the testis. Testosterone promotes wolffian duct development along with MIS, which results in regression of the müllerian duct structures. This is a paracrine effect and therefore results in gonad specific ipsilateral ductal differentiation. This effect is likely dependent on high concentrations of androgen produced by the physically proximate gonad. Decreased levels of MIS by an abnormal testis or streak gonad result in ipsilateral müllerian development. This occurs despite regression of the müllerian ducts on the contralateral side with normal testicular MIS production. Conversely, systemic administration of androgen does not result in male ductal development in a female fetus.

**Table 63-1** Derivation of the Urogenital System

Wolffian Duct (Mesonephric Duct)	Urogenital Sinus	Müllerian Duct (Paramesonephric Duct)
<i>Male:</i>	<i>Male:</i>	<i>Male:</i>
Epididymis	Bladder	Appendix testis
Vas deferens	Prostate	Prostatic utricle
Seminal vesicles	<i>Female:</i>	<i>Female:</i>
<i>Female:</i>	Bladder	Vagina (upper third)
Epoöphoron	Distal vagina	Uterus
Gartner's ducts		Fallopian tubes

MIS functions as a suppressor of müllerian duct development. It is thought that MIS acts by inhibiting the effect of growth factors on the müllerian ducts. MIS is produced by the Sertoli cells in the testis and is a specific marker for functioning testicular tissue in infancy. At puberty, MIS production in the male declines, but it increases in the female. In its absence, the müllerian structures develop by default. The concentration and timing of MIS secretion appear to be critical. Secretion occurs during week 7 of gestation. By week 9, the müllerian ducts become insensitive to MIS.<sup>11</sup>

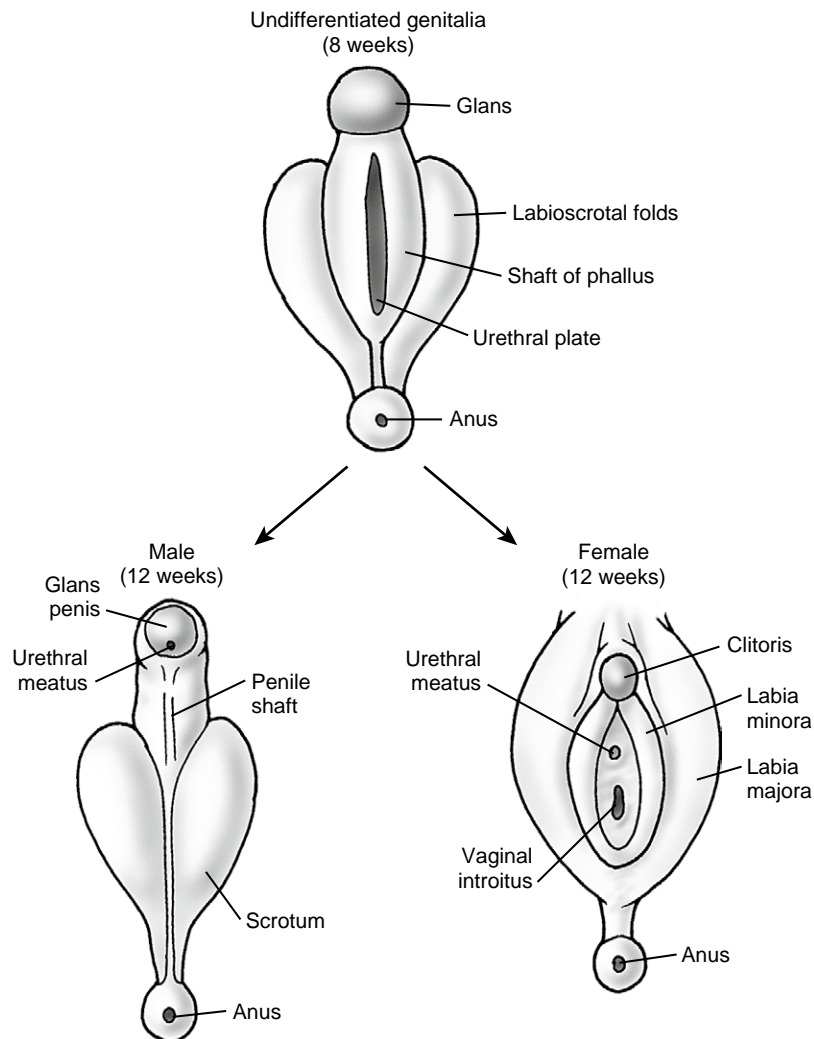

External genital development follows a similar path (Fig. 63-1). In the absence of testosterone and, more important, its metabolite dihydrotestosterone (DHT), the external genitalia develop into the female phenotype. The male and female phenotypes are identical until week 7. In the male, testosterone production by the testicular Leydig cells surges at 7 weeks and remains elevated until week 14 of gestation. Testosterone is converted to DHT by 5 $\alpha$ -reductase in the tissues of the genital skin and urogenital sinus. The testosterone-binding receptor has a four to five times higher affinity for DHT than testosterone and serves to amplify the effect of testosterone on the developing external genitalia. In the absence of 5 $\alpha$ -reductase, the internal wolffian ducts are preserved but the external structures are feminized.

After birth, neonatal testosterone levels in a male surge in response to the loss of feedback inhibition by maternal estrogens and the subsequent rise in neonatal luteinizing hormone (LH) production. This testosterone production peaks around the second to third month of life. By 6 months, the levels remain identical in males and females until puberty. Through these surges, it appears that androgen imprinting may occur on susceptible tissues, including those of the genital organs, but also on sensitive tissues in the brain related to male-type behaviors and gender orientation. This early exposure may determine how these tissues respond to subsequent androgen exposure during puberty and adulthood.

## ABERRANT GENDER DEVELOPMENT

### Incidence

In North and South America and Western Europe, congenital adrenal hyperplasia (CAH) is the most common cause of neonatal ambiguous genitalia, accounting for approximately 70% of cases.<sup>13,14</sup> The overall incidence is approximately 1 in 15,000 live births. The rate is much higher in stillborns and in certain regional populations (Yupic Eskimos and the people of La Réunion, France).<sup>15</sup> In the United States, mixed gonadal dysgenesis is the next most common intersex disorder, with ovotesticular DSD (true hermaphroditism) the third most common. In other areas of the world, different disorders predominate. Ovotesticular DSD is the most common intersex disorder in South Africa.<sup>16</sup>

**Figure 63-1.** Differentiation of the external genitalia.

## Classification

The most commonly used classification system was proposed by Allen in 1976.<sup>17</sup> This system categorizes the most common DSD well. However, as our understanding of the less common syndromes evolves, they do not fit as neatly into this paradigm. The five categories are based primarily on gonadal histology:

1. Female pseudohermaphrodite (ovarian tissue only)
2. Male pseudohermaphrodite (testicular tissue only)
3. True hermaphrodite (both ovarian and testicular tissue)
4. Mixed gonadal dysgenesis (testicular tissue and a streak gonad)
5. Pure gonadal dysgenesis (two streak gonads)

More recently, in 2006, a consensus statement was released from the International Consensus Conference on Intersex proposing new nomenclature for these disorders. This new classification system incorporates an

evolving understanding of the molecular basis of these disorders and replaces more offensive gender-based labels. For instance, intersex disorders are now called disorders of sexual differentiation. The new terminology for the more familiar previous categories is summarized in [Table 63-2](#). To facilitate this transition, both terms will be used where applicable in this chapter.<sup>18</sup>

<b>Table 63-2</b>		<b>Nomenclature for Disorders of Sexual Differentiation (DSD)</b>
<b>Current</b>		<b>Classic</b>
46,XX DSD		Female pseudohermaphrodite
46,XY DSD		Male pseudohermaphrodite
Ovotesticular DSD		True hermaphrodite
45,XX/46,XY Ovotesticular DSD		Mixed gonadal dysgenesis
46,XX Complete gonadal dysgenesis		Pure gonadal dysgenesis (common form)

## 46,XX DSD (Female Pseudohermaphrodite)

The majority of neonates with external genital ambiguity fall into this category. All patients have a 46,XX genotype and exclusively ovarian tissue in nonpalpable gonads. Simplistically, the cause of the gender ambiguity is an excess of androgen. More than 95% are due to CAH, with the remainder due to maternal androgen exposure. These patients have a normal female müllerian ductal system with an upper vagina, uterus, and fallopian tubes (see Table 63-1). They also have normal regression of the wolffian ducts. The level of virilization is largely dependent on the timing and magnitude of androgen exposure to the external genitalia. The phenotype can range from mild clitoromegaly to full masculinization.

Virilization in CAH is due to the inability of the adrenal gland to form cortisol. The precursors above the enzymatic defect are shunted into mineralocorticoid or sex-steroid pathways. Also, the end products generally have some, albeit weak, glucocorticoid function. The lack of cortisol for negative feedback inhibition of adrenocorticotropic hormone (ACTH) production by the pituitary leaves this pathway unchecked. Excess androgen is produced and is responsible for the virilization. The corticosteroid synthetic and alternative pathways are diagrammed in Figure 63-2. The most common form of CAH is 21-hydroxylase deficiency (21-OHD), which accounts for more than 90% of CAH.<sup>19</sup> 21-OHD has been mapped to the short arm of chromosome 6. The variable location of the adrenal defect and relative function of the gene results in salt-wasting and non-salt-wasting forms.<sup>20-22</sup> Type 1 (21-OHD) results in virilization but no salt wasting. The gene defect affects only the fasciculata zone of the adrenal, resulting in blocking cortisol production. However, the gene is normally expressed in the glomerulosa zone with preservation of mineralocorticoid production. In type 2 (21-OHD), also called the classic type, the gene abnormality affects both zones of the

adrenal. Salt wasting results in dehydration or vascular collapse, and hyperkalemia develops because of the block in mineralocorticoid production.

11 $\beta$ -Hydroxylase deficiency (type 3) is a less common cause of CAH. This gene has been mapped to the long arm of chromosome 8. This abnormality results in virilization associated with hypertension. This effect is related to the level of the synthetic block below deoxycorticosterone (DOC). DOC has potent mineralocorticoid function. Its excess results in sodium resorption, fluid overload, hypertension, and hypokalemic acidosis.

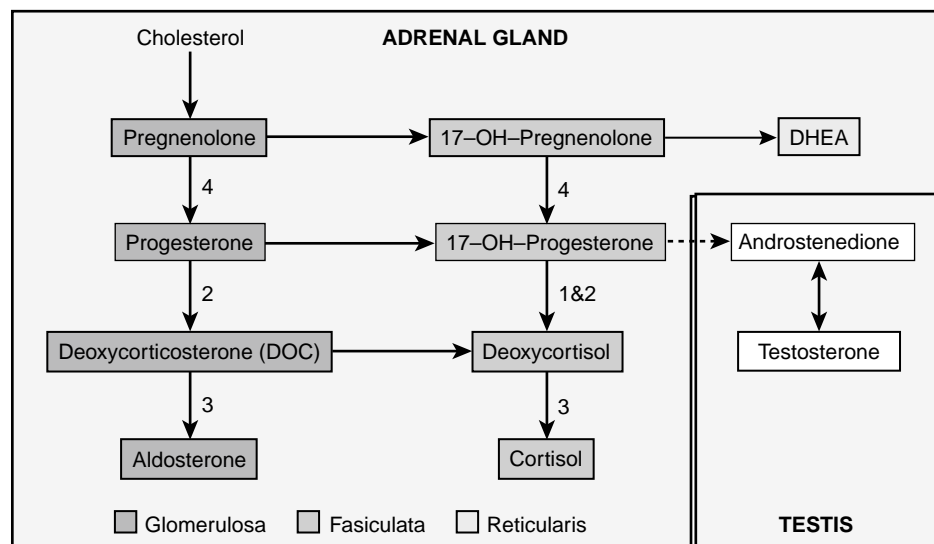

Finally, 3 $\beta$ -hydroxylase deficiency (type 4) is a rare form of CAH. It results in severe salt wasting, and survival is rare. It is the only type of CAH to occur in both genders.

Rarely, virilization of the female fetus can be caused by exogenous androgen exposure from the mother. This occurs primarily with the use of progesterone, commonly used as an adjunct to assist with fertility and with in-vitro fertilization. Previously, androgenic compounds also were administered to expectant mothers with a history of repeated spontaneous abortion as a preventive measure.

Endogenous androgen exposure due to virilizing maternal ovarian tumors also has been reported as a cause of 46,XX DSD.<sup>23</sup> Fortunately, these tumors are usually virilizing to the mother and the fetus is unaffected. Virilizing tumors include arrhenoblastoma, hilar cell tumor, lipid cell tumor, ovarian stromal cell tumor, luteoma of pregnancy, and Krukenberg's tumor.<sup>24</sup>

### Diagnosis

The diagnosis of CAH is based on the previously described clinical and electrolyte abnormalities in addition to elevated 17-hydroxyprogesterone levels. DOC and deoxycortisol levels also aid in determining which enzymatic defect is present. The physical examination is notable for the absence of palpable gonads

**Figure 63-2.** Pathways of steroid biosynthesis. The numbers correspond to CAH type and the location of the enzyme defect (see text).

and the presence of a cervix on rectal examination. Also, bronzing of the skin may be noted from excess ACTH cross-reactivity with melanocyte-stimulating hormone receptors. Palpation of a gonad virtually excludes the diagnosis of 46,XX DSD. The genitogram and an ultrasound study mirror these findings, revealing müllerian structures with a variable-length urogenital sinus.

### Treatment

Because all forms of CAH are inherited in an autosomal recessive manner, genetic counseling is recommended. Although it is controversial, in families with a history of CAH, maternal treatment with dexamethasone before week 10 of gestation can eliminate or improve the level of fetal virilization and is generally well tolerated.<sup>25</sup> Postnatally, cortisol replacement with hydrocortisone is the mainstay of therapy, with the addition of fluorohydrocortisone if salt wasting is present. Supportive management of fluid and electrolyte abnormalities may be best provided in a neonatal intensive care unit.

With regard to gender identity, the vast majority of patients with CAH identify as female.<sup>26</sup> In this subgroup, gender assignment is uniformly female and is congruous, given a 46,XX karyotype and normal ovaries imparting the potential for fertility. Surgical reconstruction, a feminizing genitoplasty, generally involves three elements: clitoroplasty, monsplasty, and vaginoplasty.

### 46,XY DSD (Male Pseudohermaphrodite)

This group is the most heterogeneous in the classification system. All patients have a 46,XY genotype and testicular gonadal tissue only. The gonads are sometimes palpable. The condition can be simplistically thought of as a deficit of either production or reception of androgen.

The androgen deficit may result from a defect in synthesis. Several rare enzyme deficiencies have been implicated, including those of 3 $\beta$ -hydroxylase, 17 $\alpha$ -hydroxylase, and 20,22-desmolase (cholesterol side-chain cleavage deficiency). All three adrenal enzymes are involved in the steps from cholesterol to androstenedione and testosterone and are associated with severe CAH and often death. 3 $\beta$ -Hydroxylase and 20,22-desmolase deficiencies are associated with cortisol and aldosterone deficits with hyponatremia, hyperkalemia, and metabolic acidosis. In 17 $\alpha$ -hydroxylase deficiency, mineralocorticoid production is preserved, resulting in excess salt and water retention, hypertension, and hypokalemia. In the male, the phenotype is variable, ranging from the appearance of a proximal hypospadias with cryptorchidism to that of a phenotypic female with a blind-ending vagina.

Defects in 17,20-desmolase and 17 $\beta$ -hydroxysteroid oxidoreductase act at the testicular level to convert androstenedione to testosterone. Because the adrenal is unaffected, CAH does not occur. The phenotype can

be quite variable, but those with complete feminization may escape detection at birth and be reared as female. In the latter disorder, however, progressive virilization is related to excess gonadotropin production at puberty, which may partially compensate for the lack of testosterone synthesis. Phallic growth and the development of male secondary sex characteristics create a conundrum with regard to gender reassignment when the diagnosis is made later in life.<sup>27</sup>

Despite adequate production of androgen, receptor defects can render cells blind to the virilizing effects of the hormone. The phenotype is variable and depends on the degree of insensitivity of the receptor for androgen.

The extreme is normal female external genitalia resulting from complete androgen insensitivity syndrome (CAIS). The incidence of this syndrome is approximately 1 in 40,000. It usually results from a point mutation in the androgen receptor gene, located on the X chromosome.<sup>28,29</sup>

Receptor defects seen in CAIS (also termed *testicular feminization*) result in normal female external genitalia and a blind-ending vagina. Testes are present but may be nonpalpable. MIS production is intact, so no müllerian ductal structures are present. These patients usually are initially seen at puberty with amenorrhea, but may be encountered earlier with the finding of a testis at the time of inguinal hernia repair.

Partial androgen insensitivity is associated with a large spectrum of phenotypic variation (e.g., Gilbert-Dreyfus, Lub's, and Reifenstein's syndromes). It can be a sporadic or inherited condition, and gender assignment and treatment are individualized.<sup>30</sup>

Testosterone is converted to DHT by 5 $\alpha$ -reductase, type 2. DHT is a much more potent androgen with regard to virilization of the external genitalia and prostate. The phenotype is ambiguous, but virilization occurs at puberty related to the increased testosterone production and peripheral conversion by nongenital 5 $\alpha$ -reductase, type 1. Unfortunately, the virilization is incomplete, and a small phallus and infertility are likely.

### Diagnosis

Metabolically, the diagnosis is made similar to that of CAH in the 46,XX DSD patient, noting excess steroid levels above the enzymatic block and elevated levels of ACTH. The physical examination confirms absence of a cervix on rectal examination. Bronzing of the skin may be noted from excess ACTH as well. Palpation of a cryptorchid or descended testis is possible. The genitogram and ultrasound study mirror these findings, revealing no vagina or uterus, but a prominent utricle may be present that lacks a cervical impression at its apex. In CAIS, testosterone levels are elevated postpubertally but the diagnosis in the prepubertal child may require human chorionic gonadotropin (hCG) stimulation and genital skin fibroblast androgen receptor studies. Receptor assays can delineate a quantitative versus qualitative receptor defect. LH levels are elevated, related to the loss of testosterone feedback

**Figure 63-3.** A 2-year-old boy presented with nonpalpable testes. A karyotype showed XY. **A**, External genitalia were male. **B**, Laparoscopy revealed bilateral gonads that were testes on longitudinal biopsy. Müllerian structures (*arrows*) were also seen. Note the rudimentary uterus (being held by the grasping forceps). This patient had abnormal MIS-receptor function.

inhibition, which requires normal receptor hormone interaction. 5 $\alpha$ -Reductase deficiency is confirmed by an elevated testosterone-to-DHT ratio and an abnormal 5 $\alpha$ -reductase type 2 gene.<sup>31</sup>

### Treatment

In CAIS, the gender assignment is always female. CAIS patients who are assigned as female in infancy later identify themselves as female.<sup>32</sup> Because the androgen receptor defect is ubiquitous, virilization of the brain does not occur. Orchiectomy is required, given the low but present risk of malignant degeneration, but this is often deferred until after puberty.<sup>33</sup> The testis synthesizes estradiol, facilitating feminine development at puberty. Orchiectomy before puberty necessitates hormone replacement for normal pubertal development.

Gender assignment in partial androgen insensitivity syndrome (PAIS) is largely based on the response of the external genitalia to exogenous testosterone. A significant virilization response argues for the male gender. If there is no response, the female gender is favored. This subgroup is the most variable and has the least consensus with regard to gender assignment. There are reports of gender reassignment at puberty.<sup>34,35</sup> Dissatisfaction with the gender of rearing occurs in approximately 25% of PAIS patients, whether raised male or female.<sup>36</sup> In 5 $\alpha$ -reductase deficiency syndrome, the brain is normally virilized and these individuals identify with the male gender. Thus, male gender assignment is recommended.<sup>37</sup>

### Müllerian Inhibitory Substance Deficiency

MIS is produced by the Sertoli cells in the testis and causes regression of the müllerian ductal structures. In this rare syndrome of abnormal MIS production or MIS-receptor abnormality, wolffian ductal development is unimpaired but the müllerian ducts also persist. Because the infant has a normal male phenotype, this syndrome is rarely encountered in the neonatal period. The most common presentation to the pediatric

surgeon is that of finding a fallopian tube adjacent to an undescended testis in the hernia sac at the time of orchiopexy (hernia uterine inguinale).<sup>38</sup>

If this scenario is encountered, a biopsy of the gonad should be performed, the hernia repaired, and all structures left intact until completion of a full evaluation with karyotype and MIS levels. Apparent males can also present with bilateral nonpalpable testes, and müllerian structures are found at laparoscopy (Fig. 63-3). Abnormal MIS-receptor gene assays also can be helpful for verifying the diagnosis in those with a normal MIS level. Subsequent management is primarily orchiopexy. This, however, may be extremely difficult because the vas deferens can be closely adherent to the fallopian tube or uterus. Excision of discordant ductal structures may be attempted, but, given the relatively low risk associated with leaving these structures, the risk of damage to the vas during this dissection likely outweighs the benefit of removal. Despite normal testosterone levels, impaired spermatogenesis is often the case.<sup>39-41</sup>

### Leydig Cell Abnormalities

Because the Leydig cell is responsible for testosterone production in the testes, impaired testosterone production can also manifest from Leydig cell hypoplasia, agenesis, or abnormal Leydig cell gonadotropin receptors. These disorders are rare. Although the karyotype is 46,XY, the phenotype tends to be female, with a blind-ending vaginal pouch and absence of internal müllerian structures. These patients usually are seen initially in the pubertal period with amenorrhea and, therefore, are reared as female. Management is similar to that for CAIS, with orchiectomy and estrogen replacement.<sup>42,43</sup>

### Ovotesticular DSD (True Hermaphrodite)

Ovotesticular DSD exists when both ovarian and testicular tissue are present. The gonadal configuration also can be quite variable, with the ovary/ovotestis

combination being most common in the United States. Ovary and testis, bilateral ovotestes, and testis/ovotestis combinations also occur. Ovotestes are usually polar with an ovary at one end and a testis at the other, but the distribution can be longitudinal, requiring deep longitudinal biopsy to sample the gonad adequately. Because of the paracrine effect of the gonad, the ipsilateral internal duct structures correlate with the type of gonad present. Ovotestes are associated with a variable duct structure, but usually fallopian tubes prevail. A decisively müllerian or wolffian duct structure is usually present rather than an ipsilateral combination.<sup>44</sup>

Ovotesticular DSD can be associated with a variety of karyotypes, with 46,XX being the most common. In the United States, the majority with this karyotype are African American, but different chromosomal content has been correlated with different races. It is thought that a translocation of the *SRY* gene or associated genes to an X chromosome or autosome explains the development of testicular tissue in the 46,XX karyotype. It is more difficult to explain ovarian tissue in a patient with a 46,XY karyotype. Likely, key genes to the ovarian development are present, but undetected to complement the normal X chromosomal content. An unappreciated mosaicism could also have occurred.

The phenotype covers the entire spectrum, with ambiguity and asymmetry the rule, but with a tendency toward masculinization. Although it is unusual for ovaries to be found in the labioscrotum, testes and ovotestes are often found descended. Fertility has been described in those raised as female, but testicular fibrosis makes this unlikely in those raised as male.<sup>29,45</sup>

### Diagnosis

The diagnosis of ovotesticular DSD is suggested by a mosaic karyotype or ductal structures, but is confirmed by the presence of ovarian and testicular tissue by biopsy.

### Treatment

Gender assignment in ovotesticular DSD is quite variable and should be based on the functional potential of the phenotype. In either case, the discordant gonads should be removed early. Retained testicular tissue will cause virilization in the female. In males, the testicular tissue is preserved and orchiopexy is performed. A 1% to 10% incidence of testicular tumor development is found in males, predominantly gonadoblastomas and dysgerminomas, so long-term surveillance is needed.<sup>46</sup> Hypospadias repair also is required in the male, and feminizing genitoplasty is performed in the female. Males tend to require hormonal replacement because of the progressive testicular fibrosis, but females usually do not. Fertility is possible in those raised as female. Females should, however, be screened for testosterone levels, which can signal inadequate resection of testicular tissue.<sup>47</sup>

**Figure 63-4.** Mixed gonadal dysgenesis. The left testis was descended, and the right streak gonad was intra-abdominal. T, testis; F, fallopian tube; S, streak gonad. (Photo taken from head of table.)

### Mixed Gonadal Dysgenesis

Mixed gonadal dysgenesis (MGD) is the second most common form of neonatal ambiguous genitalia. The patient will have a testis on one side and a streak gonad on the other, characterized by microscopically normal ovarian stroma without oocytes (Fig. 63-4). The internal duct structure mirrors the ipsilateral gonad, with the streak associated with a fallopian tube and uterus resulting from the lack of MIS. The karyotype is generally a mosaic of 45,XO/46,XY, and the stigmata of Turner's syndrome are variably present. The phenotype is ambiguous, but masculinized, and the testis may be descended but more commonly is not.<sup>48</sup>

The risk of gonadal tumor development, usually gonadoblastoma, is as high as 20%, and tumors can develop in either the testis or streak gonad.<sup>49</sup> An increased risk of Wilms' tumor also is present in MGD. The Denys-Drash syndrome occurs in approximately 5% of patients with MGD and is classically described as ambiguous genitalia, Wilms' tumor, and glomerulopathy, which is often seen with hypertension.<sup>50</sup>

### Diagnosis

The diagnosis is suggested by the physical stigmata of Turner's syndrome on examination (webbed neck, shield chest) and 45,XO/46,XY karyotype. The finding of a testis and streak gonad, however, confirms the diagnosis.

### Treatment

The majority of patients with MGD have been raised as female because of the short stature conferred by Turner's syndrome and the malignant risk of the retained testis. Females undergo early gonadectomy and feminizing genitoplasty. Males require early excision of the streak gonad, orchiopexy or orchiectomy, and hypospadias repair. Infertility is the rule despite adequate testicular endocrine function. Because of the increasing concern regarding testosterone imprinting on the brain, more masculinized patients are being raised as

male. If individuals are raised as male, close surveillance of the testis is necessary, unless elective orchiectomy and hormone replacement are chosen. Testicular biopsy at the time of puberty to exclude dysgenetic elements is generally recommended.<sup>46</sup> If carcinoma in situ is identified, low-dose radiation therapy is curative.

### Pure Gonadal Dysgenesis

Pure gonadal dysgenesis (PGD) is characterized by streak gonads bilaterally. The external phenotype and internal duct structures are female. These patients generally are seen at puberty with primary amenorrhea. The chromosomal makeup is classically 46,XX. PGD is an autosomally recessive trait, so genetic counseling is warranted. This implies that the condition can be caused by abnormalities in the X chromosome or supporting autosomal genes involved in gender differentiation. The gonads do not carry risk of malignant degeneration.

Other conditions are also closely related to bilateral streak gonads. The chromosomal makeup is quite variable and can be 46,XY (XY sex reversal, Swyer's syndrome, or male Turner's syndrome), 45,XO, or a mosaic. Variants with a Y chromosome differ in that they carry a high rate of malignancy in the retained streak gonads. The phenotype is as described earlier, but these patients may be first seen in infancy with gonadoblastomas or dysgerminomas, or with germ cell tumors that become more common in adolescence. The stigmata of Turner's syndrome are often present. Multiple chromosomal deletions and mutations have been described causing this syndrome.

### Diagnosis

The finding of a female external phenotype and an internal duct structure with bilateral streak gonads confirms the diagnosis. Follicle-stimulating hormone and LH levels are generally elevated, and estrogen and testosterone levels are decreased. The diagnosis may be suggested by the physical stigmata of Turner's syndrome on examination (e.g., webbed neck, shield chest).

### Treatment

With the presence of a Y chromosome, gonadectomy should be performed, given the high incidence of malignancy. In classic 46,XX PGD, the gonads can be left in situ because there is no malignant potential. In either case, hormonal replacement at puberty is required because the streak gonads provide no endocrine function.

### Other Syndromes of Aberrant Sexual Differentiation

Several syndromes worth mentioning do not neatly fit into the described classification systems.

Vanishing testis syndrome is characterized by a 46,XY karyotype but absent testes bilaterally. This generally results in virilization to the point of normal external genitalia and internal duct structure but absent testes.

The testes were thought to have produced androgen at some point, resulting in this masculinization, but subsequently vanished related to torsion or regression. Patients are generally raised as boys, and hormonal supplementation at puberty is required.<sup>51</sup>

Klinefelter's syndrome is characterized by a male karyotype containing two or more X chromosomes (47,XXY; 48,XXXY; etc.). Although phenotypically male prepubertally, these patients acquire abnormal male secondary sexual characteristics (tall stature with disproportionately long legs, sparse facial hair, decreased muscle mass, and a feminine fat distribution) and infertility. The testes are small and hard, with decreased androgen production and elevated estradiol levels related to primary hypergonadotropic hypogonadism. Gynecomastia often occurs with an increased risk of breast cancer.<sup>52</sup> Fertility has been reported but requires assisted means, such as intracytoplasmic sperm injection.<sup>53</sup>

46,XX Testicular DSD (XX sex reversal) is characterized by a male phenotype with a 46,XX karyotype. Most commonly this occurs from translocation of Y chromosomal material to the X chromosome, but it also can occur from mutation of the X chromosome or from mosaicism. The phenotype and management are similar to those of Klinefelter's syndrome, with the exception of shorter stature.<sup>54</sup>

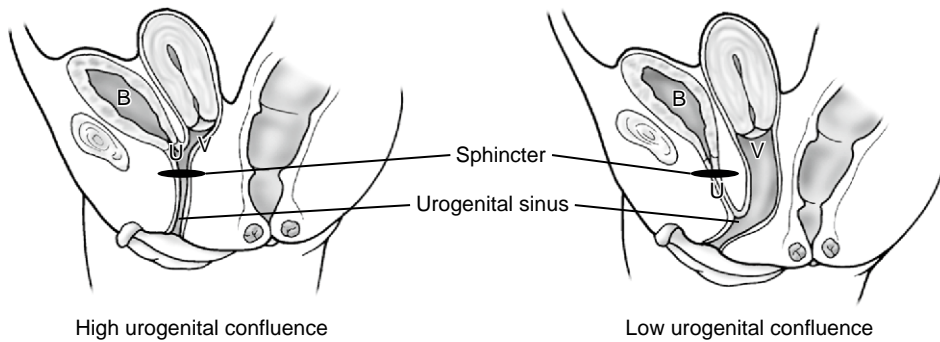

Mayer-Rokitansky-Küster-Hauser syndrome is characterized by a 46,XX karyotype with normal female external genitalia but a short, blind-ending vagina. Normal ovaries and fallopian tubes are present, but the uterus is generally rudimentary. Patients are seen initially with primary amenorrhea but may have cyclical pain related to functioning endometrium. Treatment is geared toward vaginal reconstruction to allow menses or intercourse, or both.<sup>55</sup>

### EVALUATION OF THE NEWBORN WITH AMBIGUOUS GENITALIA

The diagnosis of ambiguous genitalia is extremely disconcerting to the family and should be addressed as a medical emergency. Usually, genital ambiguity is obvious, but the finding of any degree of hypospadias in association with any undescended testis or of a normal penis with bilateral nonpalpable testes merits an intersex evaluation. In this population, a high rate of intersex conditions is found despite the absence of classic ambiguity.<sup>56</sup> Table 63-3 indicates other abnormal

**Table 63-3** Abnormal Physical Examination Findings for Disorders of Sexual Differentiation

Apparent Female	Unsure	Apparent Male

**Figure 63-5.** High versus low urogenital confluence. B, Bladder; U, urethra; V, vagina.

physical examination findings that warrant consideration for DSD.

The family history may reveal maternal hormone exposure, previous fetal death, or a history of genital ambiguity.

The physical examination should focus on the genitalia. Assessment for palpable gonads is important, because a palpable gonad represents a testis or ovotestis and rules out 46,XX DSD, in which only ovaries are present, or PGD, in which only streak gonads are present. If both gonads are palpable, this generally indicates 46,XY DSD. One palpable gonad is generally associated with MGD or ovotesticular DSD. Phallic stretched length, clitoral size, and the position of the urogenital sinus should be noted. A rectal examination may reveal a palpable uterus. The physical examination should include assessment for the stigmata of Turner's syndrome associated with MGD and PGD. Bronzing of the areola or scrotum can suggest elevated ACTH production in CAH.

The initial metabolic evaluation should include a karyotype or fluorescent in-situ hybridization to identify X and Y chromosomes. 17-OH progesterone levels should be obtained after 3 or 4 days of life, by the time spurious elevations resulting from the stress related to birth have subsided. Electrolyte levels should be monitored closely in the interim to identify salt wasting with CAH. Testosterone and DHT levels are important for evaluating 5 $\alpha$ -reductase deficiency. An elevated LH level and a low MIS level suggest testis dysgenesis or absence. ACTH or hCG stimulation tests can be performed but are more controversial.<sup>38</sup>

Early imaging studies include pelvic ultrasonography, which should identify a uterus if one is present. Although a gonad may be seen, ultrasonography is not useful in differentiating a testis, ovotestis, or ovary. A genitogram performed by retrograde contrast injection into the urogenital sinus is helpful in identifying the level of confluence of a vagina and urethra and its relation to the urethral sphincter (Figs. 63-5 and 63-6).

Gonadal biopsy is often required for diagnostic purposes, but the diagnosis of CAH can be made by metabolic evaluation alone. Endoscopy is not usually required for diagnosis, but is essential in characterizing the internal duct structure, level of confluence of the urogenital sinus, and planning for and performing the reconstructive surgical procedures.<sup>29</sup>

At my institution, a gender-assignment team including a pediatric urologist/surgeon, endocrinologist, geneticist, neonatologist, psychologist, and social worker together evaluate any newborn with ambiguous genitalia. This information is synthesized by the team and presented to the parents in a combined care conference. The goals of gender assignment and management should include preservation of sexual function and any reproductive potential with the least number of operations, appropriate gender appearance with a stable gender identity, and psychosocial well-being.<sup>57</sup>

## RECONSTRUCTIVE GENITAL SURGICAL PROCEDURES

### Controversies and Considerations

For more than 20 years, largely based on the work of John Money and the "John/Joan Case," the overwhelming bias was that gender identity was largely inducible and loosely dependent on chromosomal constitution. The focus was on one of two twin boys who was reassigned to the female gender early in life after a demasculinizing circumcision injury. The child reportedly developed normally from a psychosocial

**Figure 63-6.** Genitogram, lower confluence. White arrow, level of the confluence of urethra and vagina to become the urogenital sinus. B, Bladder; UT, uterus; V, vagina; UR, urethra; UGS, urogenital sinus.

standpoint, well adapted to life as a girl.<sup>58</sup> Only with extended follow-up into adulthood was it discovered that the individual converted back to male gender after severe dissatisfaction with a female identity (including attempted suicide).<sup>59</sup> This rattled the fundamental concepts on which gender assignment had been based for decades and brought to the forefront a tremendous controversy regarding the appropriate management of children with ambiguous genitalia and possible gender reassignment.

Because reconstruction is rarely done in response to any life-threatening issues, support groups for individuals with intersex conditions have advocated delaying any reconstruction until the child can express his or her wishes regarding gender assignment.<sup>60</sup> Although this would decrease the likelihood of a mismatch between physical and psychological gender, the period of genital ambiguity could be quite challenging for a child in our society. Despite the controversy, the International Consensus Panel on Intersex stated that, currently, the evidence is insufficient to abandon the practice of early genital reconstruction.<sup>18</sup> However, all these options must be discussed thoroughly with the family before embarking on any reconstructive efforts.

In general, if surgical reconstruction is thought to be appropriate, it is planned in the first 3 to 6 months of life. For feminizing reconstruction, the vaginal tissue is thicker as a result of maternal hormonal influence and the distance from the vagina to perineum is shorter at this age. Because parents have a great degree of anxiety surrounding the gender of their child, earlier repair may help reduce this anxiety and encourage parent/child bonding.<sup>61</sup>

### Male Gender Assignment

Reconstructive efforts for the male gender of rearing include orchiopexy or orchiectomy, when appropriate, and hypospadias repair. These techniques are described elsewhere in this text. It bears mentioning, however, that orchiopexy may be extremely difficult because the vas deferens can be closely adherent to müllerian

duct remnants, such as a fallopian tube or uterus. A portion of these structures may be left in situ if the risk of damage to the vas deferens or testicular vasculature is significant, but this adherence may severely limit mobility of the testis and preclude orchiopexy.

Methods of total penile reconstruction in cases of aphallia, demasculinizing penile trauma, or female-to-male gender reassignment by using a radial forearm or osteocutaneous fibula flap have been described with some reasonable success.<sup>62,63</sup> These corrective efforts are usually undertaken in adulthood, and their description is beyond the scope of this discussion.

### Female Gender Assignment

Feminizing genitoplasty includes three major components: monstrophy, clitoroplasty, and vaginoplasty (Figs. 63-7 and 63-8). The timing of the vaginoplasty depends on the level of confluence of the urogenital sinus. For a low confluence, it is performed in the neonatal period with monstrophy and clitoroplasty. If the confluence is high, this may be approached simultaneously. However, because vaginal dilation is often necessary after repair, this may better be deferred until the patient is peripubertal and more capable and interested in this requirement. Cystoscopy is invaluable for this assessment. We generally introduce a Fogarty balloon catheter in the vagina and a catheter in the urethra and bladder to define the confluence during dissection.

The procedure is initiated by placing a traction suture in the glans, and a dorsolateral circumcising incision is made, leaving a 4- to 5-mm distal preputial cuff, much like is done in a hypospadias repair. The lateral borders of the mucosalized plate are incised, taking this back adjacent to the urogenital sinus. The shaft of the phallus is then degloved of skin superficial to Buck's fascia. Fascial incisions are then made lateral to the neurovascular bundles. A plane is created just beneath Buck's fascia from the level just proximal to the glans back to the pubic symphysis. The mucosalized plate is elevated on the ventrum and preserved

**Figure 63-7.** Ambiguous genitalia. The patient has congenital adrenal hyperplasia, 21-hydroxylase deficiency.

**Figure 63-8.** Same patient as in Figure 63-7. Appearance of genitalia 6 months after undergoing a feminizing genitoplasty.

to fill naturally the void between the urethral meatus and clitoris. The dorsal pedicles, including the neurovascular bundles, are preserved. The corporeal bodies are suture ligated at their base at the level of the pubic symphysis, and the distal corporeal tissue is excised. An alternative technique preserving the corporeal bodies has been described to maintain the potential for reversibility, but long-term functional outcome is pending.<sup>64</sup>

I do little to reduce the size of the glans clitoris because I believe that even when it is markedly enlarged, it can be recessed and has a quite normal appearance in adulthood. By not trying to reduce the size of the clitoris, nerve injury is limited. However, alteration in sensation is more commonly associated with clitorrectomy rather than clitoral reduction.<sup>65</sup> The clitoris is anchored to the corporal stumps to secure its position, being sure not to compromise the dorsal neurovascular pedicle.

A posterior inverted “U”-shaped flap is then made from the level of the ischial tuberosities to just posterior to the urogenital meatus. For a very low confluence, dissection is carried along the posterior aspect of the urogenital sinus to the level of the confluence, the posterior wall is incised until the vaginal introitus is normal in caliber, and the “U”-flap is advanced to complete the posterior vaginal wall (Fig. 63-9). With higher confluences, my colleagues and I have favored total urogenital mobilization.<sup>66-68</sup>

For total urogenital mobilization, the urogenital sinus is incised circumferentially and mobilized as one unit to the level of the confluence (Fig. 63-10). At this point, the vagina can be carefully separated from the urethra under direct vision and the defect in the urethra is closed. The urogenital sinus can then be incised at the dorsal midline and folded back onto itself to make up the anterior vaginal wall. By using local skin flaps for the dorsolateral defects, a lengthy distance can be bridged.

Total urogenital mobilization is attractive in that one can approach even the high urogenital confluence

in the neonatal period without vaginal substitution or grafting, but the family must be appropriately cautioned. Although early results are favorable, descent of the bladder neck is counterintuitive when considering our knowledge of adult female stress incontinence and long-term continence may be an issue. To complete the monsplasty, the dorsal phallic shaft skin is incised vertically, a preputial hood is formed for the clitoris, and the majority of this tissue is used to construct the labia minor with “V”-shaped advancement flaps (Fig. 63-11).

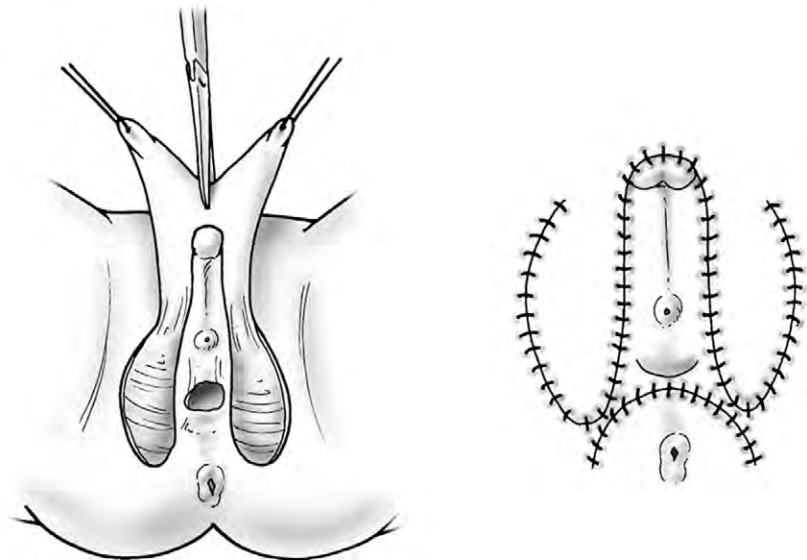

Other techniques for the high urogenital sinus include a posterior approach dividing the rectum and

**Figure 63-9.** Vaginal cutback procedure for the low urogenital confluence.

**Figure 63-10.** Total urogenital mobilization. The urogenital sinus is mobilized as a unit, bringing the confluence toward the perineum. Once visualized, the vagina is then detached and the urethral defect is closed.

**Figure 63-11.** Mons plasty. Dorsal shaft skin is degloved from the phallus and incised. These flaps are then advanced to become the labia minora. (Shown before and after excision of the corporal tissues and clitoropexy.)

an anterior transvesical approach.<sup>69,70</sup> These methods have not been used extensively at my institution.

In some patients with a high urogenital confluence, I have delayed vaginal reconstruction until the peri-pubertal period, just before menarche. The techniques described are still used, but in some patients, especially those who are obese, these methods are insufficient. I have favored vaginal substitution with a colonic segment, but ileal substitutions and split-thickness skin grafts also have been advocated. The benefit of vascularized bowel substitution is less vaginal stenosis and the natural formation of lubricating mucus, but this may require wearing a pad if there is excessive mucus production. Colonic segments appear to have a lower

rate of stenosis than do ileal segments.<sup>71</sup> Conversely, skin grafts have a tendency toward long-term stenosis and may require frequent dilation and revision, but long-term satisfaction also has been described.<sup>72</sup> The barrier function to sexually transmitted diseases is likely superior with skin grafts when compared with intestine.<sup>73</sup>

In cases of vaginal agenesis (e.g., Mayer-Rokitansky-Küster-Hauser syndrome), the substitution techniques described are often used. However, if a rudimentary vagina or depression exists, sequential dilation with the technique described by Frank and modified to a dilating seat by Ingram may be successful.<sup>74,75</sup>

# UROLOGIC LAPAROSCOPY

Craig A. Peters, MD

Laparoscopy is an adjunct to the surgical armamentarium of the pediatric urologist. As new technologies such as robotically assisted approaches emerge to augment the potential for minimally invasive procedures, they should be seen as additional tools to assist in the care of children. Uncontrolled enthusiasm may lead to inappropriate use, and unbridled skepticism about their value may lead to unrealized promise.<sup>1,2</sup> The focus of this discussion is to review the current applications and future horizons of laparoscopy and robotics as they apply to pediatric urology.

Diagnostic laparoscopy is the most common current application in pediatric urology and has become well integrated with operative laparoscopic orchiopexy. Renal, ureteral, and bladder surgical procedures have become common in many practices but have not fully supplanted conventional surgery and continue to evolve dynamically. Robotically assisted procedures are rapidly emerging as a viable means to achieve equivalent results in reconstructive procedures, particularly pyeloplasty. These are discussed in terms of the appropriate application, approaches, and results.

## DIAGNOSTIC LAPAROSCOPY

### Nonpalpable Testis

Laparoscopy in pediatric urology began with the diagnosis of undescended testes (UDTs). Over time, the interpretation of the findings and the integration with therapeutic laparoscopy have been well developed.

Because imaging studies used to locate a nonpalpable testis have repeatedly failed to demonstrate an intra-abdominal or inguinal testis in all cases, reliance on these studies might result in leaving an intra-abdominal testis in the abdomen. Given the increased risk of malignancy in these testes if undetected, the need for 100% accuracy is the foundation for using diagnostic laparoscopy. Diagnostic laparoscopy has become the most widely used method to provide information as to the presence and location of the nonpalpable testis. Although numerous studies have shown this approach to be safe and probably more accurate

than open exploration,<sup>3-5</sup> some controversy still persists.<sup>6-8</sup> The predominant argument for initial inguinal incision is that it can be diagnostic and therapeutic for an inguinal testis. However, the same applies to laparoscopy for the testis located in the abdomen.

### Indications and Preparation

Diagnostic laparoscopy for UDT is reserved for the boy with a nonpalpable testis and is usually performed between ages 6 and 12 months. Those with bilateral nonpalpable testes should have gonadotropin and müllerian-inhibiting substance (MIS) levels determined preoperatively. The role of the human chorionic gonadotropin (hCG) stimulation test is unclear because it is not definitive in proving testicular absence due to false-negative results, but it does provide some data as to the functional potential of the testis before any manipulation. Even if no laboratory evidence of testicular tissue is found, it has been my practice to perform laparoscopy, recognizing the existence of false-negative findings with the hCG stimulation test and lack of substantial experience with MIS. Patients are placed on a clear liquid diet for 24 hours before the procedure and given a rectal suppository that night to evacuate the rectum. A rectal tube is introduced before preparing the patient, and a bladder catheter is inserted in the sterile field. The abdomen is entirely prepped to allow placement of working ports for laparoscopic orchiopexy or for open exploration in the rare occurrence of a major injury.

### Technique

#### Access

A 3-mm incision is made in the inferior aspect of the umbilicus, and the subcutaneous tissues are spread to reveal the fascia. The Veress needle is aimed inferiorly about 15 degrees off vertical, while the abdominal wall is "tented" by the surgeon and assistant. Elevating the abdominal wall can aid in preventing the preperitoneal placement of the needle. Excessive lifting, however, may allow preperitoneal placement as the

needle skims along the peritoneum rather than puncturing it. Usually two distinct “pops” (the fascia and the peritoneum) are felt as the needle is passed. Without moving the needle, a syringe half full of saline is attached to the needle and aspirated. If no return occurs, the saline is instilled and re-aspirated to confirm the position of the needle in the peritoneal space and not in a viscus. With the syringe off, the abdomen is lifted and the water level should drop into the peritoneum. With insufflation to pressures between 8 and 12 mm Hg, flow should be free with low pressure initially. If not, the needle may be preperitoneal.

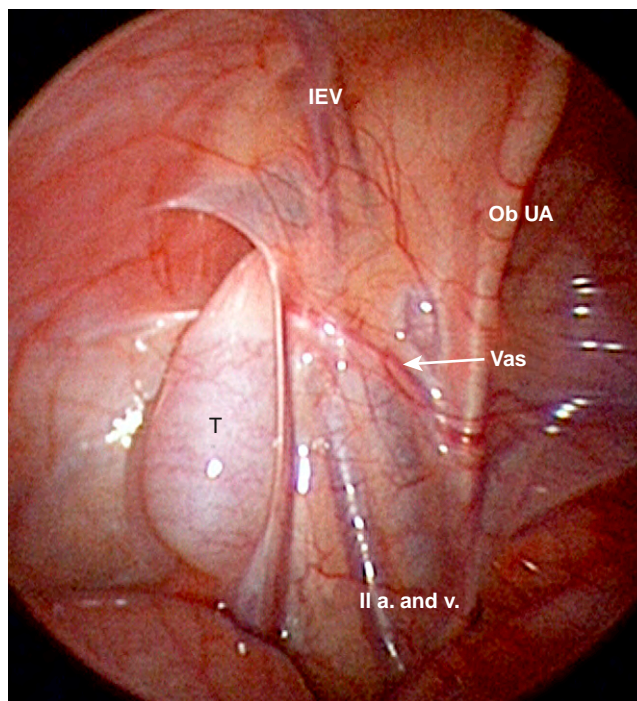

If fluid returns on the first aspiration, especially if dark, it is presumed that the intestine has been entered. In this case, the needle is withdrawn slightly until no fluid is aspirated. The peritoneum is then insufflated, and the telescope is inserted to look for the site of puncture. It should be just below the umbilicus. The umbilical fascia is enlarged and a laparoscopic grasper can be passed along the laparoscope. The intestine that has been punctured is grasped and brought out to be inspected, cleaned, and oversewn. Alternatively, the puncture can be identified and repaired laparoscopically by using two additional ports. Although a simple Veress needle puncture of the small bowel can be usually safely ignored, I prefer to repair it.

### Diagnosis

Once flow has been established through the Veress needle and a pneumoperitoneum established, the needle is withdrawn and a Step cannula (Covidien, Phillipsburg, NJ) with a blunt trocar is introduced through the sleeve. The telescope is passed through the umbilical cannula. In the case of a unilateral UDT, the normal side is inspected first to provide a comparative image for reference to the opposite side (Fig. 64-1). The affected side is then inspected, with attention first placed on establishing landmarks: the iliac vessels, the

**Figure 64-1.** Laparoscopic view of the internal inguinal ring on the left, showing the vas deferens (white arrow) and spermatic vessels (black arrows) converging at the ring (circle), just lateral to the inferior epigastric vessels.

**Figure 64-2.** Intra-abdominal left testis (T) adjacent to the internal inguinal ring. The vas deferens is indicated by the arrow. Il a. and v., Iliac artery and vein; Ob UA, obliterated umbilical artery; IEV, inferior epigastric vessels.

inferior epigastric vessels, and the obliterated umbilical artery (Fig. 64-2). The vas is often first seen, but the vessels must be visualized for an accurate diagnosis. Smaller than normal vessels in the usual position are often observed with an atrophic testis in the inguinal canal. It may be necessary to retract the colon to confirm the location of the vessels. In some cases, especially on the left side, when the testis is intra-abdominal, the vessels are more medial and hidden by the colon. Usually the vessels can be seen by using the Trendelenburg position or rotation of the table. Rarely, I have placed a second port to permit mobilization of the colon. The vas deferens can be helpful in locating an intra-abdominal testis, but it must be remembered that the vas and testis can be separate. The testis, if present, will be located by following the vessels. In some cases, gubernacular structures may resemble spermatic vessels disappearing into the inguinal ring from a testis located higher in the abdomen.

If the appearance of the vessels on the affected side differs from the normal side, further exploration is necessary. A vanishing testis is readily recognized by the blind-ending vas deferens and spermatic vessels (Fig. 64-3). Under these circumstances, no testicular tissue is present and further exploration is unnecessary. Although true testicular agenesis occurs, its frequency is small because I have not seen a patient in whom the vessels and vas were completely absent in more than 300 diagnostic laparoscopic procedures.<sup>3,9</sup> The diagnosis of testicular agenesis requires visualization of the retroperitoneum to the level of the lower pole of the kidney because I have seen testes located well above the level of the aortic bifurcation. In most

**Figure 64-3.** Laparoscopic view of vanishing testis with both vas deferens and spermatic vessels (Sp vessels) visible but dwindling away before the inguinal ring. Iliac v/a, iliac vein and artery.

cases, the very high testes are suggested by abnormal vessels or gubernacular structures between the testis and the internal ring.

Laparoscopic demonstration of vas and vessels exiting the abdomen into the internal inguinal ring (“canalicular” vas and vessels) suggests the testis has descended into the inguinal canal or scrotum. If the testis is not palpable, it is likely atrophic. These boys need inguinal exploration to confirm that no testis is present, especially if the child is obese. The appearance of normal canalicular spermatic vessels may suggest the presence of an ectopic testis. Canalicular vessels associated with an atrophic testis are usually, but not reliably, smaller.<sup>9</sup> I have occasionally seen nonpalpable perineal ectopic testes detected in this way. Five percent of atrophic testes in the scrotum or canal contain viable germ cells and should be removed. Whether these atrophic testes pose a real malignancy risk is unclear. Inguinal exploration may obviate laparoscopy, but approximately 50% of UDT patients will not need inguinal exploration for either diagnosis or treatment.

An intra-abdominal testis may require some effort to find but is easily recognizable when seen. Those located medial to the iliac vessels may be the most elusive. Some are on a long spermatic cord and drop deep into the pelvis, even along or behind the bladder.

The final component of the diagnostic laparoscopy is to determine the location of the UDT relative to the internal inguinal ring to determine the most appropriate surgical intervention: vessels-intact laparoscopic orchiopexy (VILO) or two-stage Fowler-Stephens orchiopexy (FSO). After placing the working ports, a small ruler is inserted and the distance is measured.

## DISORDERS OF SEXUAL DEVELOPMENT (INTERSEX)

Diagnostic and therapeutic laparoscopy has a significant role in the child with a disorder of sexual development.<sup>10-12</sup> The appearance of streak gonads, uterine

tissue, and inappropriate müllerian structures is readily recognized laparoscopically. The appearance of a streak gonad, as distinct from an ovotestis, is usually clear, but biopsy is needed to confirm the presence of an ovotestis (Fig. 64-4). Definition of the müllerian structures may be more precise with laparoscopy than with many imaging modalities, including ultrasonography. Removal of dysgenetic gonadal or müllerian tissue is readily accomplished.

## THERAPEUTIC LAPAROSCOPY

### Orchiopexy

Laparoscopic orchiopexy is one of the most developed applications of laparoscopy in children. Several reports have demonstrated its efficacy, and perhaps even its superiority to open orchiopexy.<sup>13</sup> However, this conclusion is limited by the fact that the true outcome of any orchiopexy, adult fertility, has never been assessed.<sup>14</sup>

### Indications

Laparoscopic orchiopexy is used for the intra-abdominal testis. This is almost always performed under the same anesthesia as the diagnostic laparoscopy that identifies the testis and determines its location. Testes high in the inguinal canal have been subjected to laparoscopic orchiopexy,<sup>15,16</sup> but it is unclear whether this represents an advantage, and I have not used laparoscopy for testes located in the canal. However, intra-abdominal dissection and mobilization of the spermatic vessels might be a useful adjunct to subsequent open orchiopexy for such cases.

Laparoscopic orchiopexy can be a single-stage VILO or a two-stage FSO. The latter should be reserved for testes that cannot be brought into the scrotum with the spermatic vessels intact. In those boys, the spermatic vessels are initially occluded with a clip, suture, or fulguration and the testis is left in situ. At a second procedure 4 or more months later, the spermatic vessels are

**Figure 64-4.** Laparoscopic view of the right ovotestis (OT) and müllerian structures (M) in a 7-year-old with ovotesticular disorder of sexual development (formerly true hermaphroditism). Removal of the ovarian tissue and orchiopexy was performed.

divided and the testis is brought into the scrotum on a pedicle of the vas deferens and peritoneum. The vasal artery provides the blood supply to the testis. Discerning which testis is best treated with which procedure is the major challenge of laparoscopic management of the intra-abdominal testis.

Some have recommended FSO for all boys with an intra-abdominal testis.<sup>17</sup> However, because many testes can be brought into the scrotum from the abdomen with the vessels intact, this does not seem uniformly appropriate. Preserving the major blood supply to the testis is intuitively more appealing. Placing the UDT into the scrotum based on the spermatic vessels also avoids a second anesthetic and surgical procedure. A single-stage FSO procedure has been advocated by some as well, but a high incidence of testicular atrophy without the interval period of collateral vascular development makes this approach unacceptable and cannot be recommended.<sup>18</sup>

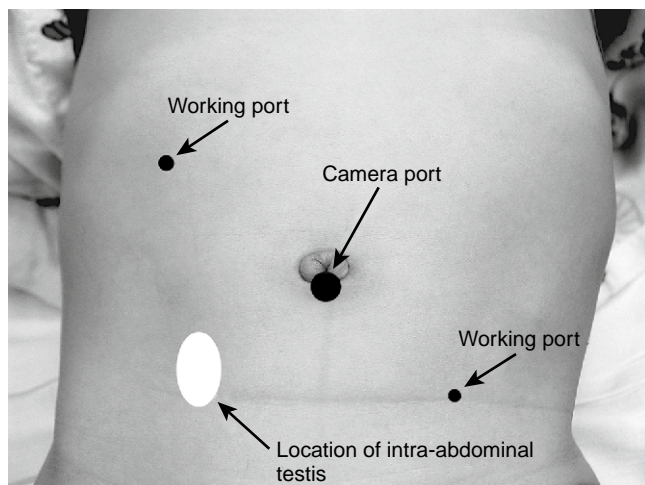

## Technique

### POSITION

The patient's position is adjusted to a moderate Trendelenburg position with the ipsilateral side rotated upward about 30 to 45 degrees. Insufflation pressures are maintained at 12 mm Hg in most patients.

### PORTS

The initial umbilical port for the diagnostic portion of the laparoscopy is maintained for the laparoscopic orchiopexy. Although using 2-mm instruments is feasible, I have found these instruments too flexible. Thus, I prefer larger, more rigid instruments, either 3.5 or 5 mm (for a clip applier, if needed). Working ports are placed in the ipsilateral upper quadrant and the contralateral lower quadrant. The ipsilateral port should not be placed too low, because it will be ineffective in mobilizing the proximal testicular vessels (Fig. 64-5). The cannulas are inserted under direct

**Figure 64-5.** Port location for laparoscopic orchiopexy is seen on the right. Approximate position of the intra-abdominal testis is also depicted.

**Figure 64-6.** First stage of a Fowler-Stephens orchiopexy with dissection of the spermatic vessels before ligation. The testis is not manipulated.

vision. A fascial closure stitch is placed before cannula placement to facilitate fascial closure at the end of the procedure.

If a two-stage FSO is indicated based on testicular location or age of the patient (>2 years), the vessels are occluded with a surgical clip after creating a window in the peritoneum 1 to 2 cm proximal to the testis (Fig. 64-6). This can be performed with only one working port in the contralateral lower quadrant.

### INSTRUMENTS

For the first stage of the FSO, I use a 5-mm clip applier. For the laparoscopic orchiopexy, I use a 3.5-mm cauterizing scissors and a curved dissector. The curved dissecting instrument is used to create the passage from the pelvis into the scrotum, and a long, curved vascular clamp is then passed retrograde by locking onto the tip of the curved dissecting instrument.

### PROCEDURE

For orchiopexy, dissection begins by incising the peritoneum lateral to the spermatic vessels and testis and dissecting it to the level of the inguinal ring. The gubernacular attachments are identified at the level of the ring and carefully transected, leaving enough gubernacular tissue attached to the testis to grasp for retraction and for delivery into the scrotum. Care must be taken to avoid injury to a looping vas deferens. Cephalad retraction of the testis will expose the vas so that it can be protected throughout the procedure. Lateral dissection continues cephalad along the spermatic vessels toward their origin from the iliac vessels. The testis and the spermatic vessels are bluntly freed from the pelvic sidewall medially. The peritoneum on the lateral and inferior side of the vas deferens is incised over the obliterated umbilical artery and into the pelvis, approaching the bladder. This leaves a triangular web of peritoneum between the vas and the vessels with the testis at the apex. Some surgeons recommend

leaving this peritoneum intact to preserve the blood supply of the vas, but it definitely hinders mobilization of the testis. I therefore incise it and mobilize the spermatic vessels proximally.

At this point, the testis is grasped and moved to the opposite side of the pelvis. When it can reach the opposite inguinal ring, it has adequate mobility to be brought over the pubic tubercle. The pathway from the abdomen to the scrotum is then developed. A dartos pouch is first created in the usual manner. A curved dissecting instrument is passed from the abdomen over the pubic tubercle, medial to the obliterated umbilical artery and lateral to the bladder, by using direct vision and finger palpation. The tip of the dissector is guided into the scrotal sac and pushed through an incision in the dartos fascia. A long, curved vascular clamp is then passed retrograde by grasping the tip of the dissecting instrument or a heavy silk suture. The clamp can be spread to open the tract for passage of the testis.

The gubernacular stump is then grasped, and the testis is brought into the scrotum. The testis can be fixed in place by using the dartos-pouch technique or with a button with a pull-out suture, or both. Excessive tension on the spermatic vessels may result in avulsion of the vessels or spasm. Further proximal dissection of the vessels may be necessary to prevent vascular insufficiency.

The determination of whether to perform a VILO or FSO remains incompletely defined. Initially I performed VILO if the testis "appeared" mobile enough before any dissection, but I found that those higher in the abdomen did not always move into the scrotum easily and some showed postoperative atrophy. Correlating the initial UDT position with the postoperative result, it became evident that when the testis was more than 2.5 cm from the internal inguinal ring, postoperative testicular atrophy occurred at an unacceptable rate. I also found that testes medial to the iliac vessels were more difficult to mobilize into the scrotum, even if located at the level of the internal inguinal ring. Therefore, testes more than 2.5 cm proximal to the internal inguinal ring or medial to the iliac vessels are managed with the FSO technique.

We have also observed that children older than age 2 years nearly always require a FSO. The second-stage FSO is performed by using identical port positions and ligating and then dividing the spermatic vessels just distal to the original clip. The stumps of vessels are used for retraction, and the testis is mobilized on the triangular web of peritoneum surrounding the vas deferens. The testis is moved into the scrotum and fixed in a dartos pouch. Indeed, the ease of the second stage has encouraged some surgeons to use the FSO technique in all patients with an intra-abdominal testis, but this seems inappropriate, considering the higher success rate of a VILO.

Robotic technology has been used for an abdominal testis but does not appear to offer any advantages except as a learning tool for the device. I have not used this approach.<sup>19</sup>

## Postoperative Care

Patients may be discharged the same day if they are able to retain oral intake. The child is examined in 6 weeks and undergoes a scrotal Doppler ultrasound evaluation in 9 months to assess blood flow and testicular size.

## Results

There are several reports of outcomes after laparoscopic orchiopexy, all with good results.<sup>13,20-25</sup> It is important to recognize that outcome parameters are based on perceived testicular viability and not on sperm production. These assessments are not really different from those used to assess open orchiopexy. No truly long-term functional assessment has ever been performed after any of the techniques for orchiopexy. The length of follow-up is important, because some testes in my patients appeared healthy at 6 months but showed a reduction in size at 12 months. Doppler ultrasound imaging has been used to assess testicular size and blood flow and seems to correlate well with physical examination.

Without any real standards of assessment of initial location or of postoperative outcome, it is difficult to stratify patients and correlate to outcome. However, it is probably reasonable to consider a success rate of about 95% for intra-abdominal testes undergoing VILO and about 90% for those undergoing FSO. Although this may be better than for open orchiopexy, correlation with the initial testicular position is undefined.

## RENAL SURGERY

### Nephrectomy

Simple nephrectomy for benign conditions was the first major laparoscopic procedure performed in children and is now well established and routine.<sup>26-35</sup> The indications are similar to those for open nephrectomy. The initial approach to nephrectomy was transperitoneal, with very good outcomes. These initial cases were performed in infants by using three 10-mm cannulas (some surgeons used four ports), and no major complications were reported.<sup>36,37</sup> In most cases, patients were discharged the next morning.

An interesting response emerged with publication of a series in which open nephrectomy for multicystic dysplastic kidney (MCDK) through a dorsal lumbar incision was performed on an outpatient basis.<sup>38</sup> Although one can remove a dysplastic kidney through a small lumbar incision, exposure is limited and compromised to the extent that, in one case, an inadvertent appendectomy was performed.

Retroperitoneal endoscopic access was developed for children with similarly good results and with smaller instruments as they became available.<sup>39-41</sup> Two basic access approaches were used: lateral and prone.<sup>42</sup> Both work well, and each has advantages in selected situations.

## Indications

The indications for a laparoscopic nephrectomy include benign disease that has resulted in a nonfunctioning renal unit with the potential for infection, hypertension, or pain. I remove MCDKs only when parents insist. The contraindications to a laparoscopic nephrectomy include severe acute coagulopathy, uncontrolled sepsis, or very severe adhesions from prior laparotomy. These are uncommon in children. Laparoscopic nephrectomy has also been shown to be feasible in higher risk patients, such as those with renal failure before transplant.<sup>43,44</sup>

Laparoscopic nephrectomy for large malignancies has not been performed in children because of the large size of the tumors. In time this may change, particularly if preoperative chemotherapy is used to shrink a tumor or if partial nephrectomy is elected for small tumors, and anecdotal reports have appeared.<sup>45</sup> These principles for laparoscopic nephrectomy are well established in adults with renal tumors and will likely be appropriate for children as well.

The choice of transperitoneal or retroperitoneal nephrectomy largely depends on the experience of the operator and the associated procedures needed. If the entire ureter must be removed, or if an intra-abdominal testis is present, transperitoneal nephrectomy may be preferred. Subtotal resection of the ureter is readily done via the retroperitoneal access. The prone approach is less suited to ureteral resection but may be more efficient for access to the hilum.

Robotic technology has been used for nephrectomy, although the advantages are limited. As with cryptorchidism, it is best used as a learning approach for nephrectomy.<sup>46</sup>

## Technique

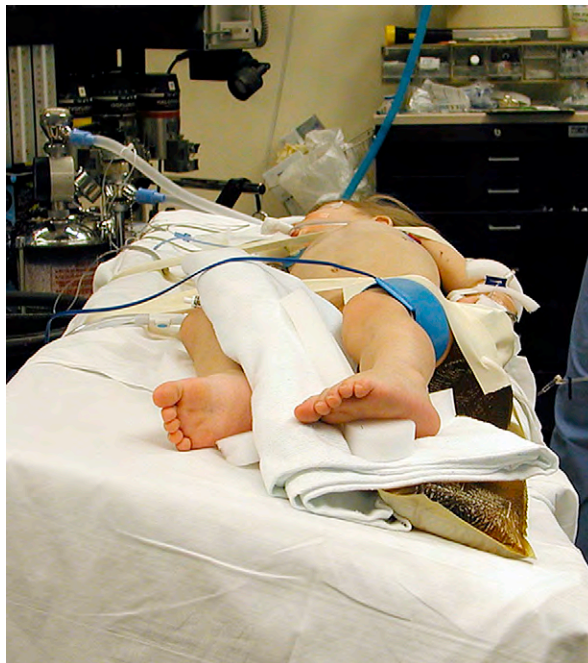

### TRANSPERITONEAL

Patients are prepared with a liquid diet for 24 hours preoperatively and a rectal suppository is given the night before. A bladder catheter and rectal tube are placed after the induction of anesthesia and before the skin is prepped. The ipsilateral side is elevated on a soft roll, and the patient is secured to the table (Fig. 64-7). The table is rotated so that the abdomen is flat for peritoneal access and port placement and then rolled back with the ipsilateral side up for the procedure. Positioning the patient with the flank up helps the surgeon reflect the colon away from the kidney. This position permits rapid return to the supine position if emergency open access is needed.

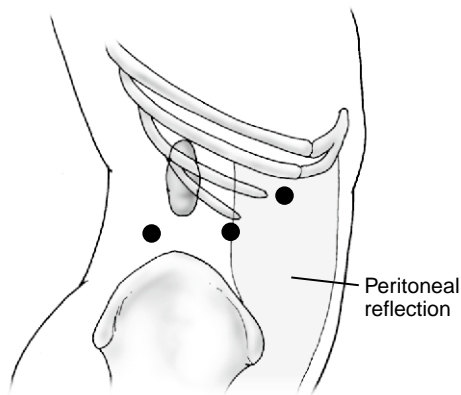

The initial port is in the umbilicus with working ports in the ipsilateral lower quadrant in the mid-clavicular line and just to the ipsilateral side of the midline between the xiphoid and umbilicus. For right nephrectomy, a liver retractor placed laterally on the right or contralaterally on the left may be useful. I have used 3.5-mm or 5-mm instruments and endoscopes. A 5-mm port is needed for the clip applier.

The kidney is exposed by incising the lateral peritoneal reflection of the colon and mobilizing the colon medially. The ureter is identified near the lower pole of the kidney (or occasionally at the level of the iliac vessels), transected, and used for traction to lift the kidney for identification of the renal hilum. If vesicoureteric reflux is present, the ureter should be dissected at least to the level of the bladder and ligated, because clips are unreliable for closure of a thick ureter. Blunt or cautery dissection are used to expose the lower pole and hilum. The artery is divided first if possible, preferably away from the hilum to limit the number of branches that must be controlled. It is divided between clips, usually leaving two on the proximal side. The vein is similarly controlled, avoiding any lumbar veins. The gonadal vessels should be preserved. Superiorly, the adrenal vessels should be avoided. The upper pole is mobilized with cautery because small vessels are frequently adjacent to the capsule. Lateral and posterior mobilization is usually rapid with blunt or cautery dissection. The kidney is removed through the umbilical port, which can be easily enlarged without increasing the size of the scar. The operative field is inspected, and the ports closed with preplaced fascial sutures.

Patients usually stay overnight but may occasionally be ready for discharge on the day of the procedure. Transperitoneal nephrectomy seems to induce more ileus than retroperitoneal nephrectomy, but the difference is minor.

**Figure 64-7.** Patient and table positioning for transperitoneal laparoscopic renal surgery. The patient is placed on a 30-degree ipsilateral wedge and secured to the table at the chest and hips. The table can then be rotated so that the abdomen is flat for port placement (shown) and rotated in either direction depending on the operative exposure that is desired.

**Figure 64-8.** Lateral retroperitoneal port placement for right renal surgery. Approximate location of the posterior peritoneal reflection (shaded).

### LATERAL RETROPERITONEAL

Patients are prepared similar to a transperitoneal nephrectomy but are positioned in a nearly full flank-up position. Initial access is gained just below the tip of the 12th rib with a 1- to 1.5-cm incision and blunt dissection through the muscle layers (Fig. 64-8). The perinephric fascia of Gerota is identified and entered. At this point, a dissecting balloon can be placed or the cannula can be positioned so that the endoscope is used bluntly to develop the working space. In both approaches, the port is secured with a purse-string fascial suture, which also provides a gas seal for insufflation. Pressures are maintained between 12 and 15 mm Hg. Once the position of the kidney is defined, the posterior port is placed. This may not be possible under direct vision, although a 30-degree telescope can facilitate insertion. The anticipated trajectory of the cannula is observed to avoid injury. The peritoneal reflection is identified and bluntly pushed medially. This can be accomplished with an instrument or the endoscope, but care must be taken to avoid disrupting the peritoneum. The medial port is then introduced, either in-line with the other two or inferiorly in a triangular fashion. Fascial sutures in a box-stitch pattern are placed before the cannulas are inserted to act as retention sutures for the cannula during the procedure and to close the fascia at the completion of the operation.

If a small tear is made in the peritoneum, the operative field will be compromised by intraperitoneal insufflation. The peritoneum can be decompressed by placing a small angiocatheter through the abdominal wall to let the peritoneal gas escape. Alternatively, the peritoneal tear can be enlarged so that the peritoneum does not separately trap carbon dioxide. It is rarely necessary to abandon the procedure and convert to an open operation because of entry into the peritoneum.

Exposure of the renal hilum is the key step for retroperitoneal nephrectomy, and it is important to prevent the kidney from falling onto the hilum. This can be facilitated by maintaining the anterior attachments of

the kidney so that it falls forward with the peritoneum, exposing the posterior aspect of the hilum. Even so, it may be necessary to use one instrument to retract the kidney as the hilum is exposed, limiting the surgeon's dissecting ability, which becomes one handed. If the pelvis is large, it will need to be retracted to adequately expose the vessels. This may be accomplished by transecting the ureter near the lower pole. The artery is encountered posteriorly and divided between clips. The vein also is divided between clips, and the rest of the mobilization is accomplished as with a transperitoneal approach. Near the upper pole, the peritoneum can be torn so care must be taken to stay close to the kidney.

If the ureter is to be removed, the lateral approach permits efficient access to the distal ureter, usually below the iliac vessels. If no reflux is present, the distal ureteric stump can be left open, whereas the stump of a refluxing ureter must be ligated as close to its junction with the bladder as possible.

The kidney is removed through the larger of the ports, usually the one at the tip of the 12th rib. If it needs to be morcellated with scissors, a laparoscopic specimen-retrieval bag is helpful. Most kidneys are small enough to be removed intact. Occasionally, removal of the specimen can be facilitated by placing it into the finger of a surgical glove as a miniature retrieval bag and then exteriorizing through the port site. All port sites are closed with the preplaced fascial sutures.

### PRONE RETROPERITONEAL

The prone approach has evolved from the dorsal lumbotomy technique and offers direct access to the kidney and hilum. The patient is in the full prone position with an indwelling bladder catheter. In small children, it is helpful to have the lower end of the table turned down, with the surgeon standing at the patient's feet. This allows the surgeon to be in-line with the working instruments. The initial port is placed at the costovertebral angle by using a 1-cm incision (Fig. 64-9). Blunt dissection through the posterior muscle layers

**Figure 64-9.** Port positions for the prone retroperitoneal approach to the right kidney.

reveals the posterior aspect of the perinephric fascia, which is entered. A lumbar fascial suture is placed for later closure. A dissecting balloon is used to develop the working space. A 5-mm cannula is inserted followed by a 3.5-mm telescope. The telescope can be moved to other ports during the dissection and at the time of placing vascular clips as needed. The endoscope is inserted as the retroperitoneum is insufflated. This should reveal the posterior aspect of the kidney, and further blunt dissection can be performed with the scope. Occasionally, the developed space is anterior to the kidney, making it difficult to immediately locate the kidney. This possibility must be considered, and the upper (posterior) abdominal wall inspected. The secondary (3.5-mm) ports are then placed, followed by insertion of 3.5-mm instruments.<sup>39</sup>

In the prone position, the kidney falls forward, revealing the hilum (Fig. 64-10). The vessels are controlled first, unless the ureter is needed for aid in mobilization of the kidney. Again, the vessels should be exposed somewhat away from the kidney to avoid the need to control multiple branches. It is important to maintain a consistent camera orientation to permit accurate identification of the vascular structures. The exposure can be so wide that the vena cava is readily seen, and this structure may seem smaller than expected because of the pneumoperitoneum. It has occasionally appeared to look like the renal vein, based on size and direction, when the telescope was not oriented correctly.

Once the vessels are secured and divided, the ureter is ligated and divided. The kidney is then mobilized to control the small upper pole vessels, with care being taken to avoid entering the peritoneum and to avoid the adrenal vessels. The kidney can be removed through the initial port, with the camera being moved to the inferior working ports.

If the ureter needs to be excised with the kidney, the instruments are reversed in direction and the

ureter traced inferiorly as far as possible. This is usually to the level of the iliac vessels. Postoperative care is similar to that with the other techniques of laparoscopic nephrectomy.

## Results

Complications have been reported in several series but are usually limited to minor occurrences, such as entry into the peritoneum or subcutaneous emphysema.<sup>26,47</sup> Conversion to an open procedure is reported in fewer than 2% of the pediatric series and is usually the result of bleeding that cannot be effectively controlled laparoscopically. Conversion rates are very much operator dependent and are not likely an inherent feature of the technique.<sup>48</sup> Injury to other organs is the major concern and has been reported (as it has for open nephrectomy in children). These are fortunately uncommon and usually involve liver, bowel, or occasionally great vessel injuries.

## Partial Nephrectomy

It has become clear that laparoscopic partial nephrectomy may be one of the most beneficial procedures to emerge from the early experience with laparoscopic nephrectomy.<sup>49-52</sup> Open partial nephrectomy is best performed through a flank incision, which has an appreciable morbidity, even in infants. Precise vascular control is essential, along with accurate visualization of the normal and abnormal renal moieties. Injury to the remnant pole is a significant complication and may be more likely to occur in an infant due to the mobilization required to expose the hilum. With the laparoscopic approach, the hilum can be exposed without significant mobilization of the remnant pole, theoretically reducing the risk of vascular spasm and injury, although a recent report contradicts this proposed advantage.<sup>53</sup> Robotic technology has been applied to partial nephrectomy as well. The robotic advantages of precise manipulation as applied to identifying, separating, and controlling what may be delicate vessels without injury to the remnant pole vessels may be advantageous. If the remnant collecting system is entered, it can be more readily controlled. Closure of the polar defect with mattress sutures can also be accomplished efficiently. I have begun using robotic technology for all partial nephrectomies in children.<sup>54</sup>

For conventional laparoscopy, my preferred access to the kidney is retroperitoneal and usually prone.<sup>39</sup> However, this limits the ability to remove the ureter, which is required in those unusual cases of obstruction combined with reflux. In such cases, the lateral approach is used or a small inguinal counterincision is made to remove the ureter to the level of the bladder neck. With simple reflux and no obstruction, total removal of the distal ureteral stump is not considered essential. The prone position allows excellent exposure of the posterior aspect of the kidney, and the delineation between the poles is usually readily evident. The ureter to be removed is identified at the

**Figure 64-10.** Posterior laparoscopic view of the right kidney after initial exposure. The hilum is on the left of the field. The entire kidney is exposed with its lateral edge to the right.

level of the lower pole and separated from the remaining ureter. The ureter draining the nonfunctioning pole is transected and used for traction to mobilize the hilum. The hilar vessels are identified, and the vessels of the affected pole are isolated and divided. If the vessels are not clearly defined, dissection of the nonfunctioning pole is started, whereupon the vessels will usually become evident. Division of the renal parenchyma can be performed by using either cautery or the ultrasonic scalpel. It is not a problem if the affected collecting system is entered as long as the entire collecting system is removed. However, if the remnant pole collecting system is entered, it should be repaired and drained. Placement of a ureteral catheter in the remnant pole and injection of indigo carmine dye to confirm closure have been advocated by some. This is useful in adult partial nephrectomy without duplication but is probably not necessary with duplication anomalies because the separation is usually quite clear.

No attempt is usually made to suture the edge of the remnant pole, but this can be accomplished robotically if desired. This maneuver should ensure hemostasis and limit the risk of leakage. I have not typically drained the operative area in small children but would recommend drainage in older children or in complex cases. A bladder catheter can be left overnight, although some of these children can be discharged on the same day.

Robotic partial nephrectomy is performed transperitoneally using an umbilical camera port, a midline port between the xiphoid and umbilicus, and an ipsilateral lower quadrant port. For right-sided upper pole nephrectomies, a fourth retraction port to lift the liver is placed in the contralateral upper quadrant in the midclavicular line. The affected ureter is mobilized and used as a traction handle to dissect the renal hilum and control the vessels. These can be ligated with clips or suture. The kidney is divided by defining the plane between the collecting systems. Using cautery or the ultrasonic scalpel, the parenchyma is transected. The cut surface is closed with two or three mattress sutures with a fat pad placed in the defect for compression. Any leak or injury to the remnant pole collecting system is repaired.<sup>54,55</sup>

The limited number of reports of laparoscopic partial nephrectomy does not allow definite conclusions regarding its ultimate potential, but the efficiency and the reduction in morbidity seem to argue strongly in favor of its further development.<sup>49-53,56-59</sup> Several reports of polar urinomas have appeared, suggesting that closure of the polar defect may be important in limiting this occurrence.<sup>52,56,57</sup>

## URACHAL CYSTS

Several reports of urachal cyst resections have been published, although it is unclear if the laparoscopic approach is advantageous.<sup>60-63</sup> It transforms a preperitoneal procedure into an intraperitoneal one. The conventional incision through the umbilicus is a very

**Figure 64-11.** Laparoscopic robotic exposure, dissection, and resection of a müllerian remnant (MR) in a boy with right gonadal dysgenesis and the ring-Y chromosomal defect with recurrent epididymitis in the left epididymis. The arrows point to the vas deferens on each side.

small incision with minimal scar. Laparoscopically, two other small incisions are needed.

Currently, I do not recommend using this approach, although I performed several initially. The situation in which this might be advantageous would be in the child with umbilical drainage of uncertain etiology. If the drainage is due to an omphalomesenteric duct or omental hernia, then laparoscopic diagnosis and subsequent therapy are efficient, including if the diagnosis is a urachal anomaly. A large inflamed mass due to an infected urachal cyst might be removed laparoscopically with some benefit, although the risk of peritoneal contamination should be considered.

## GONAECTOMY AND MÜLLERIAN REMNANTS

In various disorders of sexual development and genital maldevelopment syndromes, laparoscopic biopsy or resection, or both, of inappropriate gonadal or müllerian structures is possible.<sup>64,65</sup> This is particularly advantageous when the remnant is located in the deep retrovesical pelvis, a difficult area to access with an open procedure. Although they are not strictly intersex conditions, abnormal müllerian structures such as seminal vesicle cysts also are well managed with the laparoscopic or robotic approach (Fig. 64-11).<sup>66,67</sup>

## RECONSTRUCTIVE SURGERY

### Pyeloplasty

Laparoscopic pyeloplasty in children is emerging as a common procedure using conventional laparoscopic and, increasingly, robotic techniques.<sup>68-71</sup> Their use in infants has also increased, although less rapidly due to the efficacy of conventional techniques.

The widespread use of laparoscopy or robotics for pyeloplasty in children is still in the future.

Both transperitoneal and retroperitoneal access have been described. Most surgeons prefer the retroperitoneal approach for conventional laparoscopy, whereas robotic approaches are largely transperitoneal. Current methods as well as robotic options are discussed.

### Conventional Laparoscopic Pyeloplasty

Port placement for transperitoneal pyeloplasty is similar to that for nephrectomy, with an umbilical port, an ipsilateral upper quadrant port just lateral to the midline, and an ipsilateral lower quadrant port. A fourth port for retraction can be placed laterally if needed. Retroperitoneal access is with three ports in a line along the lower edge of the 12th rib. Prone access is possible with a similar in-line port layout.

The operation is similar to the open procedure with exposure of the renal pelvis but is facilitated by the placement of a traction suture (hitch stitch) to stabilize the pelvis. The pelvis is transected above the ureteropelvic junction and used for traction to permit spatulation of the lateral upper ureter without grasping the tissue to be included in the anastomosis. Alternatives include placing a small traction stitch on the ureter distal to the ureteropelvic junction after it is transected or leaving a bridge of pelvic tissue on the medial aspect to stabilize the ureter. The amount of pelvis removed should be limited, even in severe hydronephrosis, because the pelvis may retract and make the repair more difficult. It is not usually necessary to perform a significant pelvic resection, because this will usually shrink on its own after relief of the obstruction. For the anastomosis, most surgeons use a continuous suture anteriorly and posteriorly and use a 5-0 or 6-0 absorbable suture. A stent can be left in place if desired. I prefer using a double-J stent, which eliminates the need for a drain.

Reported outcomes are no better (or worse) than those with the open approach. Postoperative hospitalization and morbidity seems reduced, particularly for older children. Failures, primarily persistent ureteropelvic junction obstruction, have been limited to very small children (younger than 6 months) or those with massive hydronephrosis. This observation may account for the lack of enthusiasm for laparoscopic pyeloplasty in infants, who seem to recover rapidly after open surgical procedures.

### Robotic Pyeloplasty

The ability to perform delicate and precise fine suturing using the DaVinci (Intuitive Surgical Corp., Sunnyvale, CA) Surgical System has allowed the advantages of laparoscopy with smaller incisional morbidity and tissue trauma but without the challenges of suturing. The ability of the robotic system to facilitate precise use of 7-0 and 6-0 suture, particularly with pyeloplasty, has moved robotic pyeloplasty in children to an equally effective method with open surgery. Age has

not been a limiting factor except in the rare neonate needing an urgent pyeloplasty. I have used the robotic system in children as young as 3 months.<sup>72,73</sup>

### METHOD

A double-J stent can be placed cystoscopically before the procedure. However, this can decompress the pelvis and make operative identification of the pelvis more difficult. The curl of the stent should be positioned just below the ureteropelvic junction, but this is not always easily accomplished. The advantage of preplacement is having an extraction string on the double-J stent to permit withdrawal without a general anesthesia. Alternatively, a stent can be inserted antegrade during the procedure (see later).

Access is through similar port sites as with laparoscopic pyeloplasty, but the size and position of the renal pelvis should guide the position of the lower port. If the lower port is too close to the ureteropelvic junction, movement of the lower instrument may be limited. Therefore, in smaller children, the inferior port is moved medially and more caudad. Most children with a left-sided ureteropelvic junction obstruction are approached transmesenterically to limit the need for dissection of the perinephric space when the colon is mobilized. On the right, the kidney is exposed by reflecting the colon. Once the pelvis is exposed, a hitch stitch is placed through the abdominal wall using a 3-0 monofilament suture that is passed through the anteromedial aspect of the pelvis and then back out the abdominal wall where it is secured with a small clamp. Tension on the suture is adjusted to provide optimal exposure. The hitch stitch allows exposure, stability, and lifting of the pelvis from the inevitable pool of urine and blood. In obese patients this stitch can be tied intracorporeally. As with conventional laparoscopic pyeloplasty, the pelvis is dismembered, the ureter spatulated, and the anastomosis performed (Fig. 64-12). Before completing the anastomosis, the extra pelvis is removed and extracted from the abdomen.

**Figure 64-12.** Robotically assisted laparoscopic dismembered pyeloplasty showing renal pelvic closure using 5-mm instruments and 6-0 monocryl suture. The internal double-J stent is visible inside the renal pelvis.

Antegrade stent placement is performed after the back wall of the anastomosis is completed. An angiocatheter is passed through the abdominal wall and a 0.035-inch guide wire is introduced through the angiocatheter and guided into the ureter. While this is being done, the angiocatheter is removed and the appropriate-sized stent is passed over the wire, through the abdominal wall, and into the ureter. If there is uncertainty about positioning, blue dye may be instilled into the bladder to indicate when the stent is in place. However, I have not found this step necessary. After stent placement, the anterior wall of the pyeloplasty is performed.

A nearly identical strategy may be used to perform a ureteroureterostomy or ureteropyelostomy for duplication anomalies in which the upper pole is to be preserved. Whether this is preferable to partial nephrectomy when there is limited function is debatable, but both techniques are able to be performed readily with robotic assistance.<sup>46,74</sup>

Several reports of robotically assisted laparoscopic pyeloplasty in children have been published.<sup>73,75-78</sup> Ages have ranged from 3 months to teenage years, and both transperitoneal and retroperitoneal approaches have been described. Results have been excellent to date, but caution should be observed before completely accepting these initial observations. The advantages when compared with open surgery are less obvious in infants than in older children. The clear advantage in terms of morbidity and recovery in older children argues that there is likely some benefit even in younger children. Reoperative pyeloplasty has been reported in children using the robotic system as well.<sup>79</sup>

## Antireflux Procedures

Initial attempts at laparoscopic antireflux urologic procedures were frustrating. Using the extravesical Lich-Gregoir technique,<sup>80</sup> these were successful but far too time-consuming to be advantageous. After initial interest, few other attempts were made.<sup>81,82</sup> Interest returned with a reasonably successful series,<sup>83</sup> but the advantages were not clearly evident because catheterization time and hospitalization were no better than with the open approach. Robotic technology has further raised interest, and several reports of robotic extravesical procedures have been published.<sup>46,84</sup> Intravesical procedures, both conventional and robotic, have also been reported.<sup>85-88</sup> It remains uncertain if these procedures are sufficiently advantageous over open surgery to justify the investment in learning and technology. However, it is likely that efficiencies will improve with further refinement.

### Method

The reimplant is similar for both the laparoscopic or robotic approach and is performed transperitoneally, exposing the distal ureter. The antireflux tunnel is created by incising the detrusor muscle from the ureterovesical junction along the axis of the ureter down to the submucosa of the bladder. Care is taken

**Figure 64-13.** Closure of the detrusor tunnel (arrows) over the mobilized ureter (U) during a robotically assisted extravesical ureteral reimplant for vesicoureteral reflux. The ureter is being lifted by the left instrument while the first suture of the tunnel is being tied. This keeps the ureter in the tunnel as the subsequent sutures are placed.

not to injure the mucosa or enter the bladder lumen. The muscularis is dissected in an inverted-“Y” manner around the ureteral hiatus. The detrusor muscle is closed over the ureter to create the antireflux tunnel. No attempt at ureteral advancement is made. Suturing the detrusor over the ureter has been the most challenging aspect of the procedure, mainly because of the angle of approach. Robotic assistance greatly facilitates this part of the operation (Fig. 64-13).

In performing bilateral procedures, it is important to limit the amount of damage to adjacent nerves that presumably affect bladder function. Although it has been reported that these nerves can be identified and spared, this can be difficult. In my experience, the best approach is to stay as close to the ureter as possible during dissection. A risk of transient retention is possible, but this appears to be very low.<sup>84</sup>

## Results

Success seems to be close to that seen with open surgical procedures. With robotic assistance, larger series have been reported with good results. Hospital stays are slightly shorter than with open methods, but outpatient open extravesical and transvesical reimplantations have been reported with good outcomes as well.<sup>89</sup> Demonstrating an objective clinical advantage over an open approach is challenging. The value of developing techniques for bladder reconstructive procedures using minimally invasive technologies justifies continued attention.

## Intravesical Antireflux Procedures

Intravesical antireflux repair has recently emerged as an alternative to the extravesical approach. Advantages include the avoidance of urinary retention with bilateral extravesical procedures and avoiding

peritoneal entry.<sup>87,90</sup> Several earlier attempts with the Gil-Vernet approach of bringing the ureters together in the midline, without mobilization, did not prove to be effective.<sup>91</sup> Recent reports of a transvesical approach to the Gil-Vernet procedure have been successful.<sup>92</sup> The most widely used approach to date has been that of an intravesical, transtrigonal reimplantation with insufflation of the bladder (pneumovesicum).<sup>85,87,93</sup> The major technical challenges include obtaining and maintaining access to the bladder without dislodging the cannulas, leaking carbon dioxide into the paravesical space, mobilizing the ureter, creating the submucosal tunnel, and the suturing to implant the ureter. Performing this procedure efficiently may be feasible in only a few highly skilled hands. Robotic assistance has been reported as well but remains challenging, primarily because of the large ports required.<sup>86</sup> Demonstrating a clinical advantage will be difficult.

### Continent Diversion and Augmentation

Major reconstructive operations such as bladder augmentation, continent diversion, and vaginal reconstruction carry substantial morbidity with an open

approach. It may be that laparoscopic procedures for reconstruction and diversion will prove most beneficial for all age groups. The creation of an appendiceal continent catheterizable stoma (Mitrofanoff) has been reported, including the use of robotic assistance.<sup>94,95</sup> Laparoscopically assisted mobilization with a limited open incision to complete the procedure has been advocated in several reports, with excellent results.<sup>96,97</sup> Laparoscopically assisted reconstruction may be the most practical approach for the present as robotic methods begin to be developed.<sup>98</sup>

The ability to perform an entire reconstruction, including augmentation and continent stoma formation, is technically possible today<sup>99-101</sup> but is not going to be of practical value until more efficient means of suturing are developed. Tissue glues or the use of robotically assisted suturing may permit more widespread use of total laparoscopic methods in complex reconstruction. It also will require novel algorithms for harvesting bowel segments to use in the reconstruction.<sup>98</sup>

# RENOVASCULAR HYPERTENSION

James A. O'Neill, Jr., MD

The incidence of hypertension in children is 2% to 10% in all age groups, with the higher figure representative of adolescence. However, because blood pressure is not routinely measured in children, particularly infants, the diagnosis of hypertension is often delayed. Table 65-1 lists the common causes of hypertension in children according to the organ system involved. In this chapter, the focus will be on renovascular causes of hypertension, most of which are correctable.

In 1934, Goldblatt and coworkers described the relationship between coarctation of the aorta and renal artery stenosis with hypertension.<sup>1</sup> However, it was not until the 1960s that a relationship was established between renal ischemia and hypertension resulting from activation of the renin-angiotensin system, which leads to the release of renin and the production of angiotensin II (Fig. 65-1). Subsequently it has been shown that diminished renal perfusion pressure has direct effects on sodium excretion, sympathetic nerve activity, nitric oxide production, and intrarenal prostaglandin concentrations, which result in renovascular hypertension.<sup>2</sup> Recent studies have demonstrated different fractional angiotensin elevation patterns in children with renovascular hypertension as compared with essential hypertension.<sup>3</sup>

With regard to the natural history of renovascular hypertension, once it is established that the disease is progressive, there is often late recurrence of renovascular lesions in sites other than those originally identified. The progressive nature of this disorder is the best justification for an aggressive approach to correction. Second, sustained hypertension may result in left-sided heart failure and chronic renal failure based on chronic ischemic nephropathy. Also, patients with malignant forms of renovascular hypertension have a high incidence of heart failure and renal failure.

The most common cause of hypertension between birth and 20 years of age is essential hypertension in approximately 60% of patients. However, the incidence of correctable hypertension is much higher in patients younger than 15 years. In previous studies by our group, the incidence of correctable hypertension in the birth to 5-year age group was around 80%; in the

6- to 10-year age group, 45%; and in the 11- to 15-year and 16- to 20-year age groups, 20%.<sup>4</sup> Although a variety of causes were identified, the vast majority were renovascular. Renovascular disease comprises 8% to 10% of all forms of hypertension in children while it is 1% of all forms in adults. Additionally, long-term follow-up of patients with renovascular hypertension clearly indicates that patients who have had successful repair of their lesions have much longer survival than those who do not. Moreover, the younger the patient, the better the result.<sup>5</sup> Such studies support an aggressive approach to correction of identified renovascular lesions in young patients.

## ETIOLOGY

Renovascular hypertension may be congenital or acquired. Congenital causes include arterial hypoplasia or aplasia; neurofibromatosis involving the renal artery; and Williams syndrome, which includes manifestations of supravalvular aortic stenosis, peripheral vascular stenosis (particularly in the subclavian and renal arteries), hypercalcemia, and elfin facies.<sup>6</sup> Renal involvement by tuberous sclerosis tumors has been reported as well. The most common acquired form of renovascular hypertension is fibromuscular dysplasia (FMD), which may be either localized to one or both renal arteries or appear as a more generalized type of disease, such as Takayasu's arteritis and subisthmic abdominal coarctation, now more commonly referred to as the mid-aortic syndrome.<sup>7-9</sup> In the mid-aortic syndrome, stenoses of visceral arteries such as the superior mesenteric and celiac arteries are common.<sup>8</sup> Other less common forms of acquired renovascular hypertension are renal artery trauma or thrombosis, thrombosis secondary to antithrombin deficiency, Kawasaki disease, and an anastomotic stenosis, as is seen occasionally in renal transplants.<sup>10</sup>

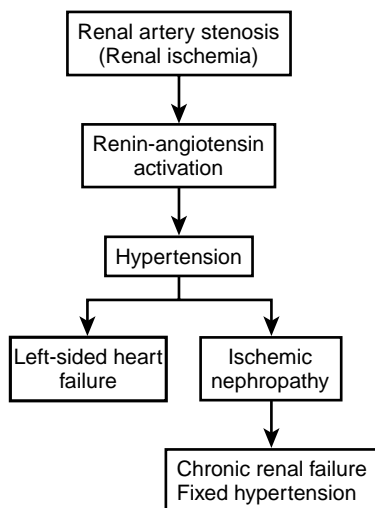

Overall, the vast majority of children with renovascular hypertension have what has been referred to as FMD or hyperplasia. Previous studies have suggested that this lesion has a congenital origin, but there is evidence to the contrary as well, because the

**Table 65-1** Causes of Hypertension in Children

Essential hypertension	
Renal	Glomerulonephritis, pyelonephritis, renal hypoplasia, polycystic kidney, Wilms' tumor, neuroblastoma, arteritis, aneurysms, trauma
Cardiovascular	Aortic coarctation, Takayasu's arteritis, neurofibromatosis, tuberous sclerosis, renovascular stenosis, collagen vascular disease
Central nervous system	Encephalitis, intracranial mass with increased pressure, dysautonomia
Endocrine	Pheochromocytoma, aldosteronoma, adrenogenital syndrome, Cushing's syndrome
Secondary hypertension	Lead and mercury poisoning, glucocorticoid drugs, oral contraceptives

disease appears to have an acquired pattern in young adults.<sup>6</sup> FMD appears to coexist with neurofibromatosis, Williams syndrome, and pheochromocytoma. Because arterial and aortic hypoplasia and aplasia are seen in neonates, it is assumed that some of these lesions are congenital (Fig. 65-2).<sup>11</sup> Conversely, the majority of patients are initially seen at several years of age, usually with an inflammatory phase followed by a quiescent phase of arteritis.<sup>4,7</sup> Although it was initially thought that FMD might be an autoimmune disease, recent evidence suggests that T-cell-based immune mechanisms, macrophages, and antigen-presenting cells are mainly responsible for renovascular arteritis and a variety of other arteritides as well.<sup>12</sup> The pathology of the vascular lesion seen in the renal artery and aorta reveals medial and perimedial fibroplasia, which has inherent implications about approaches to treatment, particularly angioplasty. Although FMD is a systemic, occlusive arteriopathy potentially involving the entire abdominal

**Figure 65-1.** The consequences of renal ischemia from renal artery disease are depicted.**Figure 65-2.** This selective renal arteriogram performed in a neonate with congestive heart failure caused by severe hypertension demonstrates significant narrowing of the left renal artery. The cause is probably congenital.

aorta and its branches, the renal arteries are the predominant vessels involved.<sup>13</sup>

## CLINICAL PRESENTATION

Children with renovascular hypertension come to attention in one of two ways in most instances. Approximately 70% of patients are asymptomatic. Commonly, an asymptomatic young child undergoing an elective surgical procedure, such as a hernia repair, is found to be hypertensive on anesthetic evaluation. Repeated measurements verify the chronic nature of this problem, which leads to diagnostic evaluation. Approximately one half of these asymptomatic patients will be found to have correctable hypertension. The remaining 30% of patients are symptomatic with headaches, vision problems, encephalopathy, congestive heart failure, oliguric renal failure, and, occasionally, leg claudication. Physical findings may indicate the presence of heart failure with enlargement of the liver and heart as well as retinopathy and retinal hemorrhage. In cases of mid-aortic syndrome, blood pressure and peripheral pulses may be diminished in the lower extremities. Although an abdominal bruit could probably be heard in the majority of instances of renal artery stenosis, it is not commonly found until a diagnosis is suspected. It is usually not known how long the hypertension has been present.

In contrast to adults with FMD, in whom women predominate, gender incidence is equal in children. Both renal arteries are simultaneously involved in approximately 70% of patients. Also, in occasional patients with unilateral lesions, FMD may develop in the opposite renal artery a number of years later. Renovascular causes of hypertension are more common in children younger than 10 years, as evidenced by an average age of 7 years in one of our studies.<sup>5</sup> In infants and toddlers, malignant forms of

hypertension with encephalopathy and retinopathy are more likely to develop than in older children.

## DIAGNOSIS

Before any invasive diagnostic studies are undertaken, clinical manifestations of severe hypertension such as headache, irritability, abdominal pain, heart failure, and seizures should be controlled with medications.

## Laboratory Studies

Renovascular hypertension cannot be diagnosed by any specific laboratory study. Most laboratory studies are performed to document the patient's overall clinical status and particularly the status of the renal function. Erythrocyte sedimentation rate (ESR) is important to assess whether the patient is in the inflammatory or the quiescent phase of the arteritis. Urinary catecholamines are studied to exclude the common endocrine causes, particularly in patients with manifestations of neurofibromatosis, such as café-au-lait spots. I have not found plasma renin or captopril-stimulated renin studies to be helpful in young children. Technetium-labeled pentetic acid (DTPA) radionuclide fractional-flow studies may indicate unilateral renovascular disease, but they are not useful when bilateral disease is present. Captopril renography has the same limitation.

## Imaging

Although a number of imaging studies exist, currently it is my policy to perform aortography and selective arteriography in all children with significant hypertension. Minimal complications have been encountered with these studies, even in very small patients. With appropriate hydration, even patients with some degree of oliguric renal failure can undergo aortography and selective arteriography by using low-osmolar or non-iodinated contrast agents in limited amounts. For patients with a distal or intrarenal vascular stenosis, nitroglycerin-enhanced selective studies promote the identification of segmental areas of ischemia in the involved kidney.

Duplex color-coded Doppler ultrasonography is capable of demonstrating the renal arteries, as well as measuring flow velocity as an index of the degree of stenosis.<sup>14</sup> However, Doppler ultrasound studies, whether performed preoperatively or postoperatively for follow-up, have limitations in terms of demonstrating precise anatomic detail, particularly in small vessels. The same is true of captopril scintigraphy. Magnetic resonance angiography (MRA) and computed tomographic angiography (CTA) are capable of demonstrating the renal arteries and the aorta and its branches better than Doppler ultrasonography, but there are resolution issues in small subjects.<sup>14,15</sup> MRA is less accurate than CTA, and the volume of contrast material for CTA is often as much as with aortography with selective angiography, so no advantage accrues

**Figure 65-3.** This 6-year-old boy was found to have severe hypertension when screened for an elective hernia repair. Aortography revealed marked narrowing of the left renal artery, some narrowing of the mid-aorta, and virtually complete occlusion of the right renal artery which fills late from collateral vessels. This is the typical appearance of fibromuscular dysplasia or hyperplasia.

from the standpoint of nephrotoxicity. If one takes the point of view that the prime purpose of an imaging study is to select the most suitable therapeutic method, aortography with selective arteriography is the most definitive study and the one most capable of demonstrating precise anatomic detail (Fig. 65-3). Doppler ultrasonography, MRA, and CTA are now considered best as screening or follow-up studies in children.

The diagnostic approach to children, who usually have bilateral renal artery stenosis associated with FMD, is simpler than the workup in adults, who primarily have atherosclerotic lesions. Consequently, many of the noninvasive tests designed for adults with renovascular hypertension are not useful in children. For example, it was recently reported that the preoperative calculation of a high renal resistance-index value derived by Doppler ultrasonography is a predictor of the lack of success of operative correction of renal artery stenosis.<sup>16</sup> However, because successful revascularization in children routinely results in alleviation of hypertension, such studies are superfluous. The same is true for renal vein renin studies because renal artery stenosis in children with hypertension is always significant. On the other hand, renal vein renin studies may be useful in determining the significance of distal stenoses or aneurysms of renal artery branches or postoperative anastomotic stenoses.

Because FMD is a systemic, occlusive arteriopathy, it is necessary to survey the entire lower thoracic and abdominal aorta to delineate those patients who have not only renal artery stenosis but also the mid-aortic syndrome, visceral artery stenosis, or other forms of renovascular hypertension.<sup>8,13,17</sup> Thus, full angiography is needed so that an appropriate single-stage operation can be performed. It is interesting to note that hypertensive children without co-morbid conditions, who have renal artery stenosis, usually have a single, focal branch artery stenosis.<sup>15</sup>

## TREATMENT

### Medical Treatment

Antihypertensive medications are needed to control blood pressure before undertaking any invasive procedure, including arteriography. Drug therapy is not an alternative to surgical care but an integral part of patient management, not only preoperatively but also intraoperatively and postoperatively. Most patients referred for surgical or interventional treatment have severe hypertension with symptoms that are most effectively managed with intravenous drugs, gradually phasing to oral medications. In severe cases, I prefer to use nitroprusside initially. Either concurrently or sequentially, intravenous labetalol or nifedipine or both are useful drugs. The same three medications are extremely useful in the postoperative management as well, because hypertension is often exacerbated after the temporary ischemia associated with the revascularization procedures. For long-term and outpatient treatment, propranolol, atenolol, minoxidil, and oral diuretics in various combinations are useful. I prefer to use long-acting drugs whenever possible, because patient and parent compliance are better when once-daily medications are utilized. Angiotensin-converting enzyme (ACE) inhibitors such as captopril are very effective antihypertensive drugs, but they must be used with great caution in patients with renovascular hypertension because of the potential for drug-induced renal ischemia and possible oliguric renal failure.<sup>5,18</sup> Thus, if a decision is made to use ACE inhibitor medication, renal function must be monitored closely.

Another consideration related to the use of medical therapy is in the management of infants with severe hypertension related to renal artery stenosis. In these instances, because of the great risk for thrombosis with repair of the tiny vessels, it may be best to administer antihypertensive drugs until the renal arteries are close to adult size, if possible (ages 5 to 8 years). After revascularization, it may take up to 6 to 12 months for the hypertension to resolve or improve, so the antihypertensive drugs must be weaned gradually.

### Interventional Procedures

Balloon angioplasty with and without stenting has been the subject of many reports with atherosclerotic disease as well as with FMD.<sup>14,19</sup> The results in patients with FMD have been more favorable in instances in which the orifice of the renal artery is not involved by the process. Balloon dilatation for orifice lesions has generally been unsuccessful, except for short periods. Experience reported in children with balloon angioplasty, which parallels my experience, indicates that balloon dilatation of orifice lesions is as ineffective as it is in adults, but it is very successful in providing long-term relief from stenosis of the main renal artery or its branches.<sup>20,21</sup> Nonetheless, there are a number of reports in the interventional radiology literature that promote percutaneous transluminal angioplasty (PTA) for children with all forms of renal artery stenosis, and

even describe the placement of stents in very small children. Unfortunately, very few of these reports describe long-term outcomes. Tobin and colleagues have recently proposed cutting balloon angioplasty in children with resistant renal artery stenosis, although that technique may be even more risky than surgical repair.<sup>22</sup> In one long-term follow-up report by Shroff and coworkers, PTA and stenting in a series of 33 children with a mean age of 10 years was associated with a high rate of restenosis, one procedure-related death, and a number of complications.<sup>19</sup> These results are not as good as with surgical repair. McTaggart and colleagues reported that PTA was ineffective for patients with neurofibromatosis lesions of the renal artery because of the fibrotic nature of the disease.<sup>21</sup> Lacombe and Ricco pointed out that when patients sustain complications of PTA such as dissection, rupture, or thrombosis, surgical repair may then be difficult.<sup>23</sup> Because of the relatively greater degree of fibroplasia seen in children with FMD, it is not surprising that a much greater incidence of intimal dissection and thrombosis occurs in children, who most often have lesions at the ostia. Because children are growing, and because so many of these children are young, averaging 6 years of age, there is a reluctance to insert stents into these lesions after balloon dilatation for fear of inducing intimal hyperplasia or of creating obstruction as the child grows. However, dissolvable stents may possibly prove useful in the future in some pediatric patients.

In the rare instances of distal segmental renal artery lesions resulting in segmental renal infarction, interventional infusion of ethanol for ablation may be curative as an alternative to segmental resection.

### Surgical Treatment

Effective surgical treatment for renovascular hypertension in children is preferable. The method selected must be based on the etiology and distribution of the lesions causing stenosis.<sup>14,24</sup>

Nephrectomy and partial nephrectomy should be avoided unless no other choice is available. For example, it may be necessary to perform nephrectomy in infants with uncontrollable hypertension who have unilateral renal involvement, particularly when severe hypoplasia is found. Partial nephrectomy has been used primarily in those instances of renal atrophy, with diffuse vascular involvement, or when the vessels are too small for successful reconstruction. It is my preference to attempt revascularization because partial or total nephrectomy is available as a last resort if the vascular repair fails. Additionally, because FMD may involve the opposite kidney many years later, nephrectomy is undesirable if revascularization is possible.

Although children with FMD have a predominance of ostial lesions, sufficient involvement of the renal artery and wall of the artery exists that the extent of the lesion is greater than what might be apparent on the arteriogram. Thus, patch angioplasty is only rarely effective. Reimplantation of the renal artery into another site on the aorta is the most effective

approach, but its success depends on the aortic wall being normal where the new orifice is to be created and on sufficient renal artery length to reach without tension. Although autotransplantation is an alternative under these circumstances, it is more complicated because both arterial and venous anastomoses are needed. Reimplantation is contraindicated in patients with mid-aortic syndrome in which the aortic wall is involved with FMD. Also, direct anastomosis to the aorta is not an option for patients with branch vessel lesions, which must be treated with balloon dilatation, bypass, or partial nephrectomy for distally placed lesions. It is unfortunate that reimplantation is so rarely possible in this group of patients because it provides the best and most durable results.<sup>5</sup>

Because of the complicating factors mentioned previously, aortorenal bypass is usually the best option for revascularization. Bypass from the aorta to the side of the renal artery distal to the stenosis was often used in the past. For the past several years, it has been my preference to divide the diseased artery from the aorta and perform an end-to-end anastomosis between the bypass graft and the distal renal artery, spatulating the end of the distal renal artery and fashioning the distal end of the bypass graft obliquely, so that a so-called cobra hood anastomosis is performed. Depending on the size of the anastomosis, either a continuous suture technique, interrupted several times, or an interrupted suture technique for the anastomosis is appropriate. The anastomosis of the bypass graft to the aorta can usually be performed with continuous suture that is interrupted at least three times. The opening in the aortic wall is made with an appropriate-sized punch instrument rather than a simple incision. I prefer 6-0 polypropylene sutures for the aorta-to-graft anastomosis, whereas 7-0 polypropylene is used for the distal graft-to-renal artery anastomosis. In instances of mid-aortic syndrome in which such severe coarctation exists that an aorto-aortic bypass is needed, the renal bypass grafts may be taken off the aortic bypass graft. Depending on the size of the patient, it is my preference to use 10- to 14-mm woven Dacron grafts with enough length to permit growth and yet not so much length as to result in kinking of the graft. A full intravenous heparinizing dose is administered before aortic clamping, and a half dose is given each hour during the procedure. The heparin effect is allowed to dissipate once all the anastomoses are completed. It has rarely been necessary to reverse the heparinization.

Some debate exists regarding what is the best choice of aortorenal bypass grafts. In adults, Gore-Tex (W.L. Gore & Associates, Elkton, MD) grafts are frequently used. Paty and associates described their experience with prosthetic renal artery reconstruction in adults with a high degree of success.<sup>25</sup> However, thrombosis occurs more commonly in prosthetic grafts than with autogenous material. Gore-Tex grafts are rarely needed in children except when autogenous grafts have failed. There is little debate that the best choice for bypass in children is autogenous hypogastric artery, provided that it is not involved with FMD and that a sufficient length of artery can be harvested for the bypass. These

two factors limit the use of the hypogastric artery, even though it clearly holds up best through the years. Additionally, because 70% of patients have simultaneous bilateral renal artery stenosis, this would require both hypogastric arteries to be harvested. Certainly some concern exists about taking both hypogastric arteries in children, although the exact risks of impotence and incontinence are not known. Because of these potential complications, the hypogastric artery is not an option for many patients. Therefore, the next best option, and the one most frequently used today for arteriorenal bypass in small patients, is the saphenous vein. Because of the risk of aneurysmal dilatation in as many as 40% of patients who have such grafts placed in the visceral location, my colleagues and I developed a procedure to cover the saphenous vein bypass grafts with a loose mandrill of Dacron mesh, which has been effective over the long term.<sup>20,26</sup> These techniques have been in use for more than 20 years.

Another debated issue relates to a subset of patients with mid-aortic syndrome who have varying degrees of narrowing of the superior mesenteric and celiac arteries.<sup>8,9,27</sup> A few scattered reports of patients with visceral artery stenosis who were initially seen with severe intermittent abdominal pain or intestinal infarction are available. However, in contrast to adults with lesions of this nature, most children are rarely symptomatic. In those rare instances in which I have encountered children with signs or symptoms related to superior mesenteric or celiac narrowing, I have performed revascularization by either direct reimplantation or bypass grafting. Currently, no consensus exists about whether asymptomatic children with marked visceral artery stenosis should have preemptive repair. Certainly, concomitant visceral artery bypass carries a high risk in a patient who is already having a bilateral renal artery bypass procedure and frequently also an aorto-aortic bypass. My group and others favor selective treatment of symptomatic patients with splanchnic artery occlusive disease.<sup>17</sup> Because the overwhelming majority of patients with lesions of this nature are asymptomatic, and because almost all of them have a remarkable amount of collateral circulation demonstrable on aortography, I have not undertaken visceral artery revascularization in asymptomatic patients (Fig. 65-4). Observation for as long as 30 years has indicated that these patients have remained well, supporting a conservative approach.<sup>5</sup>

## COMPLICATIONS AND OUTCOMES

A number of long-term follow-up studies of children who have had surgical repair for renovascular hypertension and its variants report a high degree of success and durable results, with cure rates ranging from 66% to 80%, improvement rates of 18% to 22%, and only occasional failures.<sup>5,28,29</sup> No mortality was found in our series of over 50 renal revascularization procedures.<sup>5</sup> No patients developed renal failure, and those who had preoperative oliguric renal failure invariably returned to normal afterward.

**Figure 65-4.** This aortogram performed on an 8-year-old boy with malignant hypertension shows the typical findings of mid-aortic syndrome or subisthmic coarctation associated with bilateral renal artery and visceral artery narrowing with collateral circulation from the inferior mesenteric artery. Aorto-aortic bypass and bilateral renal artery bypass from the aortic bypass graft were performed.

Intraoperative renal thrombosis, embolization during the procedure, and intraoperative and postoperative hemorrhage have not occurred. Postoperative graft thrombosis, because of kinking and flaws in technique, occur in fewer than 5% of renal repairs, even in small patients. However, it has always been my approach to manage patients medically, if possible, until their renal arteries are close to adult size. In those few instances in which graft thrombosis was encountered, because of the likelihood of an anastomotic problem, I have preferred immediate reoperation to the use of thrombolytic agents. Late thrombosis can occur, but the incidence is less in children than in adults because of the absence of atherosclerosis. In patients who have late thrombosis, repeat bypass grafting is preferable,

but often partial or total nephrectomy is required. It is important to monitor the patient's blood pressure indefinitely in follow-up because recurrence of hypertension usually indicates a problem with the vascular reconstruction or recurrent disease. Iliorenal bypass has been used in selected high-risk patients as a remedial operation with good results.<sup>30</sup>

### Postoperative Imaging

Recurrent hypertension after revascularization procedures is due to either recurrent FMD or an anastomotic stenosis. I have encountered two instances of late narrowing of the distal renal graft anastomosis. As with renal transplant arterial stenosis, balloon dilatation has been curative for 20 and 23 years, respectively. For follow-up of patients, it is best to have the family monitor the child's blood pressure frequently at home with at least 6-month follow-up visits initially. The patient's blood pressure should remain normal, even with exercise, although some patients may require medication to keep their blood pressure within the normal range. In the asymptomatic patient, noninvasive imaging such as CTA or MRA is suggested every 5 years, with definitive selective angiography performed if any question exists.

Even when complicated, complete revascularization can be performed at a single operation and results are excellent. Whether patients have aortorenal bypass to either one or both kidneys, or whether they also have aorto-aortic bypass procedures, 80% of children in our series have been cured of their hypertension without the need for medications and 18% are markedly improved, needing minimal antihypertensive medications.<sup>5,8</sup> Only about 2% of our patients are unchanged after operation. In the absence of a demonstrated vascular lesion, these patients probably have sustained hypertension because of ischemic nephrosclerosis.

# PRINCIPLES OF ADJUVANT THERAPY IN CHILDHOOD CANCER

Daniel von Allmen, MD • Stephan Shochat, MD

The significant improvement in cure rates for pediatric malignancies over the past 30 years could not have occurred without the development of multimodality therapy and the cooperative efforts of surgeons, pediatric oncologists, and radiation therapists across the country. In the 1940s, with the use of wide surgical excision, about 20% of children with localized solid tumors were cured of their malignancies. However, with the discovery of effective chemotherapeutic agents, pediatric oncologists joined with surgeons and radiation therapists in cooperative groups and developed a scientific approach to the study of these agents, rapidly improving on these statistics. Even in the earliest days of cancer therapy, it was the rare child who was not treated with the optimal standardized therapy, from which information was obtained and applied to the next generation of protocols. This carefully developed multimodality approach to the total care of the child with cancer led to the implementation of similar systems in the treatment of adult malignancies and has led to the fact that almost 85% of children with cancer will outlive their malignancy.<sup>1</sup>

## HISTORY OF PEDIATRIC ONCOLOGY

The first demonstration that chemotherapy could be effective therapy for childhood malignancies occurred in 1948 when Sidney Farber<sup>2</sup> reported temporary remissions in children with acute lymphoblastic leukemia (ALL) when the folic acid antagonist aminopterin was given. Several years later, another folic acid antagonist, methotrexate, produced cures in choriocarcinoma.<sup>3</sup> As additional chemotherapeutic agents were developed, these were combined in multidrug regimens that demonstrated significantly improved response rates and response duration compared with single agents. This was first demonstrated in children with ALL and confirmed in those with Wilms' tumor.<sup>4,5</sup>

The treatment of Wilms' tumor also served as a model for the successful use of multimodality therapy.<sup>6</sup> The adjuvant use of vincristine, dactinomycin, and regional radiation therapy after surgical resection produced substantial improvements in cure rates. Similar approaches were adopted for the treatment of rhabdomyosarcoma, Ewing's sarcoma, lymphoma, and other solid tumors. The efficacy of chemotherapy in improving survival in patients with nonmetastatic osteosarcoma after surgical therapy was demonstrated in a randomized cooperative group trial. Patients who received adjuvant chemotherapy had a 66% disease-free survival, as compared with a 17% disease-free survival in the patients who received surgical intervention alone.<sup>7</sup> This use of "adjuvant" chemotherapy to control micrometastases has now become standard practice for most solid tumors in children.

Many advances in pediatric oncology have occurred since these early discoveries. Most of them are attributable to the continued collaboration of pediatric oncologists, surgeons, and radiation therapists within cooperative groups. With the development of improved supportive care measures, dose-intensive chemotherapy programs have been successful in improving outcome for patients with Burkitt's lymphoma, neuroblastoma, and other advanced-stage solid tumors.<sup>8-10</sup> Further improvements in outcome have been made by altering the schedule of chemotherapy administration, either by alternating effective groups of chemotherapeutic agents to overcome or prevent resistance,<sup>11</sup> or by administering agents by continuous infusion rather than bolus.<sup>12</sup> Most recently, noncytotoxic biologic therapies have been developed specifically to target biologic pathways. These agents include signal transduction inhibitors, various tissue growth factor receptor inhibitors, anti-angiogenesis agents, tumor-targeted antibody therapies, and adoptive immunotherapy techniques.<sup>13</sup> Also, improvements in radiation therapy have led to the development of intraoperative radiation therapy and radiosurgery techniques. All these advances in treatment have led to profound

improvements in the quality of life and survival of children with solid tumors.

## EPIDEMIOLOGY AND SURVIVAL STATISTICS FOR CHILDHOOD CANCER

When compared with the adult incidence rates of cancer, the incidence of cancer in children is very small. However, whereas childhood cancer accounts for only 2% of all reported cancer cases, it accounts for 10% of all deaths among children and is the leading cause of death from disease among children.<sup>14</sup>

The distribution of the types of cancer in childhood is very different from that in adults. Whereas the majority of all cancers in adults are of epithelial cell origin, fewer than 10% of childhood cancers fall into this category. Table 66-1 displays the distribution of cancer in children younger than age 15 years.<sup>15</sup>

The incidence rates for specific cancers vary by age, gender, and race. Overall, the annual incidence rate for all types of childhood cancer is 133.3 per million children younger than age 15 years. The peak incidence for childhood cancer is before the age of 2 years, with an incidence rate of more than 200 cases per million. The incidence then decreases to a low of 82.5 cases per million at age 9 years, at which point it begins to climb again through the adolescent years. Before age 2 years, central nervous system (CNS) malignancies, neuroblastoma, acute myeloid leukemia (AML), Wilms' tumor, and retinoblastoma account for the majority of diagnoses. Between ages 2 and 4 years, ALL is the most common childhood cancer. After age 9 years, the incidence of Hodgkin's disease, osteosarcoma, and Ewing's sarcoma begins to increase sharply.<sup>14</sup>

According to the Surveillance, Epidemiology, and End Results (SEER) program, the average annual incidence of childhood cancer increased 10.8% between reporting year 1973-74 and 1989-90<sup>16</sup> but has been fairly stable for the last decade. The change in reported incidence may be accounted for by improved reporting of cancer cases, improved identification and diagnosis of

**Figure 66-1.** Comparison of patient survival during the period 1974 to 1976 versus 1992 to 1999 for the common childhood malignancies. (Data from SEER Cancer Statistics Review 1975-2000. Bethesda, MD, NCI, 2003. Available at [http://seer.cancer.gov/csr/1975\\_2000](http://seer.cancer.gov/csr/1975_2000).)

cancer, or a random fluctuation in the number of cases for the years studied.<sup>17</sup> Concern has been raised regarding the impact of environmental exposures resulting in increased cancer cases, but studies to date have not provided conclusive evidence for this assumption.

Survival from childhood cancer has improved so much over the past 30 years that the overall cure rate for childhood cancer is approaching 85%.<sup>18</sup> One in every 900 people between the ages of 16 and 44 years is a survivor of childhood cancer.<sup>1</sup> There has been a near 40% decline in mortality from childhood cancer between 1975 and 1995.<sup>19</sup> Figure 66-1 compares the survival statistics for specific cancers from 1974 through 1999.<sup>20</sup>

**Table 66-1** Distribution of Cancer in Children Younger than Age 15 Years

Type of Cancer	Distribution (%)
Acute lymphoblastic leukemia	23.2
Central nervous system tumors	20.7
Neuroblastoma	7.3
Non-Hodgkin's lymphoma	6.3
Wilms' tumor	6.1
Hodgkin's disease	5.0
Acute myeloid leukemia	4.2
Rhabdomyosarcoma	3.4
Retinoblastoma	2.9
Osteosarcoma	2.6
Ewing's sarcoma	2.1
All other cancers	16.4

## IMPORTANCE OF PATHOLOGY OF CHILDHOOD TUMORS IN SELECTING CHEMOTHERAPY

Unlike adult malignancies, which are primarily carcinomas, fewer than 10% of solid tumors of childhood are epithelial malignancies.<sup>16</sup> Although the spectrum of malignancies in childhood is more limited than in adults, the exact diagnosis is often more difficult because of the prevalence of "small round blue cell" tumors in childhood. These very primitive or embryonal malignancies often lack morphologically distinguishing characteristics. As a result, Ewing's sarcoma, neuroblastoma, lymphoma, small cell osteosarcoma, and primitive neuroectodermal tumors may appear quite similar by light microscopy. An error in diagnosis of Ewing's sarcoma in a patient who actually has a lymphoma of bone would lead to vastly different therapy and a poor outcome.

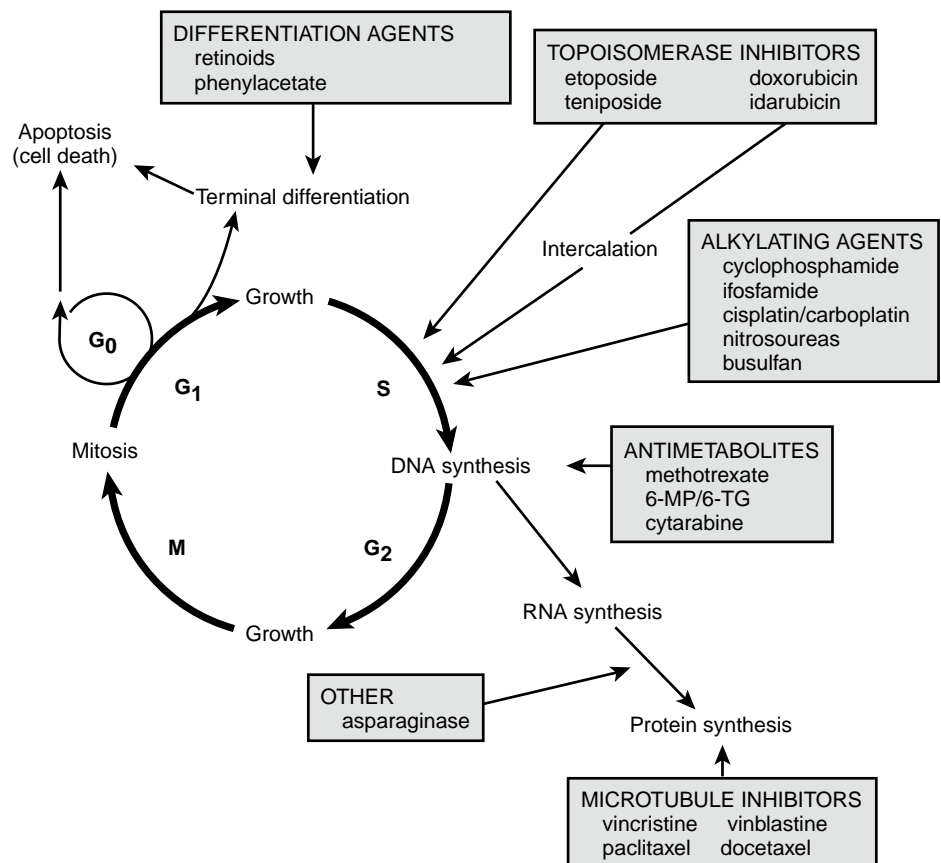

The exact diagnosis in pediatric cancer patients is crucial because chemotherapy for childhood malignancies is carefully tailored to each specific tumor type. This has become even more important over the past 2 decades as pediatric oncologists have continued to define better the prognostic subgroups for many tumors that help dictate the best therapy and the dose intensity of the therapy required for cure. Whereas the survival rate for patients with stages 1 to 3 Wilms' tumor with favorable histology is more than 90%<sup>21</sup> with standard therapy consisting of vincristine and actinomycin, with or without doxorubicin, a diagnosis of a Wilms' tumor with diffuse anaplasia carries a far worse prognosis and requires more intensive therapy for cure.

The initial step in the accurate diagnosis of a tumor is the availability of adequate material with which to make the diagnosis. Therefore, it is crucial that during the initial surgical procedure, whether it is a biopsy or resection, an adequate quantity and quality of tissue is obtained. The amount of tissue required for diagnostic purposes should be discussed with the surgeon, the pathologist, and pediatric oncologist before the procedure to ensure the proper handling of the specimen (e.g., the need for fresh tissue, frozen samples, and fixed specimens for histologic and biologic diagnostic use). Whereas light microscopy remains the primary tool of pathologists, they can now rely also on immunohistology, electron microscopy, DNA content of tumor, cytogenetic abnormalities, and specific tumor gene expression to establish a diagnosis.

## TUMOR BIOLOGY: UNDERSTANDING CHILDHOOD CANCER AND TREATMENT PRINCIPLES

Cancer is a genetic event. Genetic alterations within a single cell, those that can be identified as a cytogenetic abnormality, the activation of an oncogene, or the loss of a tumor-suppressor gene can all lead to the accumulation of cells lacking the ability to respond to growth-regulating signals and the subsequent development of cancer.

Understanding normal cell growth and regulation is a prerequisite to understanding both the genetic basis for the development of childhood cancer and the mechanisms of action of chemotherapeutic agents designed to kill rapidly proliferating cancer cells. Normal cell growth occurs by the regulated progression of the cell through the cell cycle of DNA replication and mitosis, separated by two intervening growth phases called  $G_1$  and  $G_2$ . Cells can temporarily leave the cell cycle and enter a resting state called  $G_0$  (Fig. 66-2). Cells are instructed to proceed through the cell cycle by a series of external and internal stimuli. Binding of proteins (growth factors) to cell-surface receptors stimulates a cascade of cytoplasmic signaling proteins (membrane kinases and signal transducers) that carries the stimuli to the nucleus. Other proteins (transcription factors) then bind to the DNA, resulting in the expression of growth-regulating genes. When functioning normally, these genes promote or prevent cell division, direct the

**Figure 66-2.** The cell cycle. Normal cell growth proceeds through DNA replication (S) and mitosis (M), separated by two growth phases ( $G_1$  and  $G_2$ ). Cells leave the cell cycle to enter a resting phase ( $G_0$ ) to differentiate or to die. Chemotherapy agents act at specific sites along the cell cycle, as indicated. (Adapted from Balis FRM, Holcenberg JS, Poplack DG: General principles of chemotherapy. In Pizzo P, Poplack D [eds]: Principles and Practice of Pediatric Oncology, 3rd ed. Philadelphia, Lippincott-Raven, 1997, p 219.)

cell to differentiate, or initiate apoptosis, the process of programmed cell death.

Alterations in one or several of these signaling proteins can lead to the unregulated cell growth characteristics of cancer cells. Oncogenes result from mutation or overexpression of the normal growth-promoting proto-oncogenes. Tumor suppressor genes are normally present in cells and function as negative regulators to slow the process of proliferation and allow time for cellular repair. When oncogenes become activated or tumor suppressor gene function is lost, cells lose their ability to respond to the usual regulatory protein stimuli and proliferate rapidly. Rapid cell proliferation leads to accumulation of more genetic defects, activation of additional oncogenes, and loss of more negative regulators as the cells become increasingly more malignant. Through the study of chromosomal aberrations, more than 100 oncogenes and 25 tumor suppressor genes have now been identified.

### CANCER CYTOGENETICS: A DIAGNOSTIC TOOL

The association of a consistent chromosomal aberration with a specific cancer was first made in 1960 with the discovery of the minute "Philadelphia chromosome" (9;22)(q34;q11) in chronic myeloid leukemia (CML).<sup>22</sup> With the discovery of chromosomal banding techniques in the 1970s, cancer cytogeneticists were first able to identify subchromosomal deletions, inversions, and translocations occurring in cancer cells. Study of these aberrant regions led to the identification of oncogenes and tumor suppressor genes, a process that is continuing today.

The presence of consistent cytogenetic abnormalities associated with a specific childhood leukemia or solid tumor helps in both cancer diagnosis and assignment of prognosis. Specific cytogenetic aberrations have been identified in rhabdomyosarcoma, Ewing's sarcoma, synovial sarcoma, germ cell tumors, medulloblastomas, neuroblastomas, retinoblastomas, and Wilms' tumors.<sup>23</sup> Chromosomal aberrations also can help predict prognosis. The finding of a chromosome 1q deletion, the presence of double minute chromatin bodies, or the presence of homogeneous staining regions in neuroblastoma confers a poor prognosis.<sup>24</sup>

The treatment of Wilms' tumor based on risk stratification determined by multiple tumor characteristics that impact prognosis, including loss of heterozygosity at 1p and 16q, is now being studied in the cooperative group setting. The process of using specific translocations for diagnostic purposes is enhanced by the use of the techniques of fluorescent in situ hybridization, which allows the localization and visualization of a single gene on a chromosome by using fluorescent DNA probes. Unlike standard cytogenetic analysis, which requires 5 to 14 days for the cancer cells to proliferate in culture before a karyotype can be obtained, this technique can be performed directly on tumor cells.<sup>25</sup> In the future, specific tumors may be identified by a specific "fingerprint" determined by microarray

analysis that can simultaneously analyze expression of thousands of genes on a single "chip."<sup>26</sup> The ability to tailor therapy to individual patients based on the genetic characteristics of their particular tumor is quickly becoming a reality.

### CHEMOTHERAPY PRINCIPLES IN PEDIATRIC ONCOLOGY

The goal of cytotoxic chemotherapy treatment for childhood malignancy is to maximize tumor kill while maintaining acceptable side effects. Clinical trials have led to the development of standard combination chemotherapy regimens for most childhood cancers. Adjuvant therapy (after local control measures) has remained the mainstay of cancer therapy, but neoadjuvant chemotherapy (before definitive local control measures) has proved to be effective in patients with metastatic disease and, in localized tumors, to begin to control microscopic metastatic disease immediately.

In the clinical development of promising anticancer agents, the first step is to define a tolerable dose. Phase I clinical trials are designed as dose-escalation studies to determine the maximally tolerated dose of a new drug given as a single agent. The dose of the agent is slowly increased in successive cohorts of patients until dose-limiting toxicity is consistently observed. The dose level immediately lower than the dose resulting in consistent toxicity is then selected to begin phase II trials. In a phase II trial, a consistent dose of the agent is tested for efficacy in a variety of tumor types to establish the spectrum of activity of the agent. Once an agent has demonstrated activity in a specific cancer, this agent is tested for efficacy when combined with other known active agents in that tumor system.

"Standard" therapy for a specific tumor type is established through phase III clinical trials. Classically, phase III trials use a prospective randomized design to compare two previously established effective chemotherapy combinations. At the conclusion of the trial, the chemotherapy regimen with the greatest efficacy and the least toxicity is selected as the standard regimen for that tumor system. Subsequent phase III trials then compare new regimens with this established standard therapy. It is through the development of phase I through III clinical trials within national cooperative groups that advances in cancer treatment are made.

Combination chemotherapy remains the mainstay of treatment of childhood cancer. In the 1960s, the benefit of combining several drugs together was demonstrated first for ALL. Complete remission by using single agents could be expected in only about half of the patients, whereas the combination of four or five drugs produced remission rates of more than 95%.<sup>27</sup>

Several biologic models have been devised to attempt to explain this observation. The most well known is the Goldie-Coldman hypothesis, which proposes that the response of any individual tumor to a chemotherapeutic agent is dependent on both the sensitivity of that tumor to the agent and the inherent tendency of that tumor to accumulate mutations that

will make it chemotherapy resistant. This hypothesis predicts that once a single tumor cell develops resistance to a chemotherapeutic agent, the tumor cannot be cured using that agent alone. Therefore, the best chance to cure a tumor is to give all available active agents simultaneously, after local control measures, when the tumor burden is as low as possible and the chance of any tumor cells having acquired resistance is minimal.<sup>28</sup>

This principle of designing combination chemotherapy regimens by using non-cross-resistant agents with nonoverlapping toxicities has been successfully used for childhood solid tumor treatment for the past 25 years. The improvement in survival rates over this period for neuroblastoma, Ewing's sarcoma, anaplastic Wilms' tumor, and osteosarcoma can be directly linked to effective combination chemotherapy treatment.

## ADJUVANT AND NEOADJUVANT CHEMOTHERAPY

The use of adjuvant chemotherapy is supported by the finding that fewer than 20% of sarcoma and lymphoma patients with initially nonmetastatic solid tumors can be cured by surgical therapy or radiation therapy alone (or even combined).<sup>29</sup> In the majority of these patients, recurrence is at a distant site, lending strong support to the hypothesis that micrometastatic disease exists at the time of presentation for the majority of patients with clinical nonmetastatic disease. In Wilms' tumor, as many as 40% of patients can be cured with surgical therapy or radiation therapy alone. However, survival can be increased to 90% with the addition of adjuvant combination chemotherapy.<sup>30</sup>

Because the goal of adjuvant chemotherapy is to prevent the appearance of metastatic disease, it is vital that chemotherapy begin as soon as possible after local control measures are completed. For this reason, most current chemotherapy regimens for childhood solid tumors recommend that chemotherapy is given within 2 weeks of initial surgical treatment.<sup>31</sup> In Wilms' tumor, assessment of tumor biology and risk stratification must be made by postoperative day 14 for inclusion in ongoing Children's Oncology Group studies. One approach to prevent delays in instituting chemotherapy in patients with nonmetastatic disease is to delay surgical resection until after several courses of chemotherapy can be administered. This is referred to as neoadjuvant chemotherapy, in which only a biopsy of the tumor is performed for diagnosis. Therefore, chemotherapy can begin as soon as the diagnosis is established at a time when the distant tumor burden is at its lowest. This approach has become standard in the treatment of Ewing's sarcoma and osteosarcoma and has the theoretical advantage of minimizing the appearance of chemotherapy resistance.<sup>11,32,33</sup> Furthermore, delayed surgical intervention may allow a more complete or less morbid resection and pathologic assessment of tumor responsiveness to the chemotherapy agents on an individual patient basis. For example, diagnostic biopsy followed by neoadjuvant

chemotherapy and delayed resection of the primary tumor for complex neuroblastoma reduces the operative complication rate without compromising survival.<sup>34</sup> Treating the tumors on the front end with chemotherapy reduced intraoperative blood loss and the need for nephrectomy. However, neoadjuvant chemotherapy is beneficial only for tumors for which a known highly effective combination chemotherapy program limits the risk of tumor progression at the primary site.

## SCHEDULE OF ADMINISTRATION

Children often tolerate chemotherapy better than adults because they have a superior and more rapid recovery from the toxic effects of treatment. Standard pediatric solid tumor chemotherapy protocols call for the administration of chemotherapy courses every 21 days to allow time for hematologic and organ recovery. Most combination chemotherapy programs are given over the first 1 to 5 days of the 21-day cycle. Historically, the next course of chemotherapy was withheld until the absolute neutrophil count was greater than 1000/mm<sup>3</sup> and the platelet count was greater than 100,000/mm<sup>3</sup>. The recent trend has been to maximize dose intensity and begin the next course when the absolute neutrophil count is greater than 750/mm<sup>3</sup> and the platelet count greater than 75,000/mm<sup>3</sup>, as long as mucositis or diarrhea (or both) induced by the chemotherapy has resolved. When these criteria are adhered to, the toxic death rate for standard combination chemotherapy programs is less than 5%.

Recently, changes in schedule of chemotherapy administration have led to improved efficacy of some agents. Etoposide is an epipodophyllotoxin that has been extremely effective in most pediatric solid tumors and in some epithelial cancers in adults.<sup>35,36</sup> The mechanism of action is inhibition of topoisomerase II. Classically, etoposide has been given with an alkylator and infused over a 1-hour period. However, it has been demonstrated that continuous intravenous exposure to etoposide for 3 to 21 days is superior to a 1- to 24-hour infusion.<sup>37,39</sup> In pediatric brain tumor patients, daily oral etoposide for 21 days was well tolerated and produced significant responses in patients with recurrent tumors.<sup>37</sup> Continuous exposure to etoposide has the theoretical advantage of maintaining a continuous blockage of topoisomerase II and thus preventing tumor cell repair, ultimately leading to more effective tumor kill. Similarly, prolonged exposure to combination chemotherapy agents in neuroblastoma and AML has led to improved responses.<sup>38,39</sup>

The duration of chemotherapy programs for most pediatric solid tumors has classically been 1 year. As the dose intensity of chemotherapy programs has increased, the duration of therapy has decreased. The National Wilms' Tumor Study IV demonstrated that 6 months of therapy was as effective as and could be administered at a lower total treatment cost compared with 15 months for patients with high-stage disease.<sup>21</sup> In neuroblastoma, when intensive induction therapy

is followed by consolidation with autologous stem cell transplant, the total duration of treatment is now 6 months.<sup>40</sup> As dose intensity of therapy increases, duration of chemotherapy may continue to decrease.

## CHEMOTHERAPY DOSE INTENSITY

To develop an effective combination chemotherapy program, it is important to select not only the correct combination of agents but also the correct dose of each agent. The trend for the past 10 years in pediatric oncology has been to increase chemotherapy dose intensity, with the goal of maximizing efficacy. In designing dose-intensive programs, the individual toxicities of the agents to be intensified must be considered. The best agents to use in high doses are those with limited organ toxicity and whose toxicity profile is mainly hematologic.

Most chemotherapeutic agents have a sigmoidal dose-response curve with a steep linear phase followed by a plateau phase. The principle of chemotherapy dose intensity is to administer the maximal tolerated dose of the agent that falls within the linear phase of the dose-response curve in the shortest possible interval while maintaining tolerable toxicity.<sup>41,42</sup> Dose intensity is defined as the amount of drug delivered per unit time, expressed as milligrams per square meter per week.<sup>43</sup> Therefore, dose intensity can be increased by giving higher doses of a chemotherapeutic agent, giving the agent more frequently, or both.

It has been demonstrated in animal systems that a 2-fold increase in administered cyclophosphamide dose can lead to a 10-fold increase in tumor cell kill,<sup>44</sup> whereas a decrease in dose intensity of as little as 20% in an osteosarcoma animal model can decrease the cure rate by 50%.<sup>45</sup> Similar clinical observations have been made in childhood leukemia and osteosarcoma. A prospective clinical trial of high-risk ALL patients revealed that patients receiving less than 94% of the planned dose of chemotherapy during the intensive portion of therapy had a 5.5-fold increased risk of relapse.<sup>44</sup> In osteosarcoma, patients receiving less than 80% of the proposed chemotherapy doses had a 3-fold increased risk of relapse.<sup>45</sup>

The positive impact of increasing the dose intensity on improving the response rate and survival duration has been demonstrated for Burkitt's lymphoma, osteosarcoma, Ewing's sarcoma, testicular cancer, breast cancer, and advanced ovarian cancer.<sup>8-10,41,46-48</sup> This finding has had a significant impact on the design of clinical trials for childhood solid tumors. Efforts have focused on identifying the most effective agents to intensify and then maximizing the supportive care to allow dose escalation.

Increasing the dose intensity of active chemotherapy agents in pediatric clinical trials has been possible because of recent advances in supportive care to decrease or minimize the toxic effects on normal tissues that occur from higher-dose chemotherapy. The use of cytokines to speed recovery of white blood cells and platelets (granulocyte colony-stimulating factor

[G-CSF] and interleukin-11 [IL-11])<sup>49,50</sup> and the use of cardioprotectant agents to allow a higher cumulative dose of doxorubicin to be used have helped in the development of new dose-intensive therapy for solid tumors.<sup>51</sup>

Many pediatric studies have demonstrated that collection of peripheral blood progenitor cells (PBPCs) from children as small as 10 kg is feasible.<sup>52</sup> The infusion of PBPCs has been effective in engrafting pediatric patients after myeloablative chemoradiotherapy.<sup>53,54</sup> In myeloablative therapy, "supralethal" doses of chemotherapy are given and hematopoietic recovery will occur only if a stem cell source (either PBPCs or bone marrow) is infused into the patient after completion of the myeloablative regimen. PBPCs also are effective in enhancing recovery after sub-myeloablative chemotherapy.<sup>55,56</sup> In sub-myeloablative regimens, hematopoietic recovery usually occurs in 3 to 4 weeks when combined with growth factor or PBPC support but would ultimately occur without this support in 6 to 10 weeks. The feasibility of repetitive collection, storage, and infusion of PBPCs for use with multiple-cycle dose-intensive chemotherapy in newly diagnosed neuroblastoma patients has been demonstrated in a Children's Cancer Group study.<sup>57</sup>

Myeloablative chemotherapy with total body irradiation as preparation for autologous stem cell transplant has been demonstrated to be an effective method of dose-intensive consolidation treatment after induction therapy in high-risk neuroblastoma. In a randomized Children's Oncology Group trial, high-risk neuroblastoma patients who received an autologous bone marrow transplant had an improved 3-year event-free survival compared with patients who proceeded to consolidation chemotherapy alone.<sup>58</sup> Given the success of increasing chemotherapy dose intensity by using a single myeloablative transplant in high-risk neuroblastoma, several investigators have performed pilot studies looking at the feasibility of performing two or even three consolidative stem cell transplants.<sup>59,60</sup>

## CHEMOTHERAPEUTIC AGENTS

The rational design of combination chemotherapy programs requires an understanding of the mechanism of action, the site of metabolism, the rate of drug clearance, and the toxicity profile for each drug. Most chemotherapy agents work by interfering with DNA or RNA synthesis, transcription, or repair. Unfortunately, these agents are not selective for cancer cells. The same metabolic pathways are disrupted in normal cells, leading to the toxic effects observed with chemotherapy treatment.

It is important to understand the normal cell cycle to understand how each chemotherapy agent interferes with the normal cell growth and repair processes. A normal cell proceeds through the four phases of the cell cycle in an orderly fashion. Checkpoints are in place to slow growth and allow needed repairs to prevent the accumulation of DNA or RNA errors. Malignant cells are usually lacking in some or most

of these checkpoints. As a result, these cells may be more susceptible to the toxic effects of chemotherapeutic agents. **Figure 66-2** illustrates the normal cell cycle and indicates the site of action of the major chemotherapeutic agents.

Chemotherapy agents can be divided into classes by their mechanism of action. The classes of agents include alkylating agents (cisplatin and its analogs) antimetabolites, topoisomerase inhibitors, antimicrotubule agents, differentiation agents, miscellaneous nonclassified agents, and biologic agents. Understanding the individual mechanisms of action helps in the design of drug combinations with additive or synergistic antitumor effects. The most common agents from each class, their mechanism of action, common side effects, and tumors in which they are active are listed in **Table 66-2**.

### Acute Chemotherapy Toxicity and Supportive Care

Most acute toxicities in childhood solid tumor therapy are reversible. Toxicity is greatest in the normal cells with the highest rate of turnover. Therefore, normal bone marrow cells, mucosal lining cells, liver cells, and hair cells are frequently affected. The most common side effects from combination chemotherapy include nausea and vomiting, myelosuppression, hair loss, mucositis, diarrhea, liver function test abnormalities, and allergic reactions.

Myelosuppression is an expected side effect of almost every treatment program for childhood solid tumors. Transfusions of packed cells and platelets are frequent. Of greatest concern is the risk of severe life-threatening bacterial or fungal infections that occur during episodes of neutropenia. In dose-intensive regimens, more than 75% of chemotherapy courses result in hospitalization for fever, with the incidence of bacteremia ranging from 10% to 20% per course.<sup>61</sup>

Several chemotherapeutic agents have very specific toxicities. For example, vincristine and doxorubicin are vesicants and can cause severe skin and tissue necrosis if the drug extravasates into the subcutaneous tissue. Doxorubicin and related anthracyclines have cumulative cardiotoxic effects. The total lifetime anthracycline dose must be limited for each patient to minimize the risk of developing congestive heart failure. Cisplatin has toxic renal effects and is often combined with another nephrotoxic agent, ifosfamide, in treatment of osteosarcoma and neuroblastoma. Cisplatin also can cause hearing loss, especially in high doses. Vincristine and vinblastine can cause cumulative peripheral neuropathies, and drug doses frequently must be altered to prevent significant morbidity. These toxicities must be considered when designing therapeutic programs.

Some of the success in improving outcome for children with cancer is attributable to advances made in supportive care. Routine use of hematopoietic growth factors, specifically G-CSF, results in more rapid granulocyte recovery and shorter hospitalizations for fever and neutropenia.<sup>49</sup> IL-11 enhances platelet recovery, decreases the depth of the platelet nadir, and decreases platelet transfusions requirements.<sup>50,62,63</sup> It has been

well tolerated in children and is very beneficial in combination regimens that induce severe thrombocytopenia.<sup>64,65</sup>

The gastrointestinal tract is injured by certain chemotherapy agents, specifically cytarabine, anthracyclines, and high-dose methotrexate. Leukovorin, a folate derivative, can be given to “rescue” normal mucosal and bone marrow cells from the effects of high-dose methotrexate. No rescue is known for the mucositis and diarrhea that occur with other agents. Use of IL-11, in addition to enhancing platelet production, may help speed recovery from gastrointestinal injury after chemotherapy.<sup>66</sup>

Renal toxicity can occur from the use of cisplatin, ifosfamide, and high-dose methotrexate. Cisplatin causes renal tubular damage, leading to elevation of levels of blood urea nitrogen and creatinine. Often this is reversible. Both ifosfamide and cisplatin cause renal electrolyte wasting, called Fanconi’s syndrome, in which hypokalemia, hypocalcemia, hypophosphatemia, and hypomagnesemia can occur. Renal injury from these agents can be improved by hyperhydration and forced diuresis. Ongoing studies with the organic thiophosphate compound amifostine show promise in preventing cisplatin-induced renal injury. Amifostine also may have protective effects against neurologic and cumulative bone marrow toxicities.<sup>67</sup> Mesna can prevent hemorrhagic cystitis resulting from cyclophosphamide and ifosfamide by binding to the bladder-toxic acrolein metabolites.<sup>64</sup>

It is anticipated that supportive care measures will continue to improve. In the future, some of the toxic effects of chemotherapy on bone marrow may be ameliorated by the use of gene therapy to transfer chemotherapy resistance genes into normal hematopoietic progenitor cells. This would allow higher doses of chemotherapy to be given without myelosuppression. Preliminary *in vitro* and animal studies have shown that hematopoietic progenitor cells can be made more resistant to nitrosoureas.<sup>65</sup>

### LONG-TERM SIDE EFFECTS OF CANCER THERAPY IN CHILDREN

In light of the fact that 1 of every 900 adults will soon be a survivor of childhood cancer,<sup>1</sup> emphasis on diagnosis, treatment, and prevention of late effects of childhood cancer therapy has become essential.

In general, tissues with the highest cell-turnover rate are the most susceptible to acute toxicities of chemotherapy. Tissues that replicate slowly or that can no longer regenerate may be susceptible to long-term or late effects of therapy. Children are more susceptible to certain late effects of therapy than are adults because their tissues are still growing. Damage to these tissues may affect growth, fertility, and neuropsychological development.

All aspects of combined-modality treatment can contribute to the late effects of childhood cancer therapy. Chemotherapy agents have been associated with specific late toxicities (see **Table 66-2**). Radiation

<b>Table 66-2 Chemotherapeutic Agents</b>			
<b>Class of Agent</b>	<b>Mechanism of Action</b>	<b>Antitumor Activity</b>	<b>Acute Toxicities</b>
<b><i>Alkylating Agents</i></b>			
<b>MUSTARDS</b>			
Nitrogen mustard	Alkylation, DNA crosslinking	Hodgkin's disease	Myelo, N/V, A, mucositis, phlebitis, vesicant
Melphalan	Alkylation, DNA crosslinking	Rhabdo; for BMT: Ewing's, NB	Myelo, mucositis, N/V, A, VOD (HD)
Cyclophosphamide	(Prodrug) alkylation, DNA crosslinking	Rhabdo; Wilms'; NB; Ewing's	Myelo, immuno, N/V, A, cystitis, SIADH, cardiac (HD), lung (HD), VOD (HD)
Ifosfamide	Alkylation, DNA crosslinking	Ewing's; rhabdo; osteosarcoma; NB	Myelo, N/V, A, hepatic, renal, cystitis, neuro
Busulfan	Alkylation, DNA crosslinking	Leukemia	Myelo, skin, lung, A
<b>NITROSOUREAS</b>			
BCNU	DNA crosslinking	CNS tumors; lymphoma	Myelo, N/V, A, lung, renal
CCNU	DNA crosslinking	CNS tumors; lymphoma	Myelo, N/V, A, lung, renal
<b>TETRAZINES</b>			
Dacarbazine (DTIC)	DNA methylation	Hodgkin's; sarcomas; NB	Myelo, hepatic, flulike illness, N/V, A
Temozolomide	DNA crosslinking	Brain tumors	Myelo, N/V, diarrhea, constipation, rash, lethargy, hepatic
<b>OTHER ALKYLATORS</b>			
Thiotepa	Alkylation, DNA crosslinking	CNS tumors; for BMT: sarcomas, NB	Myelo, N/V, A, diarrhea, mucositis, skin, VOD (HD)
Procarbazine	(Prodrug) methylation; free radical formation	Hodgkin's; CNS tumors	Myelo, N/V, rash, allergy, mucositis
<b>PLATINUM AGENTS</b>			
Cisplatin	DNA/platinum adduct formation; DNA crosslinking	Osteosarcoma; NB; hepatoblastoma; germ cell tumors; CNS tumors	N/V (severe), A, myelo, renal, neuro, mucositis, ototoxicity
Carboplatin	DNA/platinum adduct formation; DNA crosslinking	NB; CNS tumors; retinoblastoma; sarcomas in HD	Myelo, N/V (mild), renal and ototoxicity rare
<b><i>Antimetabolites</i></b>			
Methotrexate	Inhibitor of dihydrofolate reductase; interferes with folate metabolism	Leukemia; lymphoma; osteosarcoma in HD	Myelo, rash, mucositis, hepatic, renal (HD)
5-Fluorouracil	(Prodrug) inhibits thymidine synthesis	Hepatoblastoma; carcinomas	Myelo, N/V, mucositis, diarrhea, hyperpigmentation, neuro
Cytarabine	(Prodrug) incorporated into DNA; inhibits DNA replication	Leukemia; lymphoma	Myelo, malaise, N/V, mucositis, diarrhea, neuro (HD), eye (HD), skin (HD)
6-Mercaptopurine, 6-Thioguanine	(Prodrugs) inhibit purine synthesis	Leukemia	Myelo, N/V, hepatic, mucositis
Gemcitabine	Inhibitor of DNA synthesis	Hodgkin's disease, in phase II testing in leukemia	Myelo, rash, fluid retention, hepatic, N/V
<b><i>Topoisomerase Inhibitors</i></b>			
<b>EPIPODOPHYLLOTOXINS</b>			
Etoposide	Non-DNA-binding topoisomerase II inhibitor; stabilizes DNA double-strand breaks	NB; Ewing's; rhabdo; germ cell; leukemia; CNS tumors; lymphoma	Myelo, N/V, rash, allergy, low BP, A, mucositis, hepatic (HD)
Tenoposide	Same as etoposide	NB; leukemia	Myelo, N/V, rash, allergy, low BP, A, mucositis, hepatic (HD)

<b>Table 66-2 Chemotherapeutic Agents—cont'd</b>			
<b>Class of Agent</b>	<b>Mechanism of Action</b>	<b>Antitumor Activity</b>	<b>Acute Toxicities</b>
<b>ANTHRACYCLINES</b>			
Doxorubicin	DNA intercalation; free radical formation; topoisomerase II inhibitor	Wilms'; Ewing's; NB; lymphoma; leukemia	Myelo, N/V, A, mucositis, diarrhea, phlebitis, vesicant, hepatic, cardiac
Daunorubicin	Same as doxorubicin	Leukemia; lymphoma	Myelo, N/V, A, mucositis, diarrhea, phlebitis, vesicant, hepatic, cardiac
Dactinomycin	Same as doxorubicin	Wilms'; rhabdo; Ewing's	Myelo, N/V, A, mucositis, hepatic, vesicant
Bleomycin	DNA intercalation; free radical formation	Germ cell; Hodgkin's; lymphoma	Myelo, skin, allergy, mucositis, lung
<b>CAMPTOTHECIN ANALOGS</b>			
Topotecan	Topoisomerase I inhibitor	Rhabdo, neuroblastoma	Myelo, N/V, A, mucositis, diarrhea, hepatic
Irinotecan	Topoisomerase I inhibitor	In phase II testing in rhabdo	Diarrhea, myelo, N/V, hepatic
<b>Antimicrotubule Agents</b>			
<b>VINCA ALKALOIDS</b>			
Vincristine	Binds tubulin; prevents microtubule formation; blocks mitosis	Sarcomas; leukemia; Hodgkin's; constipation, neuro, vesicant, Wilms'; lymphoma;	SIADH
Vinblastine	Same as vincristine	Hodgkin's; germ cell	Myelo, mucositis, vesicant
<b>TAXANES</b>			
Paclitaxel (Taxol)	Binds microtubules; blocks microtubule depolymerization; blocks mitosis	Ovarian carcinoma	Myelo, A, mucositis, paresthesias, hypersensitivity
Docetaxel (Taxotere)	Same as paclitaxel	In phase II testing in sarcomas and other solid tumors	Myelo, A, skin, hypersensitivity, fluid retention, paresthesias, mucositis
<b>Differentiation Agents</b>			
<b>RETINOIDS</b>			
<i>Cis</i> -retinoic acid	Binds to retinoic acid receptor; induces differentiation	NB	Skin, mucositis, eye, pseudotumor, hepatic, electrolyte
All- <i>trans</i> -retinoic acid	Same as <i>cis</i> -retinoic acid	APML; in phase II testing in Wilms'; NB	Skin, mucositis, eye, pseudotumor, hepatic, electrolyte
Fenretinide	Still being investigated; induces cell death, not differentiation	Phase II testing in NB	Dry skin/lips, loss of night vision, increased triglycerides, hepatic, N/V
<b>Miscellaneous Nonclassified</b>			
Corticosteroids	Lympholysis; multiple other effects not well classified	Leukemia (ALL); lymphoma	Weight gain, high BP, high glucose, mood change, many others
L-Asparaginase, PEG-asparaginase	Asparagine depletion; inhibition of protein synthesis	Leukemia (ALL); lymphoma	Anorexia, hepatic, pancreatitis, coagulopathy, neuro

ALL, acute lymphoblastic leukemia; PEG, polyethylene glycol; rhabdo, rhabdomyosarcoma; BMT, bone marrow transplant; NB, neuroblastoma; CNS tumors, central nervous system tumors; HD, high dose; A, alopecia; myelo, myelosuppression; N/V, nausea and vomiting; VOD, veno-occlusive disease; neuro, neurologic toxicity; SIADH, syndrome of inappropriate antidiuretic hormone; BP, blood pressure; IT, intrathecal; APML, acute promyelocytic leukemia.

therapy can significantly inhibit further growth of bone, muscle, heart, and kidney within the radiation field and also affect fertility.

Growth retardation is the late effect unique to children. The degree of impairment depends on the dose of chemotherapy or radiation and the age of the child at the time of therapy. The younger the child at the time of the insult, the more severe the sequelae. More than 50% of childhood brain tumor patients treated with 3000 cGy or more to the whole brain will have severe growth retardation, with adult height being less than the fifth percentile.<sup>68</sup> Cranial irradiation can lead to growth hormone deficiency, which will result in poor linear growth unless growth hormone replacement is given. Patients who have received total-body radiation or spinal radiation may not be able to achieve their full height potential because the irradiated bones have limited growth potential, even with growth hormone stimulation.<sup>69</sup>

In addition to poor overall growth, adjuvant therapy can cause other musculoskeletal problems, including scoliosis, avascular necrosis, osteoporosis, and atrophy or hypoplasia of tissues. Radiation therapy to the head and neck results in hypoplasia of the jaw, orbit, or neck, with associated atrophy of the soft tissues. Associated endocrine, dental, and psychological consequences also may occur.<sup>70</sup> Aseptic necrosis of bone may affect as many as 10% of high-risk patients with ALL as a result of prolonged use of corticosteroids. Osteoporosis occurs as a result of corticosteroid treatment and from high-dose irradiation, as used for sarcoma therapy.

Most children who receive chemotherapy for solid tumors do not experience neuropsychological dysfunction. However, patients treated for brain tumors and those receiving cranial radiation for ALL are the exception and can experience a severe decline in IQ.<sup>71,72</sup>

Specific organs are often affected by chemotherapy. Heart, liver, lung, thyroid, and gonadal function can be impaired. Gonadal dysfunction (azoospermia, amenorrhea) frequently results from alkylator treatment. Therapy with mechlorethamine, vincristine, prednisone, and procarbazine has resulted in azoospermia in 80% to 100% of all male patients.<sup>73</sup> Combination chemotherapy programs for childhood Hodgkin's disease have been adjusted to replace mechlorethamine with cyclophosphamide and eliminate dacarbazine from standard treatments to attempt to decrease the infertility risk. It should be noted that the children of childhood cancer survivors are not at an increased risk for congenital anomalies.<sup>74</sup>

Cardiotoxicity from anthracycline antibiotics has been a problem in the treatment of Ewing's sarcoma, osteosarcoma, and lymphomas. Use of continuous-infusion anthracycline can decrease the risk of cardiac muscle damage and subsequent congestive heart failure.<sup>75</sup> Another new strategy has been the use of the cardioprotectant dexrazoxane to prevent anthracycline-induced cardiotoxicity.<sup>51</sup> Until a safe dose of anthracycline given with dexrazoxane can be defined, the cumulative lifetime dose of anthracycline continues to be limited to 450 mg/m<sup>2</sup>, a level at which fewer

than 5% of patients experience clinical congestive heart failure.<sup>76</sup> Other cardiovascular late effects have been reported in childhood cancer survivors. Survivors of childhood brain tumor therapy treated with a combination of chemotherapy, irradiation, and surgery had a significantly increased risk of stroke, blood clots, and angina-like symptoms compared with their siblings.<sup>77</sup>

Pulmonary toxicity is a source of significant late toxicity of cancer therapy. Many alkylating agents and radiation therapy contribute to pulmonary fibrosis, resulting in decreased lung volume, lung compliance, and diffusing capacity. The nitrosoureas and bleomycin are the most common agents to cause pulmonary fibrosis.

Other significant organ-related late effects include hypothyroidism after radiation in Hodgkin's disease, chronic renal insufficiency from cisplatin therapy, chronic cystitis from cyclophosphamide or ifosfamide treatment, and prolonged hypogammaglobulinemia and T-lymphocyte dysfunction after multiple high-dose alkylators for bone marrow transplant.<sup>78</sup>

One of the more significant late effects of cancer therapy is the risk of secondary malignancy. As the number of childhood cancer survivors increases, this has become a major concern. In a retrospective review of 1406 childhood cancer patients, the actuarial risk of a second malignant neoplasm was 5.6% at 25 years after diagnosis.<sup>79</sup> The risk of second malignancy is highest in the patients who received both chemotherapy and radiation therapy. Hodgkin's disease survivors have the highest secondary malignancy rates. The estimated actuarial incidence of any second cancer was 7% at 15 years after diagnosis. Breast cancer was the most common solid tumor, with an estimated actuarial incidence in women of 35% by age 40 years. These patients are also at risk to develop leukemia, non-Hodgkin's lymphoma, and thyroid carcinoma.<sup>80</sup> In some series of survivors of childhood Hodgkin's disease, the cumulative estimated incidence of second malignancies at 30 years has ranged from 18% to 31%.<sup>81,82</sup> Patients who have received additional multimodality therapy for recurrent Hodgkin's disease have the highest risk of second tumors. Patients with soft tissue sarcomas, retinoblastoma, and Ewing's sarcoma who receive high-dose radiation to the primary lesion are at increased risk for secondary osteosarcoma within the radiation field.<sup>83</sup> Etoposide has been recognized as causing secondary acute myeloid leukemia, usually of the M4 or M5 subtype, with a short latency period (1 to 3 years from exposure) and a characteristic chromosomal translocation involving chromosome 11q23.<sup>84</sup>

## BIOLOGIC TARGETED THERAPY

Over the past 20 years, many of the key genetic events that control carcinogenesis have been identified. In the past several years, rapid progress has been made in the development of rationally designed new agents to target biologic pathways specifically. These agents include signal transduction inhibitors (tissue growth

factor receptor inhibitors, antiangiogenesis agents, and biologic response modifiers) individual cytokines, tumor-targeted antibody therapies, and adoptive immunotherapy techniques. Many of these agents are still in preclinical and early phase I testing, especially in pediatric oncology, although efficacy of agents from each class has been demonstrated. The development of these agents differs from those used in standard cytotoxic therapy. Whereas standard phase I studies for cytotoxic agents are designed to define the maximal tolerated dose, in biologic targeted therapy the optimal therapeutic dose is well below the maximal tolerated dose. The challenge in evaluating these agents is how to select the optimal dose and schedule, combine tumor-targeted agents with classic cytotoxic therapy, and validate the intended effect on the selected target for these biologic compounds designed to treat minimal residual disease.

### Signal Transduction Inhibitors

Cellular signaling is a basic biologic function of all cells, controlling cellular proliferation and differentiation. Signaling can be extracellular (e.g., growth factor receptor tyrosine kinase) or through multiple intracellular effector and survival pathways (e.g., RAS, RAF, TP53, BCL-2). The malignant cell phenotype develops when apoptosis is inhibited or cells lose their ability to undergo normal differentiation. Specific agents have been synthesized to restore the usual cell functions by blocking aberrant signal transduction pathways.

Extracellular signaling can be accomplished via growth factor receptor proteins. Inhibition of the signaling pathways may result in decreased cell proliferation and increased apoptosis. A number of biologic agents have been developed to exploit this potential therapeutic option. Epidermal growth factor receptor (EGFR) is overexpressed in many solid tumors and is believed to play a role in tumor invasion and metastasis.<sup>85</sup> A specific inhibitor of EGFR, Gefitinib (AstraZeneca, Södertälje, Sweden), is an oral EGFR tyrosine kinase inhibitor that has demonstrated anti-tumor activity in adult phase I trials.<sup>86</sup> Potential use of this biologic agent in refractory neuroblastoma is currently in phase I testing in pediatric patients with solid tumors.<sup>87</sup> Inhibitors of the vascular endothelial growth factor (VEGF) receptor, vatalanib (PTK787/ZK22254), have been very effective inhibitors of angiogenesis, resulting in reduction in tumor size and number of blood vessels in treated patients.<sup>88</sup>

Multiple intracellular signaling pathways have recently been elucidated, and knowledge regarding the specific proteins involved in these pathways is now being exploited to develop specific targeted therapy. Production of farnesyl-protein transferase (FPTase) and BCL-2 inhibitors are examples of molecularly targeted drug development. The *ras* gene product plays a critical role in cell proliferation. Mutant forms of *ras* are associated with malignant transformation, and 30% of all human cancers express mutant *ras* genes.<sup>89</sup> Addition of a farnesyl isoprene group to the protein

(farnesylation) is required for both mutant and wild-type *ras* function. However, other cellular polypeptides require farnesylation and also may be involved in the antiproliferative effects of FPTase inhibitors.<sup>90</sup>

Another class of new targeted agents includes small peptides that are designed to bind to messenger RNA (mRNA) of signal transduction proteins and inhibit their expression. One example of such an antisense oligonucleotide inhibitor is G3139 (Genasense (oblimersen sodium) Injection, Genta Incorporated, Berkeley Heights, New Jersey). This agent binds to the first six codons of the human BCL-2 mRNA, resulting in downregulation of expression of BCL-2. Because apoptosis is regulated by BCL-2 expression, and neuroblastomas overexpressing BCL-2 have a poorer outcome,<sup>91</sup> it is hypothesized that inhibiting BCL-2 expression may improve tumor response in these patients. G3139 has completed phase I and II testing in adults, both alone and in combination with cytotoxic agents. Responses have been observed, and inhibition of BCL-2 expression has been measured in peripheral blood and tumor tissue. This agent has now undergone phase I testing by the Children's Oncology Group for relapsed and refractory pediatric solid tumor patients and shows acceptable toxicities.<sup>92</sup> Additional studies will be needed to document efficacy.

### Biologic Response Modifiers

The goal of biologic response modifiers is to stimulate the immune system to help eradicate tumors. The human immune system is designed to identify and destroy foreign cells. One of the great mysteries of oncology is why a patient's immune system is often unable to eliminate malignant cells. Studies in the mid 1990s indicated that some tumor cells may express a protein, Fas ligand, that conveys a "death signal" to T lymphocytes, causing them to undergo apoptosis.<sup>93</sup> The development of biologic response modifiers is a new branch of cancer therapy being developed to enhance or stimulate the natural products of the immune system (lymphocytes, antibodies, and cytokines) to better recognize and destroy cancer cells.

The immune system is composed of many cell types, but the lymphocyte has the primary role in controlling immune function. B lymphocytes function by secreting antibodies that mediate cell destruction by binding complement or causing opsonization, resulting in phagocytosis by macrophages. T lymphocytes can directly interact with specific cell-surface antigens on a target cell and cause cell lysis through cytotoxic granule release or programmed cell death. These cytotoxic T lymphocytes are involved with tumor cell killing. To initiate this response, antigens must be presented to the T cell by antigen-presenting cells (APCs) that express the antigens bound to major histocompatibility complex (MHC) proteins in the presence of stimulatory cytokines. Cytokines or interleukins (e.g., IL-2, interferon- $\alpha$ , tumor necrosis factor) are proteins produced by helper T lymphocytes and monocytes that help recruit other effector cells, including APCs, as well as regulate antibody production. The effector cells

of the immune system (e.g., granulocytes, monocytes, macrophages, eosinophils, dendritic cells) can become tumor selective when activated by a specific antibody, a process called antibody-dependent cell-mediated cytotoxicity (ADCC).

Immunotherapy with biologic response modifiers takes advantage of all these immune functions. The goal of this therapy is to improve the immunogenicity of a tumor and allow it to be recognized and targeted for destruction by the immune system. Immunotherapy can be divided into two major categories: adoptive immunotherapy and tumor-targeted antibody therapy.

### *Adoptive Immunotherapy*

Adoptive immunotherapy involves the use of tumor vaccines made from autologous or allogeneic tumor-associated antigens. Specific purified tumor antigens can be made more immunogenic by attachment to carrier proteins (adjuvants). The majority of all clinical trials using this type of tumor vaccine have been performed in melanoma patients.<sup>94</sup>

Another type of tumor vaccine in development is one designed to stimulate tumor-specific T-cell immunity to tumor peptides, resulting in the generation of cytotoxic T lymphocytes. For this type of vaccine to be successful, it is necessary to modify the tumor peptide to stimulate antigen presentation to the T cell. The presentation of the antigen is often restricted to specific MHC alleles. Neuroblastoma murine tumor cells have been modified to express exogenous MHC class II genes. In a murine model, this resulted in enhanced presentation of tumor antigens directly to T cells, producing a potent in-vivo tumor response.<sup>95</sup> Tumor cells also can be genetically engineered to overexpress cytokines (IL-2, granulocyte-macrophage colony-stimulating factor [GM-CSF]) that activate APCs and other immune cells.<sup>96,97</sup> Cytokines (GM-CSF, IL-2, IL-12, IL-1 $\alpha$ ) and other effector molecules (muramyl tripeptide phosphatidylethanolamine, disaccharide tripeptide) also are being used to stimulate an immune response in pediatric cancer patients.<sup>13</sup> Other forms of immunotherapy involve the use of cytokine infusions such as interferon- $\alpha$ , IL-2, and tumor necrosis factor to stimulate immune reaction against tumor cells.<sup>98</sup>

### *Tumor-Targeted Antibody Therapy*

Passive immunity involves the use of monoclonal antibodies (mAbs) or cytotoxic effector cells produced in vitro and infused into the patient. mAbs have been tested in patients with neuroblastoma. One drawback of murine mAb therapy is that when these antibodies are repeatedly infused into humans, most patients will ultimately produce a human/anti-mouse antibody, which renders further antibody treatment useless.

Recently, chimeric human/mouse antibodies have been produced that may decrease the risk of human/anti-mouse antibody generation.<sup>99</sup> Recombinant chimeric antibodies are produced by linking the constant region of human antibodies to the variable

combining region of a mouse mAb. These chimeric antibodies have been produced for the treatment of neuroblastoma<sup>100</sup> and more recently in leukemia and lymphoma with the development of anti-CD20, anti-CD52, and anti-CD33 mAbs. Rituximab (Genentech, Inc., San Francisco, CA) (anti-CD20) has been demonstrated to produce tumor responses in adult low-grade and follicular lymphomas.<sup>13</sup> The field of targeted biologic therapy is still in its infancy, but the future looks bright for the continued development of new targeted therapies, fueled by rapid advances in our understanding of cellular signaling pathways and immune mechanisms.

## **LOCAL TUMOR CONTROL**

Control of local disease is critical to favorable outcomes in pediatric oncology. Metastatic disease is more readily eradicated in young patients than in adults when the primary lesion has been adequately treated. Advancements in techniques utilized to obtain local control (other than complete surgical excision) are constantly changing as advances in technology offer more and more opportunity to effectively treat the disease locally while minimizing morbidity.

### *Radiation Oncology*

Radiation therapy implies the use of ionizing radiation to control malignant cells. An understanding of the biologic principles of radiation therapy in childhood cancer is important because radiation therapy plays an important role in the treatment of numerous pediatric tumors. There are several mechanisms of action through which radiation impacts tumor growth. Radiation may have a direct impact on the cellular DNA, resulting in impaired cell division. Alternatively, the radiation may result in the production of reactive free radicals that indirectly damage genetic material and interfere with the reproductive capacity of normal or malignant tissues. In most cases, the majority of the radiation effect is through production of these free radicals.

The sensitivity of normal cells and malignant cells to radiation varies widely between cell populations. Ionizing radiation initially results in sublethal damage to cells. The therapeutic effect of radiation therapy exploits the differences between a normal cell's ability to repair this sublethal damage and the slower response of radiosensitive tumor cells. Fractionated dosing allows normal cells to recover while having a cumulative effect on tumor cells. The effect of ionizing radiation on tumors depends on the number of actively reproducing cells at the time of exposure and on the length of the cellular regeneration cycle. Because most of the damage is indirect and focused on reproduction, malignant lesions usually show a delayed effect to radiation therapy. The tumor may begin to shrink or eventually disappear weeks to months after treatment. At some dose of therapy, the response of the malignant tissues becomes exponential, but further damage to normal adjacent cells also may occur.

Acute reactions to ionizing radiation depend on this balance between replication and cell death. They seem to be affected by increased intervals between dose fractions that allow enhanced cellular re-population. The radiation fraction size has a small impact on what volume of cells are immediately destroyed. Conversely, the long-term effects of therapy depend primarily on the total exposure dose and the size of each treatment fraction. The therapeutic ratio may be enhanced by exploiting the difference between the early and late radiation effects. Techniques may be used that reduce the late effects by lowering the dose per fraction and increasing the number of fractions delivered over the conventional treatment time.

Radiation therapy may be combined with surgery in a strategic manner to deliver the highest effective dose to a well-defined site, yet minimizes the dose to surrounding normal structures.<sup>101</sup> Preoperative radiation therapy may permit a smaller treatment area because the operative bed has not been manipulated. In larger tumors, its use may reduce the lesion volume sufficiently to allow a subsequent resection. In addition, potential tumor seeding during operative removal may be reduced because the cells that may be surgically disseminated have been rendered incapable of reproducing. On the other hand, preoperative radiation may delay the surgical procedure and alter the staging information obtained at operation.

For these reasons, many combined strategies use postoperative radiation such that the treatment fields and doses are determined after surgical resection and histologic assessment.<sup>102</sup> Higher doses can be delivered postoperatively when the target volumes have been more accurately defined. Doses to the periphery of the tumor can be fine-tuned, depending on the presence of gross, microscopic, or no residual disease. However, postoperative delivery may require a wider treatment area after extensive surgical manipulation.

Soft tissue sarcoma provides a model for the adjunctive role of radiation therapy. Surgery is the primary method of obtaining local control, but radiation therapy is effective when clear surgical margins are not possible.<sup>103</sup> Combined therapy has resulted in dramatically improved survival over the past 20 years.<sup>104</sup> In extremity lesions, radiation also allows more conservative resection with limb sparing. Although local tumor control rates of 75% to 98% have been achieved, with limb salvage rates greater than 80%, wound complications occur in as many as 40% of patients. Neoadjuvant radiation at more modest doses (30 Gy total) has decreased the complication rate while maintaining excellent (>95%) 5-year local control and ultimate limb salvage.<sup>103</sup> Postoperative radiation therapy also may be advantageous.<sup>105</sup> In that study, the wound complication rate was less than 10%. The use of brachytherapy offers potential advantages in obtaining local control while minimizing short and potentially long-term side effects.<sup>106</sup>

Several aspects of radiation treatment in pediatric patients deserve special consideration. Attention must be paid to the issues of immobilizing or sedating children so ionizing doses can be targeted to the desired

area without inappropriate exposure of surrounding tissues. Pediatric radiation oncologists may use lower treatment doses and accept a higher recurrence rate to ensure lower toxicity, especially in critical developing organs such as the brain. The normal "tolerance" of organs or tissues may be adversely affected when chemotherapeutic agents are also used. The long-term effects of combined-modality therapy must be considered in regard to musculoskeletal and dental tissues, CNS and neuropsychological sequelae, and endocrine and gonadal dysfunction, as well as direct effects on the heart, lungs, or kidneys.<sup>107</sup> The following sections describe techniques that allow safe, efficacious doses of radiation to be delivered, often in combination with surgical excision, to produce the maximal therapeutic benefit.

### BRACHY THERAPY

Brachytherapy is radiation treatment in which the ionizing source is in contact with the lesion, usually within the initial tumor volume. Catheters are placed in the tumor during surgery and may be loaded with temporary or permanent implant sources. Remote afterloading may decrease radiation exposure to personnel and family members and can be performed in the patient's room or on an outpatient basis. Low-dose-rate sources, such as cesium, provide about 1 cGy/min, whereas high-dose-rate sources, such as iridium, provide about 100 cGy/min.

Because interstitial implants allow continuous-dose delivery over a much shorter time, they offer a radiobiologic advantage in high-grade tumors with rapid cell growth kinetics. Close cooperation between surgeon and radiation oncologist during the procedure is critical to ensure the most effective mapping of the tumor bed target.

Pediatric patients with soft tissue sarcomas can benefit from specialized radiation treatment strategies. If children have microscopic residual disease after surgery, radiation produces excellent local tumor control.<sup>108</sup> High-dose-rate brachytherapy has been successfully used in pediatric patients (Fig. 66-3). Low-dose-rate techniques require sedation, immobilization, long exposure times, and hospitalization, even with low-energy sources. High-dose-rate therapy is delivered in a few minutes, which is particularly helpful in young children. The short therapy duration also allows rapid reinstatement of systemic chemotherapy. The morbidity is usually related to skin or mucosal reactions, which may progress as a "recall" phenomenon in patients treated with radiosensitizing agents such as anthracyclines.<sup>109</sup> It has been shown that brachytherapy alone or in combination with external-beam irradiation provides a high rate of local tumor control in pediatric soft tissue sarcomas.<sup>110-112</sup>

Unfortunately, radiation therapy carries a significant morbidity risk. Radiation to the CNS may cause necrosis, arteritis, leukoencephalopathy, or radiation-induced tumors. Benign meningiomas have developed in children who received initial high-dose cranial radiation for malignant brain tumors.<sup>113</sup> The carcinogenic

**Figure 66-3.** A 3-month-old infant with rhabdomyosarcoma in the base of the tongue. Eight high-dose-rate brachytherapy catheters were placed, delivering 36 Gy in 12 fractions over an 8-day period. The child is alive and disease free and has a good cosmetic result 7 years after treatment. (Courtesy of Subir Nag, MD, Chief of Brachytherapy, Ohio State University, Columbus, OH.)

effect of radiation therapy on brain tumors also has been theorized in more than 100 cases of malignant intracranial tumors.<sup>114,115</sup>

### INTRAOPERATIVE RADIATION

Intraoperative radiation therapy (IORT) can be an important adjunctive measure to external-beam irradiation for local tumor control of advanced adult cancer.<sup>116</sup> IORT allows the radiation dose to be directly applied to the target area while shielding adjacent structures. Whenever disease remains in surgically inaccessible areas, IORT may be an effective adjunct. Most applications of IORT in children have been in patients with unresectable disease at diagnosis, delayed primary or second-look procedures, residual lesions, or local tumor recurrence. Phase I/II studies have demonstrated that IORT can be done safely in the pediatric population,<sup>117</sup> and preliminary outcomes suggest that this modality may be beneficial.<sup>118,119</sup>

IORT for retroperitoneal tumors can lead to urologic complications. In six patients treated with IORT and external-beam therapy, three patients required surgical intervention for fibrotic ureteral strictures or renal artery stenosis. In two cases, the injured structures were within a supplemental external-beam treatment field. In two children, neuropathies developed, one transiently after IORT alone and one permanently after combined therapy with external-beam irradiation. Nevertheless, all patients were survivors for up to 42 months' follow-up.<sup>120</sup> Other studies suggest that

with more extensive dissection of normal structures and avoidance of overlapping radiation fields, the complication rate can be minimized.<sup>118</sup>

### INTENSITY-MODULATED RADIATION THERAPY

Techniques continue to evolve to improve the impact of radiation therapy on tumor response while minimizing the dose of radiation imparted to surrounding normal tissues. Stereotactic radiation therapy is sometimes used for CNS tumors.<sup>121-129</sup> Imaging systems, treatment-planning software, and delivery systems have undergone dramatic advancements that allow sophisticated delivery of more precise courses of radiation treatments. Intensity-modulated radiation therapy (IMRT) is an advanced form of three-dimensional conformal therapy that uses non-uniform radiation beam intensities that have been determined by using various computer-based optimization techniques. Experience with IMRT in the pediatric population is growing. Initial reports of mixed tumor cases, including pediatric patients, suggest that the technique will be effective in reducing treatment-related morbidity and allow dose escalation to the target volume.<sup>130,131</sup> Significant reductions in radiation exposure to critical structures has been shown for intracranial, cervical, and abdominopelvic lesions.<sup>132</sup>

## INNOVATIVE ADJUNCTIVE TECHNIQUES

### Cryosurgery

The basic principle involved in cryosurgery is the in-situ destruction of tissue by the freeze/thaw process. As the frozen tissue thaws, the circulation returns and, for a brief period, the tissue may appear almost normal. However, as endothelial cell damage, thrombosis, edema, and vascular stasis develop, the microcirculation progressively fails and cell death ensues.<sup>133</sup> The mechanism of tissue response is multifactorial and highly dependent on the rate of cooling. When this technique is applied to cancer, the goal is to devitalize the same volume of neoplastic tissue by freezing as would have been excised with a local resection. The most important tumoricidal mechanism appears to be the rapid freezing, slow thawing, and immediate repetition of this cycle.<sup>134</sup>

Intraoperative ultrasonography now allows precise placement of vacuum-insulated cryoprobes into the center of tumors. These probes can monitor the progression of the freeze margin in real time.<sup>135</sup> Liquid nitrogen is circulated through the tip of the probe, achieving temperatures in the range of  $-160^{\circ}\text{C}$  to  $-180^{\circ}\text{C}$ . When used for liver tumors (both primary and metastatic), survival has ranged from 12% to 38% at 18 months to 5 years of follow-up.<sup>136-139</sup> The incidence of major complications in most series is less than 5%. Hepatic enzyme elevation to about twice normal usually occurs and spontaneously resolves within the first postoperative week. Pleural effusion, myoglobinuria, hemorrhage, biliary leak, or abscess formation are rare.

Cryosurgery has been successfully used for aneurysmal bone cysts,<sup>140</sup> aggressive benign bone tumors, or low-grade malignancies.<sup>141</sup> Although cryosurgery offers the advantage of preserving supportive function of bone in these skeletal tumors, complications do occur. Most important, intraoperative venous gas embolism may rarely produce hemodynamically significant events.<sup>142</sup>

### Radiofrequency Ablation

Radiofrequency ablation (RFA) is a technique that applies thermal energy via a probe that results in coagulation necrosis of the target tissue. The technique involves image-guided application of the probe primarily using ultrasound guidance. The probe can be introduced percutaneously, laparoscopically, or using an open exposure. The most common applications for the technique in adults have been for primary or metastatic hepatic lesions, renal lesions, and pulmonary lesions.<sup>143-149</sup>

Treatment of pediatric tumors with RFA is largely anecdotal. A small series reporting the use of percutaneous RFA on fetuses with sacrococcygeal teratoma reported a 50% fetal mortality rate.<sup>150</sup> In one child treated prenatally with RFA, a severe soft tissue defect and sciatic nerve destruction were noted at birth.<sup>151</sup>

### Chemoembolization

The regional delivery of chemotherapy for hepatic tumors is possible because the liver has a dual blood supply, with the hepatic artery contributing approximately 25% of the parenchymal flow to normal cells, whereas malignant hepatic lesions derive nearly all of their blood supply from this source. This allows a selective delivery of cytotoxic agents to tumor. In addition, the liver can withstand regional dose escalation because of its ability to detoxify through “first-pass” kinetics. Whereas foreign body embolization produced temporary arterial occlusion and transient palliative effects, the most durable

responses were achieved when chemotherapeutic agents were infused distal to the ligated hepatic artery.<sup>152</sup> This therapeutic strategy involves infusing high concentrations of chemotherapy and prolonging the dwell time with a variety of embolic materials (Fig. 66-4). Multiple adult series have shown tumor reduction using chemotherapy delivery via embolic materials.<sup>153-157</sup> A prospective randomized trial for unresectable hepatocellular carcinoma compared chemoembolization against conservative therapy.<sup>157</sup> Although a trend favored survival with chemoembolization, the difference was not statistically significant. Of note, in 60% of the patients in the treatment arm, liver failure developed, which parallels previous experience.

The pediatric experience with chemoembolization is quite small, although isolated cases with limited success have been described.<sup>158,159</sup> This technique also has been extended to hepatic malignancies in infancy.<sup>160</sup> Two reports of chemoembolization experience in childhood liver tumors have been reported.<sup>161,162</sup> In one series,<sup>161</sup> a suspension of cisplatin, doxorubicin, and mitomycin-C mixed with bovine collagen and radiopaque contrast material was used in 11 children with unresectable or recurrent lesions. Six hepatoblastoma patients had initial partial response, as measured by imaging and  $\alpha$ -fetoprotein levels. Three patients underwent subsequent surgical resection, but 1 progressed and died, whereas 2 survived more than 15 months. The other 3 also eventually died of known progressive disease. Of the 3 children with hepatocellular carcinoma, 1 underwent surgical resection and was a long-term survivor for more than 65 months, 1 was alive with disease for more than 36 months, and 1 (with cirrhosis) died of progressive liver failure with no evidence of malignancy. In the other series,<sup>162</sup> 14 children received 50 courses of intra-arterial chemotherapy with cisplatin or doxorubicin (Adriamycin) or both, followed by Gelfoam embolization for hepatoblastoma (7 patients) or hepatocellular carcinoma (7 patients). Six of the 14 subsequently underwent orthotopic liver transplant, and 3 of the 6 died of metastatic disease. In 7 of the remaining patients, progressive disease

**Figure 66-4.** **A**, Celiac axis injection before embolization showing slight tortuosity of distal branches of the anterior superior segment of the right lobe, the middle hepatic artery, and the medial segment of the left lobe. **B**, Postembolization injection of celiac axis showing marked peripheral attenuation of the branches of the right and left lobes secondary to deposition of collagen laden with chemotherapy agent. (A and B, courtesy of Philip Stanley, MD, Pediatric Hematology-Oncology, UCLA School of Medicine, Los Angeles, California.)

developed, and 1 patient was awaiting transplant at the time of the report.

Overall, hepatic chemoembolization is feasible in young patients, with tolerable toxicity. This option represents a reasonable therapeutic alternative in persistent, unresectable, or recurrent hepatoblastoma, or in nonmetastatic hepatocellular carcinoma.

## Lymphatic Mapping

Accurate staging of regional disease continues to be important in pediatric and adult tumors. The initial draining lymph node, the so-called sentinel node, is reportedly predictive of regional nodal metastases in a variety of tumors.<sup>163</sup> Although lymph node mapping has been applied to a number of tumors, it is most commonly used to predict nodal status of patients with melanoma or breast cancer. The technique has been refined and validated as it has evolved. In most cases, a combination of technetium-labeled sulfur colloid and lymphazurin blue dye is used to localize the sentinel node. Preoperative lymphoscintigraphy provides information regarding draining nodal basins in truncal and head and neck cases. Intraoperative lymphatic mapping is accomplished by injecting the technetium-labeled sulfur colloid at the primary tumor site 1 hour before surgery. Just before incision, the blue dye is injected at the primary tumor site and a gamma probe is used to identify areas of high counts. The underlying tissue is then examined for lymph nodes containing the blue dye. If the sentinel node has no histologic evidence of metastases, the related regional lymphatic bed is highly likely to be tumor free, and the morbidity of lymphadenectomy can be avoided.

Lymphoscintigraphy is a reliable indicator of lymphatic drainage from cutaneous melanoma of the head, neck, and trunk. In one study, a radiolabeled tracer of <sup>99</sup>Tc sulfur colloid or human serum albumin was injected before wide local excision of the primary lesion.<sup>164</sup> Of 297 patients reviewed, 181 underwent elective dissection of the lymph node basins identified by the lymphoscintigraphy and 27% had melanoma detected within the dissected basin. The other

116 patients were observed. In 14%, lymph node metastases developed as their first sign of recurrence. Only 1 of these patients, in whom rapidly progressive disease developed, had lymph node metastases in an area not predicted by the scan. Overall, 70 of 71 patients had documented lymphatic metastases occur in a predicted lymph node bed, confirming that cutaneous lymphoscintigraphy can be reliably used to guide therapy in high-risk melanoma. Lymph node localization by gamma probe scanning also has been extended to breast cancer management.<sup>165</sup>

The implications of sentinel lymph node mapping are important in pediatric tumors such as rhabdomyosarcoma. In the Intergroup Rhabdomyosarcoma Studies I and II, the incidence of positive regional lymph nodes was 12% to 17%. However, most of these patients did not undergo lymph node sampling. More recently, when the majority of patients actually did have a lymph node biopsy, the incidence of detecting disease increased to 40%.<sup>166</sup> These findings also were confirmed subsequently in the Intergroup Rhabdomyosarcoma Study III, which demonstrated that when regional lymph nodes were sampled, 39% contained metastatic disease.<sup>167</sup> Patients with positive nodes underwent radiation therapy to the involved lymph node bed, resulting in improved survival, documenting the need for accurate lymph node staging.

The technique of lymph node mapping has been successfully applied to a small series of pediatric patients.<sup>168</sup> On the day before operation, the patient is injected around the palpable lesion or the previous incision site with 0.2 to 0.5 mL of <sup>99</sup>Tc sulfur colloid. Immediately before surgery, the same area is injected with 0.5 to 1.0 mL of vital blue dye. When a handheld gamma probe is used, signal localization parallels the presence of the blue dye in the lymphatic channels leading to the sentinel lymph node, which is stained blue and scans positive. An excisional biopsy is performed for histologic assessment, which should predict involvement of the remaining lymphatic bed. No therapy is necessary for negative biopsies. Histologically positive tissue leads to lymph node dissection and regional lymphatic radiation.

# RENAL TUMORS

Robert C. Shamberger, MD

Renal tumors are the second most common abdominal tumor seen in infants and children after neuroblastoma. They represent a wide spectrum of tumors from benign to extremely malignant. Advances in the management of these tumors have been significant over the past 4 decades since Sidney Farber first administered dactinomycin (Actinomycin D) for advanced-stage Wilms' tumors.<sup>1</sup> Much of what we know about renal tumors today has resulted from two cooperative group organizations, the National Wilms' Tumor Study Group (NWTSG) and the Société Internationale d'Oncologie Pédiatrique (SIOP). Together they have performed multiple randomized therapeutic trials, which have established the basis for how these tumors are treated. Central pathologic review of the specimens of patients enrolled in these studies has provided the current pathologic classification and staging, which could never have been established without multi-institutional participation because of the relative rarity of pediatric renal tumors. In this chapter, the early history of this tumor is described, followed by a discussion of the etiologic factors in tumor formation, pathologic subtypes and premalignant syndromes, and treatment algorithms for Wilms' tumors and other tumors of the kidney.

## WILMS' TUMOR

### History

The first descriptions of Wilms' tumor have been variably attributed to either Rance in 1814 or Wilms' in 1899.<sup>2</sup> Ironically, however, the first known specimen of this tumor was preserved by the British surgeon John Hunter between 1763 and 1793, when he was collecting specimens for his museum.<sup>3</sup> To this day, this specimen of a bilateral tumor in a young infant remains in the Hunterian Museum of the Royal College of Surgeons in London. Wilms' name became indelibly fixed to the mixed embryonal tumor of the kidney occurring in children after publication of his comprehensive monograph on mixed tissue tumors of the kidney in 1899.<sup>4</sup>

William E. Ladd and Robert E. Gross<sup>5,6</sup> described the principles of surgical therapy for Wilms' tumor, including transperitoneal exposure and early ligation of the renal pedicle. They stressed the need to remove the perirenal fat to include lymphatic extensions and to avoid rupture of the renal capsule, principles we continue to follow today. Adoption of their techniques significantly reduced the operative mortality of nephrectomy in children. Gross and Neuhauser<sup>3</sup> later proposed the routine addition of abdominal radiation to the therapy of Wilms' tumors and reported an estimated 47% frequency of cure. Under Gross's tutelage, pediatric surgeons in North America generally performed primary resection of Wilms' tumors, while in Europe the Paris school led by Schweisguth and Bamberger reported early success with preoperative irradiation, establishing a precedent for preoperative therapy.<sup>7</sup>

From 1931 to 1939, survival from surgical resection alone, involving ligation of the renal pedicle before removal, was 32% at The Children's Hospital in Boston.<sup>1</sup> Beginning in 1940, most of the patients received postoperative irradiation to the renal fossa, which decreased the local recurrence rate but did not significantly affect the frequency of pulmonary metastases or improve the long-term survival. Dactinomycin was the first active agent identified for the treatment of Wilms' tumor. Of the 53 patients who had no demonstrable metastases on admission treated with combined therapy of operation, local radiation, and dactinomycin from 1957 to 1964, an 89% 2-year disease-free survival was reported, a very reasonable survival even today.<sup>1</sup> In patients with metastases identified at presentation, 18 (58%) of 31 were alive and free of disease more than 2 years later. Subsequently, vincristine sulfate was identified as an active agent against Wilms' tumor and was added to the standard therapy.<sup>8</sup>

Wilms' tumor was the first malignancy in which the importance of adjuvant treatment was recognized. This principle was espoused by Sidney Farber decades before it would be applied to other pediatric and adult solid tumors. The concept of adjuvant therapy "was based upon the supposition that in the children

with Wilms' tumor who died, the tumor must have metastasized already at the time of discovery of the primary tumor" although no evidence of spread was available.<sup>1</sup>

## Incidence and Etiology

Wilms' tumor is the most frequent tumor of the kidney in infants and children. Its incidence is 7.6 cases for every million children younger than 15 years, or one case per 10,000 infants.<sup>9</sup> Its frequency varies by race. It is less common in East Asian populations than in whites but more frequent in black children.<sup>10</sup> In just under 10% of cases, it is associated with several congenital syndromes, including sporadic aniridia, isolated hemihypertrophy, the Denys-Drash syndrome (nephropathy, renal failure, male pseudohermaphroditism, and Wilms' tumor), genital anomalies, Beckwith-Wiedemann syndrome (visceromegaly, macroglossia, omphalocele, and hyperinsulinemic hypoglycemia in infancy), and the WAGR complex (Wilms' tumor with aniridia, genitourinary malformations, and mental retardation). All these associations suggested a genetic predisposition to this tumor.<sup>11,12</sup> Wilms' tumor also is reported in individuals with Simpson-Golabi-Behmel syndrome, another overgrowth syndrome similar to Beckwith-Wiedemann syndrome in many respects.<sup>13</sup> These congenital disorders have now been linked to abnormalities at specific genetic loci implicated in Wilms' tumorigenesis.

## Genetic Origins

The identification of a large chromosomal deletion of band p13 of chromosome 11 in children with the WAGR syndrome led to a search at this site for a gene producing the Wilms' tumor. Subsequent molecular studies of children with Wilms' tumor demonstrated a deletion at this site in some cases.<sup>14</sup> This deletion includes the aniridia gene (*PAX 6*) and a putative Wilms' tumor suppressor gene (*WT1*). It should be recognized that children can lack the *PAX6* gene but not the *WT1* gene and not be at increased risk for the development of Wilms' tumors. In fact, from the Danish aniridia registry, 44 of 144 cases of aniridia were sporadic. Of these sporadic cases, 5 patients had a deletion of the *WT1* gene but only 2 developed a Wilms' tumor.<sup>15</sup> None of the patients with the familial cases lacked the *WT1* site. Therefore, for patients with aniridia, the risk appears low, but in the children with sporadic aniridia, it is estimated that the risk of developing a Wilms' tumor is 67 times higher than in a normal population. This risk is entirely attributable to the small proportion who lack the *WT1* gene. Finally, it is estimated that between 45% and 57% of children with the WAGR syndrome will develop a Wilms' tumor.<sup>16,17</sup>

The protein product of the *WT1* gene is a developmentally regulated transcriptional factor of the zinc-finger family, which regulates the expression of other genes, including growth-inducing genes such as those encoding early growth response, insulin-like growth factor-2 (IGF-2), and the platelet-derived growth

factor A chain.<sup>18,19</sup> Suppression of these growth-associated genes may explain the tumor suppressor role of *WT1*. Recently, the *WT1* gene product has been found to bind physically to the TP53 protein.<sup>20</sup> Children with the WAGR syndrome have constitutional deletions of band 11p13, and virtually all patients with Denys-Drash syndrome carry point mutations in *WT1* in their germline.<sup>14</sup> These result in a dominant negative oncogene and more severe somatic abnormalities than those seen in the WAGR syndrome, attributed to the inhibition by the mutated protein on the action of the normal "wild-type" protein produced by the normal chromosome.<sup>21</sup> The second *WT1* allele is lost in the Wilms' tumor cells in patients with WAGR. Similarly, the tumors in children with Denys-Drash syndrome have loss of the remaining "wild-type" allele.<sup>22</sup> Excluding aniridia, the most common phenotypic abnormality in the WAGR syndrome is cryptorchidism, which is found in 60% of male patients, whereas abnormalities of the internal reproductive organs including streak ovaries and bicornuate uterus are seen in 17% of females. Mental retardation was found in 70% of children and renal failure in 29%, which occurred due to both nephrectomy and glomerulonephritis, predominantly focal segmental glomerulosclerosis. Studies have demonstrated that children with WAGR syndrome more frequently have bilateral tumors (17% vs. 6%) and are younger at diagnosis (22 vs. 39 months) than children without WAGR.<sup>23</sup>

Dysregulation of imprinted genes at chromosome 11p15 that control prenatal and childhood growth are believed to be the cause of the Beckwith-Wiedemann syndrome.<sup>24</sup> These include isolated hypomethylation of a differentially methylated region known as KvDMRI in approximately 50% of cases.<sup>25,26</sup> At the *WT2* site, there are several imprinted genes that are expressed preferentially from one of the parental alleles.<sup>27</sup> Some children with Beckwith-Wiedemann syndrome have overexpression of a gene normally expressed by only one of the parental alleles, paternal uniparental disomy in 20% of the cases. In some cases, a constitutional duplication of the paternal 11p15 chromosomal fragment has been identified (trisomy at 11p15).<sup>28</sup> These findings led to speculation that the Beckwith-Wiedemann gene is expressed only by the paternal allele and that these genetic abnormalities that lead to the presence of two paternal alleles would double the expression of this gene and may result in the overgrowth.

Loss of expression of *H19*, a tumor suppressor gene, also has been reported in Wilms' tumors.<sup>29</sup> The *H19* gene is expressed from the maternal allele. With loss of heterozygosity (LOH), the cell may lose the maternal (active) copy and hence its tumor suppressor function.<sup>30</sup>

Children whose manifestations of the Beckwith-Wiedemann syndrome include hemihypertrophy appear to have a greater risk for the occurrence of malignancy than do those who do not. In a series reported by Wiedemann, cancer was reported in 7.5% of all children with the syndrome but was found in

more than 40% of children with both the syndrome and hemihypertrophy.<sup>31</sup>

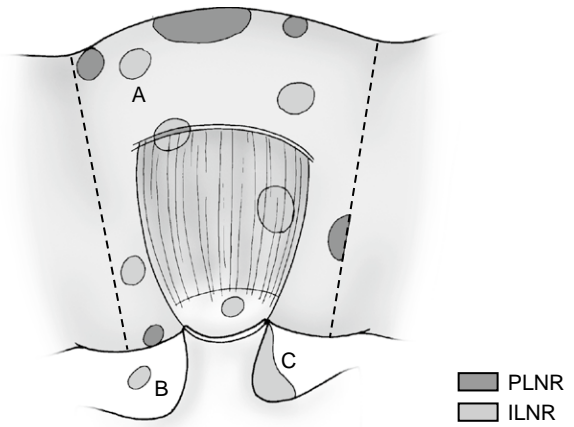

The Simpson-Golabi-Behmel syndrome is a sex-linked syndrome linked to Xq25-27. It is an overgrowth syndrome phenotypically similar to the Beckwith-Wiedemann syndrome comprising macroglossia, coarse facial features, and visceromegaly. The less frequent manifestations of diaphragmatic and heart defects and polydactyly are unique to Simpson-Golabi-Behmel syndrome. The protein product glypican-3 may interact with the IGF-2 receptor.<sup>32,33</sup>

Familial cases of Wilms' tumor account for only 1% to 2% of cases and have not been associated with these syndromes. Analysis of two kindreds revealed a link with chromosome band 17q12-21, and the putative tumor gene at this locus has been named *FWT1*.<sup>34</sup> Recent studies in five kindreds have demonstrated an inherited Wilms' tumor predisposition gene at 19q13.3-q13.4, called *FWT2*.<sup>35,36</sup> In addition, LOH was seen at 19q in tumors from individuals from two families whose predisposition is not due to the previously defined 19q locus, suggesting that alterations at two distinct loci are critical rate-limiting steps in the etiology of these familial Wilms' tumors involving both germline-predisposing mutations and somatic alteration at a second focus.

In marked contrast to the *MYCN* gene in neuroblastoma, *WT1* and *WT2* do not appear to have any prognostic significance for children with Wilms' tumor. They also appear in a small percentage of children with Wilms' tumor who have the associated syndromes. Recent studies have suggested that LOH on chromosome 16q in Wilms' tumors (observed in 15% to 20% of cases) was associated with a 3.3 times greater incidence of relapse and a 12 times greater incidence of mortality as compared with those in children without these chromosomal changes.<sup>37</sup> This region of loss has now been localized to an area of 6.7 megabases that contain three recognized tumor suppressor genes. One of them, *E-cadherin*, has been shown to have reduced expression in Wilms' tumors with LOH at 16q.<sup>38</sup> A similar trend was seen for children with LOH for 1p, which occurs in approximately 10% of Wilms' tumors, but these trends were not statistically significant. One of the primary goals of the fifth NWTSS study is to assess whether identified chromosomal abnormalities are of prognostic significance in Wilms' tumor (see later).

Identification of increased expression of the TP53 protein has also been associated with advanced stage at presentation and increased disease relapse.<sup>39</sup>

Routine radiographic screening of children with syndromes associated with Wilms' tumor has been recommended. Ultrasonograms are generally obtained every 3 months until the children are 5 years old. No prospective studies, however, have been performed to evaluate the cost-effectiveness or efficacy of this recommendation.<sup>40,41</sup> Retrospective reviews of routine ultrasound screening report conflicting results on the purported benefits of prospective screening, as assessed by the stage distribution at presentation or the outcome of the children.<sup>42,43</sup>

**Figure 67-1.** Diagram of a renal lobe and adjacent calyx and intervening sinus with potential sites of distribution of perilobar (PLNR) and intralobar (ILNR) nephrogenic rests. (From Beckwith JB, Kiviat NB, Bonadio JF: Nephrogenic rests, nephroblastomatosis, and the pathogenesis of Wilms' tumor. *Pediatr Pathol* 10:1-36, 1990.)

### Pathologic Precursors: Nephrogenic Rests, Nephroblastomatosis, and Multicystic Dysplastic Kidneys

The presence of nephrogenic rests (NRs; persistent metanephric tissue in the kidney after the 36th week of gestation) has been associated with the occurrence of Wilms' tumor. These rests may occur in a perilobar (PLNRs) or intralobar (ILNRs) location and may be single or multiple (Fig. 67-1). In children with aniridia or the Denys-Drash syndrome, the lesions are primarily ILNRs, whereas children with hemihypertrophy or the Beckwith-Wiedemann syndrome have predominantly PLNRs.<sup>44</sup> The presence of multiple or diffuse nephrogenic rests is termed *nephroblastomatosis*.

The frequency of NRs was established in an autopsy series of infants younger than 3 months. Nine (0.87%) of 1035 infants had PLNRs, and ILNRs occurred in only 2 (0.1%) of 2000 cases.<sup>45</sup> When identified, most NRs are sclerosing, an apparently indolent or involutinal phase. The vast majority will spontaneously resolve without the appearance of a tumor, because the incidence of NRs is about 100 times greater than that of Wilms' tumor (1/10,000 infants).

NRs are classified histologically as incipient or dormant NRs, regressing or sclerosing NRs, and hyperplastic NRs (Fig. 67-2).<sup>46</sup> Incipient or dormant rests are composed predominantly of blastemal or primitive epithelial cells, resembling those in the embryonic kidney and Wilms' tumor, but are microscopic with sharp margins from adjacent renal parenchyma. In infants and young children, the term *incipient* is used, whereas *dormant* is used in older children. Regressing or sclerosing rests demonstrate maturation of the cellular elements and progress to obsolescent rests, which are composed primarily of hyaline stromal elements. Hyperplastic NRs are problematic, in that they are often difficult to distinguish from small Wilms' tumors. They contain diffuse or synchronous proliferation of components throughout the rest. This uniform growth leads to preservation

**Figure 67-2.** Diagrammatic depiction of nephrogenic rests and their classification. Thick arrows indicate tumor induction. (From Beckwith JB: Precursor lesions of Wilms' tumor: Clinical and biological implications. *Med Pediatr Oncol* 21:158-168, 1993.)

of the original shape of the rest, in contrast to neoplastic proliferation of a single cell, which produces a more spherical expanding nodule within the rest. It is almost impossible for even the most sophisticated pediatric pathologist to distinguish a hyperplastic NR from a Wilms' tumor based on an incisional or needle biopsy specimen that does not include the margin between the rest and the remaining kidney. Preservation of the shape of the original rest is the most obvious clue that one is dealing with a hyperplastic, rather than a neoplastic, change.<sup>46</sup> Most hyperplastic nodules lack a pseudocapsule at their periphery, whereas most Wilms' tumors will have one. Often this is the most helpful histologic finding in distinguishing these two lesions. Thus, biopsy specimens that do not contain the lesion and its margin will rarely adequately differentiate between these two lesions.

NRs are frequently found in association with Wilms' tumors despite their relatively rare occurrence. In a review of cases of Wilms' tumors reported in the NWTS-4, 41% of the unilateral Wilms' tumors were associated with NRs,<sup>44</sup> whereas in children with synchronous bilateral Wilms' tumor, the incidence of NRs was 99%. These were primarily PLNRs, possibly because these lesions are much more prevalent than the ILNRs. Similarly, an increased incidence of NRs is seen in children with the syndromes associated with Wilms' tumor (Table 67-1).<sup>46</sup>

It has been demonstrated that magnetic resonance imaging (MRI) can be particularly helpful in monitoring children with nephroblastomatosis. Rohrschneider and co-workers later confirmed that MRI or contrast-enhanced computed tomography (CT) was preferable to ultrasonography in this setting.<sup>47,48</sup> Alterations in imaging characteristics of the lesions may suggest a transition from NRs to Wilms' tumor, as does growth of isolated lesions.

Diffuse hyperplastic perilobar nephroblastomatosis (DHPLN) is a distinct entity that must be distinguished clinically from Wilms' tumor. Infants with DHPLN may initially have large unilateral or bilateral flank masses (Fig. 67-3). A characteristic radiographic finding is massively enlarged kidneys that maintain their normal configuration and lack evidence of necrosis. As with the isolated NRs, proliferation of the thin rind of NRs on the periphery of the kidney will preserve the normal configuration of the kidney, but with marked enlargement of its size. This is in contrast to Wilms' tumor, in which the normal renal configuration and collecting system is generally distorted. Nephrectomy is not required in cases of DHPLN. Chemotherapy, however, has been used to control the proliferative element of the size of the masses and decrease the respiratory compromise they may produce. However, it has not been established that treatment with chemotherapy will decrease the risk of malignancy arising in these lesions. A recent review of 52 cases of DHPLN revealed a mean age of 16 months at diagnosis. Involvement was bilateral in 49 children. Thirty-three patients had biopsy and adjuvant therapy. Eighteen (55%) developed Wilms' tumors at a mean of 35 months. Sixteen patients had initial nephrectomy and adjuvant therapy, and 3 (19%) developed a Wilms' tumor at a mean of 36 months from diagnosis. All 3 patients who did not receive adjuvant therapy developed Wilms' tumors by 10 months after diagnosis. In total, 24 of 52 children developed Wilms' tumors that were single in 13 and multiple in 11 children. Eight of the 24 children had anaplastic tumors, an extremely high proportion.<sup>49</sup>

An increased risk of Wilms' tumors arising in multicystic dysplastic kidneys has been suggested. In the past, many of these lesions were resected to prevent the occurrence of Wilms' tumor. Narchi summarized 1041 infants and children with multicystic dysplastic kidneys reported in the world's literature from 26 series and found no case associated with a Wilms' tumor.<sup>50</sup> He concluded that nephrectomy was not required for

**Table 67-1** Association of Nephrogenic Rests with Wilms' Tumor and Associated Syndromes

Population	PLNR (%)	ILNR (%)
Unilateral Wilms' tumor	25	15
Bilateral Wilms' tumor (synchronous)	74-79	34-41
Bilateral Wilms' tumor (metachronous)	42	63-75
Beckwith-Wiedemann/hemihypertrophy & Wilms' tumor	70-77	47-57
Aniridia and Wilms' tumor	12-20	84-100
Denys-Drash and Wilms' tumor	11	78

Adapted from Beckwith JB: Precursor lesions of Wilms' tumor: Clinical and biological implications. *Med Pediatr Oncol* 21:158-168, 1993.) PLNR, perilobar nephrogenic rests; ILNR, intralobar nephrogenic rests.

**Figure 67-3.** **A**, MR image of a 10-month-old infant who presented with large bilateral flank masses demonstrates a picture characteristic of diffuse hyperplastic perilobar nephroblastomatosis (DHPLN) with extensive involvement of the entire cortex of the kidney with no evidence of necrosis and general preservation of the shape of the kidney. **B**, Photograph of a kidney resected with a similar pattern of DHPLN reveals extensive involvement of the periphery of the cortex by severely hypertrophied nephrogenic rests (arrows). Resection of such kidneys should be avoided because, in most cases, the hypertrophy will resolve and the kidney will have excellent preservation of its function. (B courtesy of J. B. Beckwith by permission.)

this condition. The frequency of NRs in multicystic dysplastic kidneys has been estimated to be 4%, approximately five times the prevalence in a random autopsy population of infants younger than age 3 months.<sup>51</sup> If one were to estimate the frequency of Wilms' tumor in these kidneys, the standard risk of 1 in 10,000 infants might be increased to 1 in 2,000. Review of the NWTSG pathology files, however, identified only three cases of dysplastic kidneys in more than 7000 children with Wilms' tumor over a 26-year interval and only 1 case in more than 1500 referral cases sent to Dr. Beckwith from around the world. Although it is impossible to estimate the number of children at risk from Wilms' tumors in remaining dysplastic kidneys, it must be concluded that this risk of developing a Wilms' tumor or congenital obstruction must be extremely low and does not justify nephrectomy to avoid the development of tumors. It has been suggested that because all of the reported Wilms' tumor cases in multicystic dysplastic kidney occurred before 4 years of age, then ultrasound surveillance up to that age should be recommended.<sup>52</sup>

## Pathology

The collection of large numbers of renal tumor specimens by the cooperative group trials has facilitated the development of accurate pathologic classifications in a much shorter period than would ever have been feasible without these trials. Early reports of Wilms' tumors and the initial cooperative group trials included essentially all renal sarcomas under this rubric. With time and experience, however, several subgroups of tumors have now been identified as having a particularly high risk of recurrence and adverse outcome.<sup>3,53</sup> In NWTSG-1, anaplastic and sarcomatous variants comprised only 11.5% of the tumors, yet they accounted for 51.9% of the deaths due to tumor. Unfavorable histology proved to be the most important factor in patient outcome in NWTSG-1, and this finding continues through

the current trials. Wilms' tumors are currently divided into those with "favorable" histology and those with "unfavorable" histology (Table 67-2). The latter group includes tumors with focal or diffuse anaplasia.<sup>54,55</sup> Clear cell sarcoma of the kidney and malignant rhabdoid tumors of the kidney were initially grouped with the unfavorable-histology Wilms' tumors. They are now considered distinct entities from Wilms' tumor, based on their pathologic appearance and response to quite different therapies.<sup>56,57</sup>

The staging system used by the NWTSG is a pre-treatment surgical staging system (Table 67-3). It must be carefully distinguished when comparing treatment results with children treated on the SIOP protocols in which the staging information is obtained after preliminary treatment of the tumors (Table 67-4). The intensity of adjuvant treatment in the NWTSG protocols is determined by such factors as regional lymph node involvement and penetration of the renal capsule by tumor. These prognostic variables cannot be accurately determined by radiographic studies. The staging criteria are continually adjusted during the course of the NWTSG studies as the prognostic significance of criteria are established.<sup>58</sup>

**Table 67-2** Pathologic Classification of Renal Tumors

Wilms' tumor
Favorable histology
Unfavorable histology
Diffuse anaplasia
Focal anaplasia
Clear cell sarcoma
Malignant rhabdoid tumor of the kidney
Renal cell sarcoma
Renal adenocarcinoma
Renal neurogenic tumors
Renal teratoma

Stage	Description
Stage I	Tumor limited to the kidney and completely excised without rupture or biopsy. Surface of the renal capsule is intact.
Stage II	Tumor extends through the renal capsule but is completely removed with no microscopic involvement of the margins. Vessels outside the kidney contain tumor. Also placed in stage II are cases in which the kidney has been sampled before resection or where there is "local" spillage of tumor (during resection) limited to the tumor bed.
Stage III	Residual tumor is confined to the abdomen and not from hematogenous spread. Also included in stage III are cases with tumor involvement of the abdominal lymph nodes, rupture of the tumor with "diffuse" peritoneal contamination extending beyond the tumor bed, peritoneal implants, and microscopic or grossly positive resection margins.
Stage IV	Hematogenous metastases at any site
Stage V	Bilateral renal involvement

The SIOP classification was recently revised based on a review of the outcomes of children relative to the histologic appearance of the tumors at resection and after initial chemotherapy.<sup>59</sup> Tumors are now classified as completely necrotic (low-risk tumor), blastemal (high-risk tumor), and others (intermediate-risk tumors). The prognostic implications of this classification will be assessed in the current study, as will the potential for decreasing extent of therapy of the more favorable groups. Wilms' tumor is characterized as a triphasic embryonal neoplasm with blastemal, stromal, and epithelial components (Fig. 67-4).<sup>3</sup> Each of these components can express several patterns of differentiation, which define the histologic subgroups of Wilms' tumors. One particular subtype, the fetal rhabdomyomatous nephroblastoma, has been associated with a poor response to chemotherapy but a generally favorable prognosis.<sup>60</sup> In contrast, the diffuse blastemal subtype is associated with presentation at an advanced stage but also with a rapid response to chemotherapy. The anaplastic tumors are characterized by large, pleomorphic, and hyperchromatic nuclei with abnormal multipolar mitotic figures. Anaplasia can occur in the epithelial, stromal, or blastemal populations or any combination of these three. Anaplasia occurs primarily in children older than 2 years. In NWTS-1, 66.7% of the patients with anaplasia experienced relapse and 58.3% died of their tumor.<sup>53</sup> Even in this early report, the distinct implications of the "diffuse" versus the "focal" pattern were appreciated, with a higher frequency of relapse and death in the "diffuse" subgroup. This was confirmed in review of the NWTS-2 and NWTS-3 data. Whereas children with stage I anaplastic tumors generally did well, children with stage II to IV tumors did poorly. The severity of dysplasia was not a predictive factor. However,

anaplasia in extrarenal tumor sites and a predominantly blastemal tumor pattern were both adverse prognostic factors.<sup>61</sup>

Approximately 1% of children initially seen with a unilateral tumor will develop contralateral disease. In 58 of 4669 (1%) children registered in the first four NWTSG studies, metachronous disease developed.<sup>62</sup> Analysis of this cohort by a matched case-control study demonstrated that the children with NRs had a significantly increased risk of metachronous disease, particularly those with PLNRs. This finding was especially true for young children, in whom a Wilms' tumor occurred in 20 of 206 children younger than 12 months, in comparison with none of 304 children older than 12 months. These infants younger than 12 months with Wilms' tumor and NRs, as well as the syndromic patients, require regular surveillance for several years for the development of contralateral disease. This increased risk for metachronous tumors in children with Wilms' tumor and nephrogenic rests has been confirmed by others.<sup>63</sup>

Clear cell sarcoma of the kidney (CCSK) is a highly malignant tumor with an unusual proclivity for bony metastasis. It generally appears as a large unifocal and unilateral tumor with homogeneous mucoid, tan, or gray/tan cut surface, often with foci of necrosis or prominent cyst formation.<sup>3,64</sup> This tumor invades surrounding renal parenchyma rather than compressing the margin into a pseudocapsule, as seen in Wilms' tumor. Its classic appearance is that of a deceptively bland tumor with uniform oval nuclei with a delicate chromatin pattern, a prominent nuclear membrane,

Stage	Description
Stage I	Tumor limited to the kidney, complete excision
Stage II	Tumor extending outside the kidney, complete excision Invasion beyond the capsule, perirenal/perihilar Invasion of the regional lymph nodes* (stage II N1) Invasion of extrarenal vessels Invasion of ureter
Stage III	Invasion beyond the capsule with incomplete excision Preoperative or perioperative biopsy Preoperative/perioperative rupture Peritoneal metastases Invasion of para-aortic lymph nodes† Incomplete excision
Stage IV	Distant metastases
Stage V	Bilateral renal tumors

\*Hilar nodes and/or periaortic nodes at the origin of the renal artery.

†Para-aortic nodes below the renal artery.

**Figure 67-4.** A, CT scan of a 10-year-old boy who presented with a large left upper quadrant abdominal mass identified on a routine “well child examination” demonstrates the characteristic findings of Wilms’ tumor. The tumor mass is well circumscribed and can be seen with a margin of renal parenchyma along the periphery (arrow). B, The gross pathologic specimen shows the lobular nature of this standard histology Wilms’ tumor. Again, the tumor can be seen extending from the normal renal parenchyma (arrow).

and sparse, poorly stained vacuolated “water-clear” cytoplasm with indistinct cell membranes. Although the cells often appear in cords or nests divided by an arborizing network of vessels and supporting spindle cell septa, nine major histologic patterns have been identified.<sup>64</sup> The cell of origin of this tumor is not known. In addition to osseous metastases, clear cell sarcomas also have a significant incidence of metastases to the brain. Late recurrences also are seen with this tumor, with 30% of the relapses occurring more than 2 years after diagnosis.<sup>65</sup> For this reason, clinical trials must consider results after an extended interval of follow-up.

Malignant rhabdoid tumors of the kidney occur in young infants with a median age of 11 months, and 85% of the cases occur within the first 2 years of life.<sup>57</sup> A characteristic involvement of the perihilar renal parenchyma is seen. Histologically, rhabdoid tumors are characterized by monomorphous, discohesive, rounded to polygonal cells with acidophilic cytoplasm and eccentric nuclei containing prominent large “owl eye” nucleoli reminiscent of skeletal muscle, but lacking its cytoplasmic striations, ultrastructural features, and immunochemical markers.<sup>3</sup> A large periodic acid-Schiff (PAS)-positive hyaline cytoplasmic inclusion occurs in a variable population of tumor cells and is a hallmark of this tumor.<sup>66</sup> Ultrastructural examination reveals parallel cytoplasmic filamentous inclusions packed in concentric whorled arrays, a distinctive feature of this tumor, which suggests a neuroectodermal origin. The tumor tends to infiltrate surrounding renal parenchyma rather than to compress it. These tumors are notable for the occurrence of second primary neuroglial tumors in the midline of the brain, resembling medulloblastoma.<sup>67</sup> A consistent deletion of 22q11-12 has been described in both renal and extrarenal rhabdoid tumors.<sup>68,69</sup> These deletions delineate an area of overlap at the site of the *hSNF5/INI1* gene and tumors have biallelic alternations or deletions of this gene.<sup>70,71</sup>

The occurrence of primitive neuroectodermal tumors (PNET) of the kidney is well documented.<sup>72</sup> It is clearly distinct from Wilms’ tumor and the other

variants previously discussed and demonstrates spread to lymph nodes, lung, bone, liver, and bone marrow, as occurs from PNET at other anatomic locations.<sup>73</sup> Treatment including resection, chemotherapy, and irradiation must follow that of PNETs and not that of other renal tumors.

## Clinical Presentation

The classic presentation of a Wilms’ tumor is the identification of an asymptomatic flank mass in an otherwise healthy toddler. It is often noted during a bath or by the pediatrician at a routine visit, and the mass may be of considerable size. This is in marked contrast to neuroblastoma, which is seen in the same age group but frequently presents as pain, often from osseous metastasis. Wilms’ tumor also may be associated with hematuria, but with a much lower frequency than is seen with renal cell carcinoma. Uncommon presentations include hypertension or fever. Occasionally a child may have abdominal trauma and demonstrate pain and an abdominal mass out of proportion to what is expected. Radiographic examination will reveal a mass that cannot be attributed to the trauma alone.

## Treatment

As a result of the work that demonstrated the role of adjuvant therapy in this tumor, all children treated on the early protocols of the NWTSG and SIOP received chemotherapy. Only in the past decade has adjuvant therapy been avoided in a small proportion of children with an extremely low risk of local recurrence and metastasis. Optimal chemotherapy regimens have been established by a series of well-designed randomized studies performed primarily by the NWTSG in the United States and Canada and SIOP in Europe. Despite advances in chemotherapy, surgery continues to play a critical role in the treatment of Wilms’ tumor. Accurate staging and safe and complete resection of the tumor are key elements in achieving cure. Local control is rarely achieved with chemotherapy and radiation therapy alone.

Stage	Treatment	Results	
Stage II	Vcr, Dac	4-Year DFS 87.4%	4-Year OS 91.1%
	Vcr, Dac + XRT (20 Gy abd)	NS	NS
	Vcr, Dac, Dox	NS	NS
	Vcr, Dac, Dox + XRT (20 Gy abd)	NS	NS
Stage III	Vcr, Dac + XRT (10 Gy abd)	Improved survival with addition of doxorubicin	
	Vcr, Dac + XRT (20 Gy abd)		
	Vcr, Dac, Dox + XRT (10 Gy abd)	82.0%	90.9%
	Vcr, Dac, Dox + XRT (20 Gy abd)	No difference in local recurrence between 10 and 20 Gy	
Stage IV	Vcr, Dac, Dox	79.0%	80.9%
	Vcr, Dac, Dox, Cyclo	NS improvement from the addition of cyclophosphamide	
	All abd XRT 20 Gy & pulmonary XRT 12 Gy

Vcr, vincristine; Dac, dactinomycin; XRT, radiation therapy; abd, abdomen; Dox, doxorubicin; Cyclo, cyclophosphamide; DFS, disease-free survival; OS, overall survival; NS, not statistically significant.

## Chemotherapy

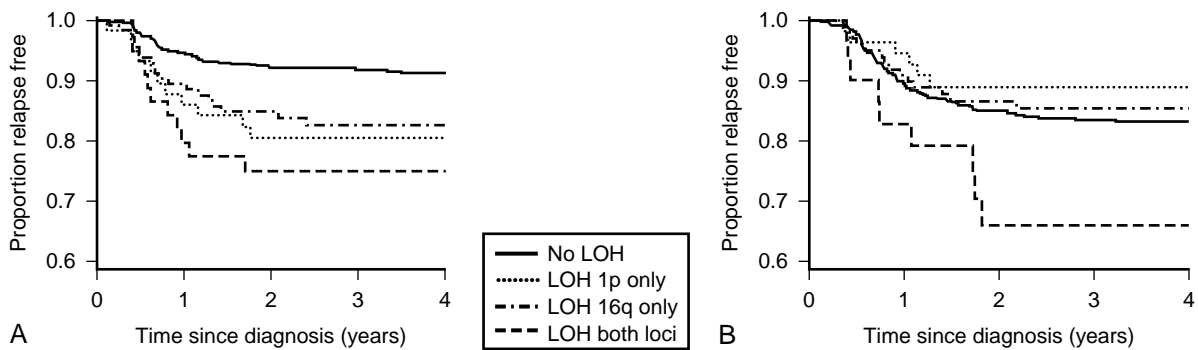

Wilms' tumor was the first malignant pediatric solid tumor with a demonstrated response to dactinomycin.<sup>1</sup> Many additional effective agents have been subsequently identified: vincristine, doxorubicin, cyclophosphamide, ifosfamide, and etoposide. Children with stage I tumors were treated on the third NWTSG protocol (NWT-3) with an 11-week regimen composed of vincristine and dactinomycin, without abdominal irradiation, based on the results of the initial two studies. The 4-year relapse-free survival (RFS) and overall survival (OS) were 89.0% and 95.6%, respectively.<sup>74</sup> The other three stages were treated on a regimen that involved randomization of two or four arms (Table 67-5). This study supported the addition of doxorubicin to the treatment of children with stage III tumors but did not demonstrate any benefit from the addition of doxorubicin or radiation therapy for children with stage II tumors or benefit from the addition of cyclophosphamide to the treatment of children with stage IV tumors.

NWT-4 built on the lessons learned from the prior studies and addressed the issue of whether dose intensification could be safely used to decrease the number of visits for chemotherapy and yet maintain the favorable results previously achieved. Dactinomycin and doxorubicin were administered in single moderately high doses, compared with the traditional divided dose regimens for each drug. This study also evaluated the use of two time intervals for the administration of chemotherapy: a short course (18 to 26 weeks, depending on the regimen and stage) versus a long course (54 to 66 weeks). The findings in this study were that the pulse-intensive regimens actually produced less hematologic toxicity than the standard regimens, allowing greater dose intensity with comparable outcomes.<sup>75,76</sup> The second randomization demonstrated no benefit in any of the stages to the long interval of therapy over the short interval.<sup>60</sup>

A recent analysis of patients with stage II and III Wilms' tumors with favorable histology treated on NWT-3 and NWT-4 assessed the efficacy of the addition of doxorubicin.<sup>77</sup> Whereas no benefit was seen in the stage II patients, a decrease in the 8-year event-free survival (EFS) and OS of randomized patients was seen for those with stage III disease who received doxorubicin, dactinomycin, and vincristine (84% and 89%) compared with those who received dactinomycin and vincristine alone (74% and 83%). When a large group of nonrandomized patients were added to the analysis, the beneficial effect on OS was not seen. Unfortunately, this addition of nonrandomized patients added some question of bias.

The goal of NWT-5 was to evaluate preliminary findings from pilot studies that LOH for chromosomes 1p and 16q were associated with an adverse prognosis. To most efficiently address this question, this was the first study from NWTSG that did not involve randomization of treatment. This study demonstrated that LOH at either site in children with favorable-histology stage I and II disease was predictive of decreased EFS. Also, in children with stage III and IV disease, the presence of LOH at both sites was predictive (Fig. 67-5).<sup>78</sup> A subsequent analysis has suggested that expression of telomerase RNA may also be an adverse prognostic factor for favorable-histology Wilms' tumor, but confirmatory studies will be required.<sup>79</sup>

Two additional components of the NWT-5 study have been reported for favorable-histology patients. Fifty-eight children with initial stage I and II disease experienced relapse after treatment with vincristine and dactinomycin.<sup>80</sup> Their relapse therapy included alternating courses of vincristine/doxorubicin/cyclophosphamide and etoposide/cyclophosphamide along with surgery, if feasible, and radiation therapy. The lung was the only site of relapse in 31 children. These patients did fairly well with an EFS at 4 years of 71.1% and OS of 81.8%. Those with only pulmonary relapse

**Figure 67-5.** A, Relapse-free survival with loss of heterozygosity (LOH) at chromosomes 1p and 16q for patients with stage I/II Wilms' tumor of favorable histology. B, Relapse-free survival for patients with stage III/IV Wilms' tumor with favorable histology and LOH at chromosome 1p and 16q. (From Grundy PE, Breslow N, Li S, Loss of heterozygosity for chromosomes 1p and 16q is an adverse prognostic factor in favorable-histology Wilms' tumor: A report from the National Wilms' Tumor Study Group. *J Clin Oncol* 23:7312-7321, 2005, with permission from the American Society of Clinical Oncology.)

were similar with an EFS of 67.8% and an OS of 81.0%. Sixty patients on NWTS-5 relapsed after initial therapy with vincristine, dactinomycin, and doxorubicin along with radiation therapy for stage III and IV disease.<sup>81</sup> Their relapse therapy included alternating cycles of cyclophosphamide/etoposide and carboplatin/etoposide along with surgery and radiation therapy. The lung was the sole site of relapse in 33 patients. EFS in these patients at 4 years was 42.3% and OS was 48.0%, whereas it was 48.9% and 52.8%, respectively, for those with only pulmonary relapse. The lower survival in this cohort could be due either to intrinsically more aggressive disease or to the significant prior treatment of the tumors.

Treatment of children with anaplastic tumors with standard therapy has resulted in a high rate of failure. Thus, in sequential studies, therapy has been intensified. Review of the NWTS-3 and NWTS-4 studies demonstrated that children with focal anaplasia had an excellent outcome when treated with vincristine, doxorubicin, and dactinomycin.<sup>55</sup> The addition of cyclophosphamide to this regimen improved the 4-year EFS in children with diffuse anaplasia with stages II to IV disease from 27.2% to 54.8%. Subsequent studies in NWTS-5 have further intensified therapy with the use of doxorubicin, cyclophosphamide, vincristine, and etoposide for 24 weeks plus flank/abdominal irradiation in children with stages II to IV disease. Patients with stage I disease were treated with vincristine and dactinomycin for 18 weeks. The 4-year EFS and OS of stage I patients were 69.5% and 82.6%, respectively, compared with the same survivals for stage I favorable histology of 92.4% and 98.3%.<sup>82</sup> The EFS progressively declined for increasing stage from 82.6% for stage II, 64.7% for stage III, and only 33.3% for stage IV disease. **Clearly, even with this intensification of therapy, patients with anaplasia do not fare well.**

Doxorubicin was found to be particularly effective in the treatment of clear cell sarcoma of the kidney.<sup>83,84</sup> However, the results have remained below those of standard-histology Wilms' tumors. No benefit was seen to pulse-intensive administration of the agents, and no difference in survival was noted at 5 and 8 years between patients treated for 6 or 15 months.<sup>85</sup>

Treatment consisted of vincristine/doxorubicin/cyclophosphamide alternating with cyclophosphamide/etoposide for 24 weeks on NWTS-5 with local radiation therapy. Five-year EFS and OS of 79% and 89% respectively were achieved, but results remained very stage dependent with survival by stage I of 100%; II, 87%; III, 74%; and IV, 36%.<sup>86</sup> The most frequent site of relapse was the brain in 11 of 21 cases.

The rhabdoid tumors have remained the most resistant of all pediatric renal tumors. Current studies have used an intensive therapy with carboplatin, etoposide, and cyclophosphamide. Analysis of 142 children treated on NWTS-1 to NWTS-5 showed an overall survival of 23.2% at 4 years.<sup>87</sup> Survival was stage dependent and children with stage I/II disease had a 41.8% 4-year survival, while children with stage III, IV, or V tumors had a 15.9% 4-year survival. Survival was also clearly related to the age at presentation, with the 4-year survival worst for those birth to 5 months of age at diagnosis (8.8%) and best for those older than 2 years of age (41.1%). NWTS-5 used an intensive therapy with carboplatin, etoposide, and cyclophosphamide. Unfortunately, no improvement in survival occurred with the series of treatments from NWTS-1 to NWTS-5 and no survival benefit was demonstrated with the use of doxorubicin.

SIOP has promoted the use of preoperative treatment of children with Wilms' tumor with radiation therapy or chemotherapy since the early 1970s. Histologic confirmation of the diagnosis before therapy is not routinely performed in SIOP protocols. This approach has several risks. One is the potential for administration of chemotherapy for benign disease. Second, modification of tumor histology by the chemotherapy may occur. Third, staging information may be lost. Fourth, a malignant rhabdoid tumor of the kidney or clear cell sarcoma, if present, will not respond to standard therapies. Treatment without an initial diagnosis is difficult to sustain when NWTSG and SIOP studies have demonstrated a 7.6% to 9.9% rate of benign or altered malignant diagnosis in children with a prenephrectomy diagnosis of Wilms' tumor.<sup>88,89</sup> The histologic diagnosis after preoperative treatment in a group of children followed by NWTSG

did not appear impacted by treatment, but it is less certain if staging is altered.<sup>90</sup>

The major driving force for the use of preoperative therapy by SIOP was the high rate of operative tumor rupture that occurred in their early series, in which patients did not receive preliminary treatment. The rupture rate decreased from 33% (20 of 60) to 4% (3 of 72) with preoperative abdominal irradiation (20 Gy) in the first randomized SIOP study of renal tumors (SIOP-1), begun in 1971.<sup>91</sup> It must be noted, however, that 33% is an extremely high frequency of rupture. Survival was not improved by the decrease in operative rupture, and the incidence of local recurrence was not reported. In NWTs-1 and NWTs-2, operative rupture occurred in 22% and 12% of children, respectively.<sup>88,92</sup> In a subsequent SIOP randomized study of Wilms' tumors begun in 1977 (SIOP-5), the rate of rupture was essentially the same for children receiving abdominal irradiation (20 Gy) and dactinomycin (9%, 7 of 76) or a combination of vincristine and dactinomycin (6%, 5 of 88).<sup>93,94</sup> Radiation therapy after resection was based on the stage of the tumors, with stage I patients receiving no postoperative irradiation and stage II and III patients receiving 15 Gy in the group treated initially with radiation therapy and 30 Gy in those treated initially with chemotherapy. In SIOP-6, begun in 1980, all patients received initial preoperative chemotherapy (vincristine and dactinomycin). Radiation therapy was performed after resection to those children with stage II N1 (stage III disease). Children with stage II N0 (lymph node negative) were randomized to receive either 20 Gy of radiation therapy or no radiation to the tumor bed. All children received vincristine and dactinomycin for 38 weeks. After pretreatment, 52% of cases were stage I, and a low frequency of rupture was noted (7%). The radiation therapy randomization was halted after 108 children were randomized, 58 to radiation therapy and chemotherapy and 50 to chemotherapy alone. Six local recurrences occurred in the 50 children who did not receive radiation therapy versus no recurrences in the group that did. This suggested that nephrectomy treatment altered the pathologic findings that would have led to a diagnosis of stage II N1 (stage III disease: lymph node involvement or capsular penetration) and to the standard administration of local irradiation. Extended follow-up studies of these children showed ultimately no statistical difference in survival, because those who experienced relapse had more treatment alternatives.<sup>95,96</sup> The SIOP-6 protocol also extended chemotherapy to infants older than 6 months.<sup>97</sup> The overall favorable outcome was not improved, and an unacceptable toxicity occurred in the young infants. For the SIOP-9 study, a reduced dose in infants was recommended.

In the SIOP-9 study initiated in 1987, a randomization was performed between 4 and 8 weeks of preoperative therapy with dactinomycin and vincristine to determine whether the additional 4 weeks of therapy produced a larger proportion of stage I tumors.<sup>98</sup> This study also replaced postoperative radiation therapy in stage II N0 children with administration of an

anthracycline (epirubicin or doxorubicin). Preoperative treatment consisted of four weekly courses of vincristine and two 3-day courses of dactinomycin every 2 weeks versus 8 weeks of the identical therapy for patients without distant metastasis. No advantage was seen from the extended therapy in terms of staging at resection between the 4-week and 8-week courses: stage I, 64% versus 62%, or of intraoperative tumor rupture, 1% versus 3%. Therapy after resection was based on the pathologic findings. Children with stage I disease and favorable or anaplastic histology received vincristine and dactinomycin for 17 weeks. Those with stage II and III tumors with favorable histology received vincristine, dactinomycin, and epirubicin (an anthracycline) for 27 weeks, with no abdominal irradiation for stage II N0 disease or with 15 Gy of abdominal irradiation in cases of stages II N1 and III disease. This therapy resulted in a 2-year EFS of 84% versus 83% for the 4- and 8-week therapies and OS of 92% and 87%, respectively. For cases with metastatic disease, children received 6 weeks of therapy including weekly vincristine, three courses of dactinomycin, and two courses of epirubicin on weeks 1 and 5. The tumor size decreased by more than 50% in 52% of the cases. During the second 4 weeks of therapy, there was another 50% reduction in 33% of the cases (Fig. 67-6). Inappropriate preoperative therapy was given to 5.5% of the cases, including 1.6% who proved to have benign lesions or malignant lesions not expected to respond to the therapy, including neuroblastoma, lymphoma, malignant rhabdoid tumors of the kidney, and renal cell carcinomas. In a recent report, the United Kingdom Children's Cancer Study Group (UKCCSG) identified 12% of cases that were clinically and radiographically consistent with Wilms' tumor but had other diagnoses established by biopsy.<sup>99</sup>

In SIOP-9, the surgical procedure-related complications were reported to be 8%.<sup>100</sup> In this treatment regimen, patients with post-therapy stage II disease received an anthracycline, whereas in the NWTs studies, patients with stage II disease received vincristine and dactinomycin alone. In SIOP-9, an evaluation of children with completely necrotic tumors at the time of resection demonstrated that they had an extremely favorable prognosis.<sup>101</sup> Complete necrosis was seen in 10% of 599 children enrolled into the study. In total, 37 children in this cohort had stages I to III disease and 22 had stage IV disease. Disease-free survival was 98% at 5 years versus 90% for the other patients on SIOP-9. The only death in the stage I to III group was related to chemotherapy, and survival was 100% in the stage IV group.

The goal of both NWTs and SIOP has been to decrease the intensity of therapy and yet achieve the maximal long-term survival. Both groups have decreased the amount of radiation therapy used during the course of their studies. Among the children with unilateral nonmetastatic Wilms' tumors of favorable histology, 24% of those enrolled in NWTs (275 of 1160) were given radiation therapy and 18% of those in SIOP (81 of 447) have received irradiation in the most recent studies.<sup>102</sup> SIOP has elected, however, to

**Figure 67-6.** Diagram of the results from the GPOH subgroup of SIOP-9 demonstrates the progressive decrease in the volume of the renal tumors after 4 and 6 weeks of preoperative chemotherapy. The pie charts demonstrate the distribution of tumor stages that reveal an increase in low stage I tumors compared with historical controls (not shown). (From Graff N, et al: The role of preoperative chemotherapy in the management of Wilms' tumor: The SIOP studies. *Urol Clin North Am* 27:443-454, 2000.)

use an anthracycline rather than irradiation for their postchemotherapy stage II N0 patients in whom excessive local relapse occurred without additional therapy. This results in about 48% of patients in SIOP studies with unilateral nonmetastatic tumors of favorable histology receiving an anthracycline, which is significantly greater than the 24% of comparable patients on NWTSG regimens.

Significant complications have occurred in some children treated with doxorubicin, particularly that of cardiomyopathy.<sup>103,104</sup> In children treated on NWTS-1 to NWTS-4, the cumulative frequency of congestive heart failure was 4.4% at 20 years after diagnosis for those treated initially with doxorubicin, although recent estimates of the 20-year risk of congestive heart failure for children treated on NWTS-3 and NWTS-4 is now reported as 1.2%.<sup>77</sup> The relative risk was increased in female subjects, by cumulative dose, lung irradiation, and left-sided abdominal irradiation. Subclinical echocardiographic abnormalities have been demonstrated in children who received as little as 45 mg/m<sup>2</sup> of doxorubicin.<sup>105</sup> Only long-term follow-up of children who have received doxorubicin will document what dose, if any, is free of long-term implications.

Second malignant neoplasms also are a concern. NWTSG reported a 1.6% incidence of second malignant neoplasms at 15 years after treatment.<sup>106</sup> Second malignancies correlated with prior treatment of relapsed tumor, the amount of abdominal radiation, and the use of doxorubicin. Acute myelogenous leukemia was seen in patients whose treatment included either doxorubicin or etoposide.<sup>107</sup>

Whereas renal failure can be produced by bilateral nephrectomy, it also results from the nephropathy associated with several of the genetic syndromes. A significant incidence of renal failure most frequently developed from focal segmental glomerulosclerosis in children with WAGR syndrome and from diffuse mesangial sclerosis in children with Denys-Drash syndrome. The cumulative incidence of end-stage renal failure at 20 years after diagnosis of unilateral Wilms' tumor was 74% for 17 patients with the Denys-Drash

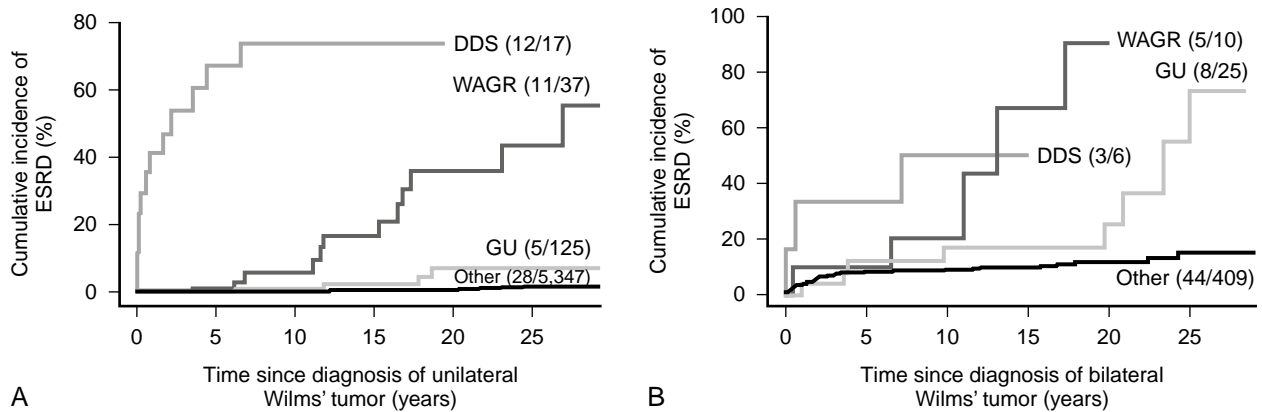

syndrome, 36% for 37 patients with WAGR, 7% for 125 males with hypospadias or cryptorchidism, and 0.6% for 5347 patients without any of the other conditions (Fig. 67-7).<sup>108</sup> In children with bilateral tumors, all of these incidences are increased: 50% for the Denys-Drash syndrome, 90% for WAGR, 25% for associated genitourinary abnormalities, and 12% for those without associated conditions.

Other complications identified in patients after treatment for Wilms' tumor include diffuse interstitial pneumonitis, loss of stature, and difficulties with pregnancy primarily related to abdominal and pelvic irradiation.<sup>109-112</sup>

Current guidelines for radiation therapy in the North American protocols are determined by the histology and stage of the tumor. All patients receive a relatively low dose of radiation (1200 cGy) to the lung if pulmonary metastases are present, although the SIOP studies have recently excluded pulmonary irradiation in many of these children. The current protocol of the Children's Oncology Group has made two significant changes with regard to patients with pulmonary disease. First, lesions seen by CT scan only will be considered to have pulmonary metastasis unless biopsy proven not to have metastatic disease. In past protocols this has been based on standard radiographs of the chest. Second, in an attempt to spare pulmonary radiation in those children who appear to have responsive disease, children will not receive radiation therapy if the pulmonary lesions radiographically resolve by CT scan after 6 weeks of chemotherapy.

Abdominal irradiation (1080 cGy) is employed for all patients with Wilms' tumor of favorable histology who have stage III disease in the abdomen. Recent long-term results from NWTS-3 and NWTS-4 have shown that increasing the dose of radiation therapy to the flank from 10 to 20 Gy will decrease the frequency of flank relapse. Overall survival of the patients is not improved because of the lower postrecurrence mortality among nonirradiated patients.<sup>113</sup> Current doses employed are 1080 cGy for stage I to III focal anaplasia, stage I and II diffuse anaplasia, and stage II and III clear cell sarcoma of the kidney. Higher doses of 1980 cGy

**Figure 67-7.** A, Cumulative incidence of end-stage renal disease (ESRD) in children with unilateral Wilms' tumor with Denys-Drash syndrome (DDS), WAGR syndrome, associated genitourinary anomalies (GU), and other anomalies (Other) over time. B, Similar plot of children with bilateral Wilms' tumors. In both groups of children, a very significant incidence of ESRD is documented. (From Breslow NE, et al: End stage renal disease in patients with Wilms' tumor: Results from the National Wilms' Tumor Study Group and The United States Renal Data System. *J Urol* 174:1972-1975, 2005, with permission from the American Urological Association.)

are utilized for stage III diffuse anaplasia, and for rhabdoid tumor of the kidney in infants 12 months and older. Younger infants still receive 1080 cGy.

### Surgical Procedures

The NWTSG has advocated initial resection of the tumor in all of its protocols. Although most Wilms' tumors are first seen as a large mass, resection is generally feasible (Fig. 67-8). Wilms' tumor, in contrast to neuroblastoma, is much less likely to invade surrounding organs and lymph nodes. Children undergoing initial nephrectomy in the NWT-3 study had a complication rate of 19.8% in a group that was very closely monitored.<sup>106</sup> The most frequent complication was intestinal obstruction, occurring in 6.9% of the

**Figure 67-8.** CT scan of a 3-year-old boy who presented with a history of abdominal pain, fever, and a right flank mass. The tumor is very large with extension outside the renal capsule into the retroperitoneal tissues posterior to the kidney. Despite its size, this lesion was able to be completely resected. Lymph nodes and specimen margins were negative for tumor. This tumor was therefore stage 2, and the infant was able to avoid both anthracycline therapy and abdominal irradiation because of the complete resection.

children, followed by extensive intraoperative hemorrhage (>50 mL/kg) occurring in 5.8%.<sup>114</sup> Injuries to other visceral organs (1%) and extensive vascular injuries (1.4%) were much less frequent. Nine deaths in the series were attributed to surgical complications (0.5%), only one of which was intraoperative. The factors associated with an increased risk of surgical complications were advanced-stage local disease, intravascular extension of the tumor, and resection of other organs. The latter were often found not to be invaded by the tumor but rather compressed, distorted, or adherent, without actual tumor infiltration. Extensive resection involving removal of other organs or operations that are of a magnitude to be life threatening should be aborted. In some cases, tumor biopsy and biopsy of the regional lymph nodes should be performed, followed by administration of chemotherapy before a second attempt at resection (Fig. 67-9). With the use of this algorithm, 93% of 131 children enrolled in NWT-3 who were initially judged to have unresectable disease at operation or by imaging studies successfully underwent resection after initial chemotherapy or irradiation or both.<sup>115</sup> Only 8 children with tumors that grew or failed to respond did not undergo subsequent nephrectomy.

Complications in the NWT-4 study have also been assessed.<sup>116</sup> In this study, surgeons were discouraged from performing extensive operations involving resection of adjacent organs or massive tumors. Complications occurred in 12.7% of a random sample of 534 of the 3335 patients treated in this study. Again, intestinal obstruction was the most frequent complication (5.1%), followed by extensive hemorrhage (1.9%), wound infection (1.9%), and vascular injury (1.5%). The factors associated with an increased risk of complications were again assessed. Intravascular tumor extension into the inferior vena cava or atrium and nephrectomy performed through a flank or paramedian incision were both significant factors. Tumor diameter of 10 cm or larger also was associated with increased complications. Finally, the risk of complications was

**Figure 67-9.** A, MR image of a 2 1/2-year-old girl who presented with a massive right-sided abdominal mass. Chest radiograph revealed pulmonary nodules. Because of the massive size of the primary and metastatic disease, she received initial chemotherapy after a needle biopsy demonstrated a standard risk tumor (diffuse blastemal subtype). She received three courses of dactinomycin, vincristine, and cyclophosphamide, which achieved some shrinkage of the tumor. At surgery, there was a very extensive tumor that was densely adherent to the posterior aspect of the liver and the vena cava. It was clear that resection of a portion of the liver would be required with the nephrectomy. Efforts at resection were terminated. Repeat biopsies again demonstrated a standard histology Wilms' tumor with tumor invasion into the liver. She was treated on a new protocol involving cisplatin and etoposide as well as abdominal and thoracic radiation. B, MR image, after additional therapy, showed remarkable shrinkage of the tumor, allowing a much easier and safer resection.

increased if the resection was performed by a general surgeon rather than a pediatric surgeon or pediatric urologist. In a recent study involving 598 patients registered on SIOP-9, a complication rate of 8% was reported. These patients were pretreated with vincristine, dactinomycin, and epirubicin or doxorubicin before nephrectomy.<sup>75</sup> The most frequent events were small bowel obstruction (3.7%) and tumor rupture (2.8%). The latter is not reported as a complication in the NWTs reviews. Other complications occurred in 2.0% of patients.

### Surgical Details

Radiographic imaging is critical before surgical resection of a renal tumor (Fig. 67-10). The most important factors to assess in these imaging studies are the

presence of two functioning kidneys, presence of contralateral tumor, and evidence of intravascular extension of the tumor. Intraoperative identification of intravascular extension has been associated with an increased incidence of surgical complications.<sup>117</sup> The organ of origin of the tumor can be determined in most cases, with the differential diagnosis generally between neuroblastoma and Wilms' tumor. This can generally be determined by the configuration of the kidney and the mass. In neuroblastoma, the mass will generally indent the kidney, whereas in Wilms' tumor the mass will arise from within the kidney and distort its internal configuration. Often a thin lip of renal parenchyma can be seen extending over the neoplasm in Wilms' tumor (see Fig. 67-4A). Intra-abdominal staging has been difficult to assess radiographically unless extensive lymph node involvement

**Figure 67-10.** A, CT scan of a 7-year-old boy who presented with a left-sided abdominal mass demonstrates tumor extending through the left renal vein (white arrow) into the inferior vena cava (black arrow). B, Higher levels on the CT scan demonstrated tumor completely occluding the intrahepatic inferior vena cava (black arrow).

or intrahepatic metastases are present. A radiograph of the chest and CT scan will help determine the presence of pulmonary metastases. If the lesions are seen on the radiograph, their malignant nature must generally be assumed. Smaller lesions seen only on the CT scan should generally be sampled to confirm their malignant nature because recent studies demonstrated that these lesions were malignant in 82% of cases if the lesion was isolated and 69% if there were multiple lesions present.<sup>118</sup> Bone scans and brain scans are routinely performed only if the renal tumor proves to be a clear cell sarcoma or rhabdoid tumor.

Renal tumors must be resected through an adequate subcostal or thoracoabdominal incision. Struggling through an inadequate incision will often result in rupture of the tumor, increasing both the stage of the tumor and the risk for intra-abdominal recurrence.<sup>119</sup> A flank incision should not be used for resection in pediatric renal tumors because of the limited exposure it allows.

Initial exploration of the abdomen should be performed, including inspection for hepatic metastases or intraperitoneal spread. The vena cava, if it is accessible, also should be palpated to assess for intravascular extension of tumor. Exploration of the contralateral kidney with opening of Gerota's fascia was recommended by the NWTSG based on the 5% occurrence of synchronous lesions. In NWTSG-2 and NWTSG-3, contralateral involvement was not detected by intravenous pyelography (IVP) or CT in approximately one third of the children with bilateral tumors.<sup>36</sup> Review of children with bilateral tumors treated on NWTSG-4 identified 9 of 122 children in whom the diagnosis of bilateral disease was missed by the preoperative imaging studies (CT, ultrasonography, or MRI).<sup>120</sup> All but one of these lesions were small: five were smaller than 1 cm, and three were 1 to 3 cm in diameter. Recent review of this material, however, has suggested that some of the small lesions on the contralateral kidney that were initially thought to be small Wilms' tumors would now be more correctly defined as hyperplastic NRs.<sup>121</sup> The overall outcome of children with these small lesions was also extremely favorable with no recurrences. Current studies by the Children's Oncology Group do not require examination of the contralateral side if there is no suggestion of involvement on the preoperative radiographic studies.

After initial evaluation, the colon is then mobilized off the anterior aspect of the kidney and the renal mass. Although early descriptions of the operative technique recommended initial control of the renal hilum, this is often not feasible with extremely large tumors and must await mobilization of the mass to allow safe exposure of the hilum. Premature attempts at vascular control, particularly of left-sided tumors, may result in ligation of the superior mesenteric artery.<sup>122</sup> Biopsy of the renal mass should not be performed unless the decision is to not proceed with a complete resection. Biopsy will produce contamination of the peritoneum and increase the stage of the tumor to stage III.

Biopsy of lymph nodes in the renal hilum and along the vena cava or aorta is critical for adequate staging.

Even in children with stage IV disease, local staging is critical because it will determine whether abdominal radiation therapy is used in children treated on Children's Oncology Group protocols. Studies have demonstrated that the surgeon's gross evaluation and assessment of lymph nodes does not reliably correspond with the pathologic involvement of tumor with false-negative and false-positive rates of 31.3% and 18.1%, respectively.<sup>123</sup> An increased incidence of local recurrence was seen in children enrolled in NWTSG-4, in whom biopsy of lymph nodes was not performed, particularly stage I cases.<sup>119</sup> This suggested that undertreatment of local disease in these children due to inadequate staging resulted in an increased frequency of local recurrence. Although grossly involved lymph nodes are generally resected, an extensive retroperitoneal lymph node resection has not been demonstrated to improve local control.<sup>92</sup>

As the tumor is being mobilized, the ureter is resected close to the bladder to avoid a "diverticulum" on the bladder, which might produce recurrent urinary tract infection, but primarily to make certain that any extension of tumor into the ureter is entirely resected. Gross hematuria in children with Wilms' tumor is infrequent, but its occurrence suggests extensive involvement of the renal pelvis with possible extension down into the ureter. Cystoscopy should be considered in these children to identify extension of the tumor into the bladder and to avoid transection of the tumor thrombus during division of the ureter. Ureteral extension that is entirely resected does not increase the local stage of the tumor. If the tumor involves the upper pole, the adrenal gland is generally resected to provide adequate margins around the tumor and also to obtain periaortic or pericaval lymph nodes. With lower-pole lesions, the adrenal gland may be preserved.

The factors associated with an increased risk of local recurrence are stage III disease, unfavorable histology (especially diffuse anaplasia), and tumor rupture during operation.<sup>119</sup> Tumor rupture is the only factor that the surgeon can impact. Multiple regression analysis adjusting for the combined effects of histology, lymph node involvement, and age reveal that tumor spillage remained significant and was greatest in children with stage II disease who received less intensive therapy. Most tumor ruptures occur during mobilization of the posterior aspects of the tumor where it is adherent to the diaphragm. This can be best prevented by the use of an adequate incision for exposure and resection of a segment of the adherent diaphragm, if necessary.

Resection of adjacent organs (liver, spleen, or pancreas) or resection of massive Wilms' tumors are discouraged in the recent NWTSG and Children's Oncology Group studies based on reviews of complications. Such extensive resections are associated with a significant increase in surgical complications.<sup>116</sup> Only in this situation should the surgeon sample the primary tumor along with perihilar and periaortic/caval lymph nodes.

Preoperative evaluation of children with renal tumors should also include studies of coagulation. An

“acquired” von Willebrand’s disease has been seen in children with Wilms’ tumor. This coagulopathy can produce problems with hemostasis if it is not identified and corrected before operation.<sup>124</sup>

### Preoperative Therapy

Preoperative adjuvant treatment of Wilms’ tumor is generally accepted in certain circumstances: the finding of Wilms’ tumor in a solitary kidney, bilateral renal tumors, tumor in a horseshoe kidney, intravascular extension of the tumor above the intrahepatic vena cava, and respiratory distress from extensive metastatic tumor. In such cases, pretreatment biopsy should be obtained. Percutaneous biopsy is often used, although needle-tract seeding has been reported.<sup>125</sup> The aim of treatment (before surgical resection in the bilateral tumors and tumor in a horseshoe or solitary kidney) is to preserve maximal renal parenchyma and function. The anatomy of the kidney has not been recognized before surgical exploration in many of the cases of Wilms’ tumor arising within a horseshoe kidney.<sup>126</sup> This is often due to the large size of the tumor distorting the anatomy. An increased incidence of urine leak and ureteral injury occurs in this situation because of the aberrant anatomy of the collecting systems.

Although growth of the remaining kidney has been documented (achieving 180% volume augmentation), the occurrence of focal segmental glomerulosclerosis has been reported in children with a unilateral kidney.<sup>127,128</sup> In the NWTS-1 to NWTS-4 population, the incidence of renal failure after unilateral nephrectomy was only 0.25%.<sup>98</sup> Studies from Europe on pretreatment of unilateral Wilms’ tumor have demonstrated that, in most instances, a nephrectomy is still required, rather than a partial nephrectomy, because of the extent of tumor involvement in the kidney at presentation.<sup>129</sup>

The efficacy of preoperative chemotherapy in allowing the safe performance of partial nephrectomy for Wilms’ tumor has been evaluated by several centers. In Toronto, percutaneous biopsy in 37 children with Wilms’ tumor was followed by multiple-agent chemotherapy for 4 to 6 weeks. A partial nephrectomy was then performed in 9 children (4 with unilateral and 5 with bilateral tumors).<sup>130</sup> Two children had intra-abdominal relapse. Only 4 (13.3%) of the 30 unilateral tumors were amenable to a partial nephrectomy. Another analysis of the feasibility of partial nephrectomies was performed at St. Jude Children’s Research Hospital.<sup>131</sup> Preoperative CT scans of 43 children with nonmetastatic unilateral Wilms’ tumor were reviewed retrospectively. Criteria used to determine whether a partial nephrectomy would have been feasible were involvement by the tumor of one pole and less than one third of the kidney, a functioning kidney, no involvement of the collecting system or renal vein, and clear margins between the tumor and surrounding structures. With these criteria, only two (4.7%) of 43 scans suggested that partial nephrectomy was feasible. The primary concerns regarding the use of preoperative chemotherapy to create “resectable”

small tumors is that these children with small tumors at presentation may be curable with surgical resection alone without subjecting them to the toxicity of additional treatments.<sup>102,103</sup> Whereas the role of partial nephrectomy has been suggested in children with Beckwith-Wiedemann syndrome or hemihypertrophy in whom smaller tumors may be identified by prospective screening, the efficacy of this approach has not been established.<sup>132</sup>

One additional indication for the use of preoperative chemotherapy has been suggested in those patients with contained retroperitoneal rupture.<sup>133</sup> The concern expressed is that primary resection will result in rupture of the hematoma and require total abdominal radiation therapy. In two reported cases, preoperative chemotherapy allowed resorption of the rupture and resection without positive margins or contamination of the peritoneal cavity. This indication for preoperative chemotherapy will have to be confirmed in a larger number of patients.

### Bilateral Wilms’ Tumor

Children with bilateral tumors are generally younger than those with unilateral lesions, with a mean age of 25 versus 44 months.<sup>134</sup> Preservation of renal parenchyma is a critical issue for these children. In the NWTSG review of renal failure in 55 children from NWTS-1 to NWTS-4, 39 children had bilateral tumor involvement. Increasing efforts to preserve renal parenchyma in bilateral cases in the sequence of the NWTSG studies resulted in a decline in the incidence of renal failure from 16.4% in NWTS-1 and NWTS-2 to 9.9% in NWTS-3 and 3.8% in NWTS-4.<sup>135</sup> Although the incidence may increase in the more recent studies as children age, this declining frequency also is due in part to increased attempts to save part of the kidney by initial treatment of the tumor with chemotherapy. Preliminary treatment in most cases after biopsy and staging will produce shrinkage of the tumor and facilitate its resection with preservation of a portion of the kidney. It is important to perform biopsies of all tumors because “discordant” pathology does occur, with a favorable lesion on one side and unfavorable lesion (generally anaplastic) on the other. Bilateral lesions are rarely seen in association with clear cell sarcoma or rhabdoid tumors of the kidney. Ninety-eight children with bilateral Wilms’ tumors underwent a partial nephrectomy of 134 kidneys during NWTS-4.<sup>136</sup> Complete resection of gross disease was accomplished in 118 (88%) of the 134 kidneys. A higher incidence of positive surgical margins (16%, 19 of 134) and local tumor recurrence (8.2%, 11 of 134) was seen in this group of children. These were justified by the attempt to preserve renal tissue and avoid renal failure. Overall, portions of 72% of the kidneys were preserved, and the 4-year survival rate was 81.7%. The UKCCSG also reported attempts at maximal preservation of renal parenchyma with preoperative chemotherapy.<sup>137</sup> Survival was equivalent for those with initial resection versus preoperative chemotherapy, but

greater preservation of renal parenchyma was seen in those treated with initial chemotherapy. The presence of rhabdomyomatous histology has been associated with a poor response to preoperative chemotherapy, as defined by a decrease in size on radiographic evaluation, but it has been found to be associated with favorable survival.<sup>138</sup> Irradiation has been advocated to prevent relapse in children with partial nephrectomy for bilateral disease, but it may impair the ability of the kidney to grow.<sup>139,140</sup>

### *Intravascular Extension*

Intravascular extension of a tumor thrombus occurs in 4% of children with Wilms' tumor. Identification of vascular extension by preoperative radiographic studies or early in the surgical exploration is critical to avoid a tumor embolus during mobilization of the kidney. Ultrasonography is probably more sensitive for detecting vascular extension than CT. The presence of intravascular extension does not affect the prognosis of the tumor as long as it is successfully resected.<sup>141</sup> Traditionally, intravascular extension has been managed by nephrectomy with resection of the tumor thrombus into the renal vein or vena cava. Cardiopulmonary bypass has been required for children with atrial extension of the tumor thrombus but is associated with a significant incidence of complications (70%).<sup>117,142</sup>

In an NWTSG report of intravascular extension of Wilms' tumor, 30 children (15 with caval and 15 with atrial extension) were treated initially with chemotherapy after biopsy of the renal mass. After treatment, a decrease in the size of the intravascular extension was noted in 23 children and complete resolution of the tumor thrombus was seen in 7 children.<sup>143</sup> Of the 15 children with tumor initially extending into the atrium, a complete or marked response occurred, and the tumor was removed transabdominally without bypass. Tumor embolism did not occur during chemotherapy. Fibrosis of tumor to the caval wall developed in some cases, and in two cases occlusion of the inferior vena cava occurred postoperatively. A similar review of children treated in the United Kingdom with extensive intravascular involvement also demonstrated a decrease in the extent of vascular involvement in 16 of 21 children and showed that children receiving preoperative chemotherapy had a better outcome.<sup>144</sup>

More recently, a review of all of the children treated on the NWTSG-4 protocol described 165 of 2731 patients with intravascular extension into the inferior vena cava (134 patients) or atrium (31 patients).<sup>145</sup> Sixty-nine of these patients received preoperative chemotherapy (55 with inferior vena cava extension and 14 with atrial extension). Five complications were encountered during preoperative chemotherapy, including tumor embolism and tumor progression in 1 patient each, and 3 patients with adult respiratory distress syndrome, one of whom died. Intravascular extension of the tumor regressed in 39 of 49 children with comparable pre- and post-therapy radiographic studies, including regression in 7 of 12 in whom the tumor regressed from an atrial location, avoiding the need for

cardiopulmonary bypass. A high frequency of surgical complications occurred in these patients: 36.7% in the children with atrial extension and 17.2% in those with extension to the inferior vena cava. The frequency of surgical complications was 26% in the primary resection group versus 13.2% in children with preoperative therapy. When all the complications were considered, including those that occurred during preoperative chemotherapy (1 of these 5 patients also had a surgical complication), the incidence of complications among those receiving preoperative therapy was not statistically different from the incidence among those who underwent primary resection. However, most of the severe complications occurred in the primary resection group. Also, preoperative therapy clearly facilitated surgical resection by decreasing the extent of the tumor thrombus.

### *Resection Alone for Select Favorable Wilms' Tumors*

A small group of children with Wilms' tumor may require only resection of the primary tumor and kidney without adjuvant treatment. The outcomes of children younger than 2 years with stage I tumors weighing less than 550 g who have been registered in the NWTSG studies were reviewed.<sup>146</sup> The 4-year RFS for children meeting these criteria exceeded 90%, suggesting that they could be selected for treatment with resection alone. A similar review by the UKCCSG, in which children with stage I tumors received only vincristine "monotherapy," also demonstrated that infants younger than 2 years of age had particularly favorable 4-year EFS and OS of 93.2% and 98.1%, respectively.<sup>147</sup>

A pathologic review of children treated on NWTSG-4 also demonstrated that age younger than 2 years and specimen weight of less than 550 g was highly associated with the absence of adverse microstaging variables.<sup>148</sup> A prospective pilot study looking at this question was performed at Children's Hospital in Boston. Eight children with stage I disease who were younger than 2 years of age with unilateral, favorable-histology tumors with a combined tumor and kidney weight under 550 g underwent tumor resection and were followed without adjuvant therapy.<sup>149</sup> In one child, a metachronous tumor was cured by resection and chemotherapy. Continued follow-up of patients in this series has not shown any episodes of local recurrence.<sup>150</sup>

One component of NWTSG-5 was a trial of operation only for children younger than 2 years with small (<550-g tumor and kidney) stage I tumors of favorable histology. Seventy-five infants were enrolled in this study.<sup>151</sup> In 3 infants, metachronous, contralateral Wilms' tumors developed, and 8 patients experienced relapse 0.3 to 1.05 years after diagnosis. The sites of relapse were pulmonary (five cases) and operative bed (three cases). The 2-year disease-free (relapse and metachronous) survival including both relapse and metachronous tumors was 86.5%. The 2-year survival rate was 100%, with a median follow-up of 2.84 years.

The 2-year disease-free survival, excluding metachronous contralateral Wilms' tumor, was 89.2%, and the 2-year cumulative risk of metachronous contralateral Wilms' tumor was 3.1%. The stopping rule for the study required closure after these 75 infants were enrolled, but continuing evaluation of this cohort has demonstrated that they have done very well with a high rate of salvage for recurrence, perhaps because they had not been treated with chemotherapy. Further studies of these infants will be required to establish their optimal therapy. Treatment by surgery alone should be utilized only in patients enrolled in prospective studies.

### Neonatal Wilms' Tumor

Wilms' tumor occurs rarely in the neonate. A review of the 3340 children entered into the NWTS studies from 1969 to 1984 revealed only 27 (0.8%) neonates (30 days old or younger) with renal tumors.<sup>152</sup> More than half of the neonates (18) had mesoblastic nephroma, and 4 others had non-neoplastic lesions. One infant had a malignant rhabdoid tumor, and 4 had Wilms' tumors. All of the Wilms' tumors had favorable histology and had not metastasized. The neonates did well, receiving a variety of treatments ranging from resection alone to 15 months of three-drug therapy. A subsequent report of 15 cases of Wilms' tumor occurring in neonates in the first 30 days of life again demonstrated tumors of favorable histology and the absence of metastatic disease.<sup>153</sup> Ten of these infants received postoperative chemotherapy, and 5 were observed without additional treatment. Only one of these 5 children had recurrence in the renal fossa and lungs and ultimately died of her disease at age 16 months. The other children are all disease free at a median follow-up of 31 months.

### Extrarenal Wilms' Tumor

An extrarenal site of primary Wilms' tumor is uncommon. These extrarenal tumors behave identically to tumors arising within the kidney and should be treated both locally and systemically based on the same criteria.<sup>154,155</sup> Common sites of occurrence of extrarenal Wilms' tumors include the retroperitoneum, inguinal canal, scrotum, and vagina. Less common sites are the uterus, cervix, ovary, and presacral space.

## RENAL CELL CARCINOMA

Children with renal cell carcinoma are generally older than those with Wilms' tumor and frequently initially have symptoms of flank pain and gross hematuria.<sup>156</sup> Renal cell carcinoma in children displays gross and microscopic pathologic features similar to those seen in adults. Clinical stage at the time of diagnosis is the most important prognostic factor, and the identification of renal vascular invasion did not appear to be an adverse predictor. Radical nephrectomy and regional lymphadenectomy have been the primary modality for cure,

and children with distant spread have a grave prognosis. In a study of 22 children, the mean age at presentation with renal cell carcinoma was 14 years.<sup>157</sup> Overall survival is much worse than for Wilms' tumor, with a 5-year survival in a recent series of only 30%. Analysis of multiple factors including age, tumor size, location, and histology failed to demonstrate that they were predictors of survival. Only stage and successful complete tumor resection were meaningful prognostic factors. Survival was 60% in children with complete resection of the primary tumor and zero in those with only partial resection. Survival was stage dependent: 92.5% for stage I, 84.5% for stage II, 72.7% for stage III, and 12.7% for stage IV. It should be noted, however, that those with positive nodes but no distant metastasis had survival rates three times that of adult historical controls.<sup>158</sup>

Renal cell carcinoma is remarkably resistant to chemotherapy, preventing cure in most children with metastatic disease.<sup>159</sup> Ten to 20 percent of patients have nodal involvement identified at operation but lack evidence of distant metastatic disease. No benefit has been found for adjuvant therapy in children.<sup>158</sup>

Nephron-sparing resection has been used in adult patients with small polar lesions in whom no evidence of a multicentric tumor is found. In these selected cases with tumors smaller than 4 cm and a normal contralateral kidney, the risk of local recurrence is reported to be 2% or less, which is comparable to the frequency of metachronous recurrence in the contralateral kidney after unilateral radical nephrectomy.

The occurrence of late relapses long after nephrectomy, prolonged stability of disease in the absence of systemic therapy, and rare cases of spontaneous regression of tumors have led to an interest in immunotherapy comparable to that used for melanoma. Trials of immunomodulating therapy with interferon- $\alpha$  and interleukin-2 (IL-2) have demonstrated some efficacy, but maintenance of a durable cure has been elusive.<sup>160</sup> A trial with 294 patients with advanced-stage renal cell carcinoma randomized to receive placebo or 9 months of subcutaneous lymphoblastoid interferon demonstrated similar recurrence rates of the two groups and worse survival than those randomized to placebo alone.<sup>161</sup> With the significant toxicity involved with immunotherapy, demonstration of improved survival in randomized trials will be required before this can be adopted as standard therapy.

## MESOBLASTIC NEPHROMA

Congenital mesoblastic nephroma, also referred to as fetal renal hamartoma or leiomyomatous hamartoma, is the most common renal tumor identified in the neonatal period. Although it was initially diagnosed and treated as a congenital Wilms' tumor, mesoblastic nephroma was defined as a distinct entity in 1967.<sup>162</sup> Mesoblastic nephromas appear most frequently in the neonatal period as a palpable flank mass, which can be massive. Additional symptoms seen at presentation include hematuria, hypertension, vomiting, and jaundice.<sup>163</sup>

Mesoblastic nephroma accounted for 2.8% of 1905 renal tumors submitted to the early NWTSG studies. Grossly, these tumors have a homogeneous rubbery appearance resembling a uterine fibroid in color and consistency (Fig. 67-11). Microscopically they are composed of sheets of fibrous or mesenchymal stroma, within which bizarre and dysplastic tubules and glomeruli are irregularly scattered.<sup>164</sup> The tumor can invade intact renal parenchyma, and extrarenal infiltration into the perihilar connective tissues is common. The histologic subtypes of this tumor include the classic type (24% of cases), the cellular type (66%), and the mixed type (10%). The pluripotency of these tumors is revealed by their differentiation into angiomatoid patterns, cartilaginous nests, and their elicitation of intratumoral hematopoiesis in addition to the tiny nephroblastic epithelial foci.

Recently, a characteristic chromosomal translocation, (t12;15)(p13;q25), was described. It results in fusion of the *ETV6* (also known as *TEL*) gene from 12p13 with the *NTRK3* neurotrophin-3 receptor gene (also known as *TRKC*) from 15q25.<sup>27,29</sup> This results in a chimeric RNA, which is characteristic of both infantile fibrosarcoma and the cellular variant of congenital mesoblastic nephroma. This may be helpful in differentiating the cellular variant from other lesions that must be considered in the differential diagnosis, including clear cell sarcoma and rhabdoid tumors. It also suggests a close relation between infantile fibrosarcoma and the cellular variant of mesoblastic nephroma.<sup>64</sup>

This generally benign tumor usually can be cured with nephrectomy alone. This should include generous margins around all gross tumors to avoid local recurrence. Particular attention should be paid to the medial aspect of the kidney, including the hilum and great vessels, because of the tumor's proclivity to have extensions into these perirenal soft tissues. Several children have been reported with local recurrence<sup>165</sup> or metastases to the brain, bones, lungs, and heart.<sup>166-169</sup> In some of these cases, the histology has revealed an unusual degree of mesenchymal cell immaturity and hypercellularity, suggesting a more aggressive tumor.<sup>164</sup> These rare occurrences, however, support the concept that mesoblastic nephroma cannot be considered a simple hamartoma and that complete nephrectomy with negative pathologic margins for tumor is critical in all cases.

In a series of 51 children with mesoblastic nephroma identified in the NWTSG series, adequate operative excision was achieved in 43 of 51 children, whereas 8 had local extension and 10 had tumor spillage during resection.<sup>163</sup> The use of adjuvant therapy in these cases depended on the era in which the children were treated. Twenty-three infants treated principally since 1978 had surgical resection alone. Prior to 1978, 24 had operation plus chemotherapy, and before 1976, 4 children also received irradiation. Survival was excellent in this entire group, and only 1 child died of sepsis during chemotherapy. One child's tumor recurred at 6 months despite receiving dactinomycin and vincristine. The tumor was surgically re-excised, and the

**Figure 67-11.** Cross section of a mesoblastic nephroma identified in an infant on a neonatal examination. Note the rubbery appearance of this tumor, which resembles a fibroid tumor of the uterus with a very thin margin of normal renal parenchyma around the periphery.

child was treated with cyclophosphamide and doxorubicin and remained without disease 18 months later.

A SIOP report of 29 children with mesoblastic nephroma confirmed the early age at which this tumor is seen. Only 5 infants were older than 4 months at presentation in the series.<sup>170</sup> Five children with the cellular type of tumor received some chemotherapy. Two infants in this series died of sepsis after surgical treatment, but the remainder are alive and free of disease 4 years later. A proclivity for this tumor to infiltrate the renal hilum or perirenal tissue was seen again. Treatment of a neonate with an extensively infiltrating tumor with eight weekly courses of vincristine before resection is reported.<sup>171</sup> Shrinkage of the tumor occurred with treatment, facilitating its eventual resection and cure.

Beckwith reported the largest cohort of children with recurrent or metastatic lesions from his large collected series.<sup>166</sup> Twenty-four cases of aggressive tumor were seen in a series of 330 mesoblastic nephromas. Of these cases, 8 had metastatic disease, 17 had relapse in the peritoneum or retroperitoneum, and 6 of the infants have died of persistent disease. Recurrences occurred in children after initial chemotherapy or irradiation, which suggests that conventional adjuvant therapy may not decrease the incidence of recurrence. Histologic criteria were not helpful in predicting outcome. Beckwith supports aggressive surgical attempts to remove all gross tumor. He also stresses the need for close monitoring for 1 year after resection because relapse in 23 of the 24 cases was apparent within 11 months of resection. Ultrasonography of the local site is adequate, and scans for metastatic disease are unrewarding.

## CYSTIC NEPHROMA

Cystic nephroma is indistinguishable grossly and radiographically from its malignant neoplastic "cousins," cystic partially differentiated nephroblastoma (CPDN)

**Figure 67-12.** A, MR image obtained in a 2-year-old infant with an asymptomatic left flank mass. Note the multilocular cystic mass extending out from the normal renal tissue posteriorly. B, Cross section of the tumor and kidney reveals thin-walled septa within the mass. Histologic examination of this tumor revealed a cystic partially differentiated nephroblastoma.

and cystic nephroblastoma. All lesions are composed of purely cystic masses characterized by multiple thin-walled septations (Fig. 67-12). In cystic nephroma, the septations are lined by flattened, cuboidal or hobnail epithelium and are composed entirely of differentiated tissues without blastemal or other embryonal elements that are the distinguishing characteristics of CPDN.<sup>172</sup> Although the term *multilocular cyst of the kidney* has been used, *cystic nephroma* is preferred because the lesion appears to be neoplastic and not congenital. In the cystic nephroblastoma or cystic Wilms' tumor, solid nodules on the septa of blastemal or embryonal elements are characteristic of Wilms' tumor. An unexplained synchronous occurrence has been reported between cystic nephroma and pleuropulmonary blastoma.<sup>173,174</sup>

These lesions should not be confused with cystic clear cell sarcoma, cystic mesoblastic nephroma, or multicystic dysplastic kidney.<sup>172</sup> Cystic nephroma, CPDN, and cystic nephroblastoma can be distinguished from multicystic dysplastic kidney because they are confined to only a portion of the kidney with normal renal parenchyma being identified, whereas the cystic changes of multicystic dysplastic kidney almost always involve the entire kidney (its cause is early in utero urinary tract obstruction). Contralateral renal anomalies are frequent in dysplastic kidneys, including ureteropelvic junction obstruction and reflux. A multicystic dysplastic kidney is often identified antenatally or in the neonatal period, whereas the other lesions occur later.

Generally, nephrectomy will be curative in both cystic nephroma and CPDN.<sup>175</sup> Twenty-three children

with these cystic lesions were identified in the NWTSG series: 5 with cystic nephroma and 18 with CPDN. Only one patient with CPDN had local recurrence, and no distant metastases were found. A more recent review of the NWTSG and SIOP files of the CPDN cases has again confirmed that primary resection appears to be adequate for all lesions removed intact.<sup>176,177</sup> In cases in which the lesion is isolated to one pole of the kidney, a partial nephrectomy may be considered. However, it must be remembered that these tumors can resemble cystic variants of clear cell sarcoma of the kidney, which carry an entirely different prognosis.<sup>178,179</sup> This is the major concern regarding the use of nephron-sparing surgery, as suggested by some authors for these cystic lesions.<sup>180</sup>

## OSSIFYING RENAL TUMOR OF INFANCY

Ossifying renal tumor of infancy is a relatively rare tumor occurring entirely in infancy. In many cases, children with this lesion initially have gross hematuria, although a palpable mass may be present.<sup>144</sup> These lesions are attached to a renal papilla but are seen primarily within the lumen of the calyx and may extend into the renal pelvis. They have been confused occasionally with staghorn calculi. Histologically, they contain osteoid, osteoblastic cells, and spindle cells. Their true histogenesis has not been proved, although it has been suggested that they represent hyperplastic ILNRs. Metastasis or local spread of these tumors has not been reported. Renal-sparing procedures may be

# NEUROBLASTOMA

Andrew M. Davidoff, MD

Neuroblastoma (NB) is the most common solid extracranial malignancy of childhood and the most common malignant tumor in patients younger than 1 year of age.<sup>1</sup> Its incidence is 1 per 100,000 children in the United States. In addition, NB represents 7% to 10% of all malignancies diagnosed in pediatric patients younger than 15 years of age and is responsible for approximately 15% of all pediatric cancer deaths.<sup>2</sup> However, NB is a heterogeneous disease.<sup>3</sup> Tumors can spontaneously regress or mature, or can display a very aggressive, malignant phenotype. Because of these unique characteristics, NB has been of great interest to both clinicians and basic scientists. Progress in molecular and cellular biology in the past 20 years has contributed greatly to a better understanding of this disease. However, this progress has not significantly altered the clinical outcome for patients with advanced-stage NB. Although the prognosis for these patients has improved somewhat in the past 2 decades, the long-term outcome still remains very poor.

The etiology of NB is currently unknown, and no environmental factors have been convincingly linked to its development. The disease generally occurs sporadically, but familial NB does occur in about 2% of cases. Interestingly, however, substantial biologic and clinical heterogeneity is often observed in familial cases.<sup>4</sup> Recently, the germline mutation associated with hereditary NB has been identified: activating mutations in the tyrosine kinase domain of the anaplastic lymphoma kinase (ALK) oncogene on the short arm of chromosome 2 (2p23).<sup>5</sup> These mutations can also be somatically acquired, although the prevalence of ALK activation in sporadic NB remains to be determined. NB has also been reported in infants with Beckwith-Wiedemann syndrome, Hirschsprung's disease, fetal alcohol syndrome, and in the offspring of mothers taking phenytoin for seizure disorders.<sup>6-9</sup>

The treatment of NB requires a multidisciplinary approach. Although surgical resection may be the only therapy required for patients at "low risk" of disease recurrence, the surgeon provides but one element of the modern multimodal treatment of children with "high-risk" disease. Pediatric oncologists, radiation therapists, and bone marrow transplantation (BMT)

specialists are among the other important members of the pediatric oncology team. The therapy for patients with NB, as for children with other malignancies, is generally driven by clinical research protocols. Many of these protocols are sponsored by the Children's Oncology Group (COG) or by the larger children's hospitals, working individually or in small groups.

## PATHOLOGY

NB is an embryonal tumor of the sympathetic nervous system. These tumors arise during fetal or early postnatal life from sympathetic cells (sympathogonia) derived from the neural crest. Therefore, tumors can originate anywhere along the path that neural crest cells migrate, including the adrenal medulla, paraspinal sympathetic ganglia, and sympathetic paraganglia such as the organ of Zuckerkandl. The German pathologist Rudolph Virchow is generally credited with being the first to describe the histologic appearance of what is now known as NB in his 1864 article entitled, "Hyperplasia of the Pineal and Suprarenal Glands."<sup>10</sup> The first to use the term *neuroblastoma* was James Homer Wright, who, in 1910, described the classic appearance of rosettes of tumor cells around central neural fibrils. He also noted the association between the common sites of tumor development and the pattern of migration of primitive neural cells.<sup>11</sup>

As one of the "small, round blue cell" tumors of infancy and childhood, NB, particularly when undifferentiated, must be distinguished from other neoplasms of this group (e.g., Ewing sarcoma family of tumors, non-Hodgkin lymphoma, and rhabdomyosarcoma). NB can be distinguished histologically by the presence of neuritic processes (neuropil) and Homer-Wright rosettes (neuroblasts surrounding eosinophilic neuropil). Scattered ganglion cells or immature chromaffin cells may also be seen. The appearance of the tumor cells may vary from undifferentiated cells to fully mature ganglion cells. In addition, NBs have variable degrees of schwannian cell stroma, which is reactive non-neoplastic tissue recruited by the tumor cells. This stroma is intermixed, to a greater or lesser degree, as

**Figure 68-1.** Characteristic histologic appearance of neuroblastoma. **A**, Histologic appearance of an NB with a high MKI ( $\times 10$ ). A clump of karyorrhetic tumor cells (*dotted arrow*) and a tumor cell undergoing mitosis (*solid arrow*) are shown in the *inset* ( $\times 60$ ). **B**, A differentiating NB with a low MKI ( $\times 10$ ). A primitive neuroblast (*dotted arrow*) and a differentiating tumor cell (*solid arrow*), with features of differentiation in both the nucleus and cytoplasm, are shown in the *inset* ( $\times 60$ ). Abundant neuropil is also seen. (Courtesy of Jesse Jenkins, MD, and Christine Fuller, MD, St. Jude Children's Research Hospital, Memphis, TN; reprinted from Davidoff AM: Neuroblastoma. In Oldham KT, Colombani PM, Foglia RP, Skinner MA [eds]: Principles and Practice of Pediatric Surgery. Philadelphia, Lippincott Williams & Wilkins, 2005.)

wavy bundles and sheets of spindle cells throughout the tumor and produces antiproliferative and differentiation-inducing factors that are crucial to neuronal differentiation.<sup>12,13</sup> In addition, the schwannian stroma appears to produce a variety of anti-angiogenic factors, including pigment epithelium-derived factor (PEDF)<sup>14</sup> and secreted protein acidic and rich in cysteine (SPARC).<sup>15</sup> Histopathologic variables among neuroblastic tumors include the degree of differentiation, maturation, lymphoid infiltration, calcification, anaplasia, necrosis, mitotic activity, neurofibrillary material (neuropil), and the presence of multinucleated cells. Finally, immunohistochemical analysis usually generates positive staining when antibodies to NB-specific antigens such as synaptophysin, neuron-specific enolase, and chromogranin are used and is negative when antibodies to actin, desmin, cytokeratin, leukocyte common antigen, vimentin, and CD99 are used.

NB is characterized by several unique clinical behaviors, including the secretion of catecholamine products and the potential to regress or mature, either spontaneously or in response to treatment. Small nodules of primitive neuroblasts are routinely found in the developing adrenal gland, even during the early postnatal period. Beckwith and Perrin described microscopic nodules that they referred to as “neuroblastoma in situ” in the adrenals of infants undergoing autopsy after death from non-malignancy-related causes.<sup>16</sup> The incidence of this finding was more than 200-fold greater than the clinical incidence of NB, which suggests that perhaps many NBs spontaneously regress or mature into lesions that never become clinically apparent. The process of involution is well described during embryonic life, especially in the developing central and peripheral nervous systems. Although initially thought to be mediated by the immune system, the process of involution may be the result of withdrawal of neurotrophic maintenance factors such as nerve growth factor (NGF). Clinically apparent NB can also regress

or spontaneously mature, but the mechanism(s) of NB maturation and regression remain unknown.

## CLASSIFICATION

In 1984, Shimada and colleagues first developed an age-linked classification system of neuroblastic tumors based on tumor morphology in which NBs were divided into two prognostic subgroups: favorable histology and unfavorable histology.<sup>17</sup> In 1999, the International NB Pathology Classification (INPC) was devised.<sup>18</sup> It was then modified in 2003<sup>19</sup> and is an adaptation of the original Shimada system. The INPC is based mainly on morphologic changes associated with the maturational sequence of neuroblastic tumors. It remains an age-linked classification that depends on the differentiation grade of the neuroblasts, the cellular turnover index (mitosis-karyorrhexis index [MKI]), and the presence or absence of schwannian stroma. The INPC classifies neuroblastic tumors into three morphologic categories: NB, ganglioneuroblastoma, and ganglioneuroma (Fig. 68-1).

NBs are, by definition, schwannian stroma poor (<50% of the tumor tissue) and can be subtyped as undifferentiated (requires supplemental diagnostic methods such as immunohistochemistry, electron microscopy or cytogenetics; and neuropil is not present) (see Fig. 68-1A); poorly differentiated (<5% of tumor cells have features of differentiation, and neuropil is present); or differentiating (>5% of tumor cells show differentiation toward ganglion cells) (see Fig. 68-1B). To classify a cell as a differentiating neuroblast, there must be synchronous differentiation of the nucleus (an enlarged, eccentric nucleus with a vesicular chromatin pattern and a single prominent nucleolus) and eosinophilic cytoplasm.<sup>18</sup>

Additional factors that contribute to the prognostic NB as favorable or unfavorable subtypes include

**Table 68-1** Prognostic Evaluation of Neuroblastic Tumors According to the International Neuroblastoma Pathology Classification

International Neuroblastoma Pathology Classification		Prognostic Group
Neuroblastoma <1.5 yr	Schwannian stroma-poor Poorly differentiated or differentiating and low or intermediate MKI tumor	Favorable
1.5-5 yr <1.5 yr	Differentiating and low MKI tumor (a) Undifferentiated tumor or (b) high MKI tumor	Unfavorable
1.5-5 yr	(a) Undifferentiated or poorly differentiated tumor or (b) intermediate or high MKI tumor	
≥5 yr	All tumors	
Ganglioneuroblastoma, intermixed	Schwannian stroma-rich	Favorable
Ganglioneuroblastoma, nodular	Composite schwannian stroma-rich/stroma-dominant and stroma poor	Unfavorable or favorable (based on nodule histology)
Ganglioneuroma Maturing Mature	Schwannian stroma-dominant	Favorable

MKI, mitosis-karyorrhexis index.

Adapted from Shimada H, Ambros IM, Dehner LP, et al: The International NB Pathology Classification (the Shimada System). *Cancer* 86:364-372, 1999.

the MKI, which is defined as the number of tumor cells in mitosis or karyorrhexis per 5000 neuroblastic cells (i.e., low MKI, < 100 cells; intermediate, 100-200 cells; high, > 200 cells) and the patient's age (<1.5 years, 1.5-5 years, > 5 years) (Table 68-1). The favorable-histology subgroup of NBs includes poorly differentiated and differentiating tumors with low or intermediate MKI in patients younger than 1.5 years of age and differentiating tumors with low MKI in patients ages 1.5 to 5.0 years. The unfavorable-histology subgroup includes undifferentiated tumors or those with high MKI in patients of any age, poorly differentiated tumors or those with intermediate-MKI tumors in patients ages 1.5 to 5.0 years, or any tumor in a patient older than 5 years. The age of the patient appears to be a crucial component of the prognostic assessment of the INPC. It has been hypothesized that neuroblastic cells with maturational potential require an in-vivo latent period before demonstrating histologic evidence of differentiation. Therefore, there is a certain allowance for mitotic and karyorrhectic activities of neuroblastic cells in tumors in infants and younger children.<sup>20</sup>

The importance of this histopathologic classification was confirmed in a large, retrospective analysis reported by Shimada and associates.<sup>21</sup> The INPC classification of tumor histology provided independent prognostic information that was able to distinguish patients with tumors of favorable histology (probability of 5-year event-free survival [EFS], 90.8%) from those with tumors of unfavorable histology (EFS, 31.2%). More recently, the INPC classification has been shown to add independent prognostic information beyond the prognostic contribution of age.<sup>22</sup> Therefore, histopathology remains in the current multifactorial risk stratification for patients with NB. This determination is particularly important in patients who are older than age 1 year and have localized disease. Because

the histopathologic pattern within a tumor can be heterogeneous, Shimada has recommended analyzing representative sections from at least 1 cm<sup>3</sup> of viable, non-necrotic tissue to determine histopathologic classification. The prognostic value of assessing the histopathology of a NB after chemotherapy or radiation therapy has not been validated.

Stroma-rich neuroblastic tumors are classified as either ganglioneuroblastomas or ganglioneuromas (Fig. 68-2). Ganglioneuroblastomas contain cells that are transitioning toward differentiation but are not completely differentiated/mature and have residual microscopic foci of neuroblastic cells (<50% of the total volume) distributed throughout the tumor. Ganglioneuroblastomas can be further divided into "intermixed" and "nodular" subtypes, depending on the distribution of the neuroblastic cells. This distinction is important because of the significantly worse prognosis associated with the latter subtype. In this subtype, the neuroblastic clones that comprise grossly distinct nodules appear to be responsible for the aggressive phenotype for this subtype.<sup>20</sup> Ganglioneuromas contain either maturing cells (i.e., those that contain a minor component of scattered differentiating neuroblasts not forming distinctive nests), or mature cells, which lack any neuroblastomatous component. Most stroma-rich tumors (ganglioneuroblastoma, intermixed; ganglioneuroma, maturing subtype) are classified as "favorable" by the INPC. However, the pathologic/prognostic classification of the ganglioneuroblastoma, nodular subtype is based on the morphologic evaluation of the neuroblastomatous nodule(s), and can, therefore, be unfavorable. Tumors that fit the criteria for ganglioneuroma, mature subtype, with abundant schwannian stroma and fully mature ganglion cells, in the absence of neuroblasts, are considered benign and are generally not considered for enrollment in protocols for neuroblastic tumors.

**Figure 68-2.** More mature neuroblastic tumors. **A**, A stroma-rich ganglioneuroblastoma with infrequent neuroblasts intermixed within abundant schwannian stroma and ganglion cells ( $\times 10$ ). **B**, A stroma-rich ganglioneuroma with ganglion cells (*arrow*) ( $\times 10$ ). Infiltrating lymphoid cells are also seen, but no neuroblasts are present. ## MOLECULAR BIOLOGY

Advances in molecular biology research in the past 2 decades have resulted in an increased understanding of the genetic events in the pathogenesis and progression of many human malignancies, including those found in children. NB, in particular, has served as a model for a molecular approach to treating patients with cancer, highlighting the utility of genetic analysis for diagnosis, risk stratification, and treatment planning. Chromosomal structural changes play a role in NB, particularly those that result in the loss of tumor suppressors or gain of oncogenes, gene amplification, and activating or inactivating mutations of relevant genes or their regulatory elements. The end result of alterations in these genetic elements, regardless of their specific mechanisms, is the disruption of the normal balance between cell proliferation and cell death. NB is characterized by marked clinical and biologic heterogeneity, which is also evident at the genetic level. Although there is no single genetic abnormality or initiating event common to all NBs, a number of different genetic alterations have been identified that provide powerful prognostic information and play crucial roles in risk assessment and treatment planning.

### DNA Content

Normal human cells contain two copies of each of 23 chromosomes. Thus, a normal diploid cell has 46 chromosomes. The majority (55%) of primary NBs are triploid or "near-triploid/hyperdiploid" and contain between 58 and 80 chromosomes. The remainder (45%) are either "near-diploid" (35-57 chromosomes) or "near-tetraploid" (81-103 chromosomes).<sup>23</sup> The "DNA index" of a tumor is the ratio of the number of chromosomes present to a diploid number of chromosomes (i.e., 46). Therefore, diploid cells have a DNA index of 1.0, whereas near-triploid cells have a DNA index ranging from 1.26 to 1.76. NBs that are near-diploid or near-tetraploid usually have structural genetic abnormalities, most frequently chromosome

1p deletion and *MYCN* amplification. Near-triploid or hyperdiploid tumors are characterized by three almost complete haploid sets of chromosomes with few structural abnormalities. Importantly, patients with near-triploid tumors typically have favorable clinical and biologic prognostic factors and excellent survival rates when compared with those patients who have near-diploid or near-tetraploid tumors.<sup>24</sup> This association is most important for infants with advanced disease.<sup>25</sup> The prognostic significance of tumor ploidy appears to be lost in patients older than 2 years.

### Amplification of *MYCN*

Investigation of the molecular biology of NB began with the cytogenetic characterization of tumor-derived cell lines. These studies showed the frequent presence of extrachromosomal double-minute chromatin bodies (DMs) and chromosomally integrated homogeneously staining regions (HSRs) characteristic of gene amplification (Fig. 68-3).<sup>26</sup> Since that time, it has been shown that the amplified region was derived from the distal short arm of chromosome 2 (2p24) and contained the *MYCN* proto-oncogene. *MYCN* encodes a 64-kD nuclear phosphoprotein MYCN that forms a transcriptional complex by associating with other nuclear proteins expressed in the developing nervous system and other tissues.<sup>27</sup> Enforced expression of *MYCN* increases the rates of DNA synthesis and cell proliferation and shortens the  $G_1$  phase of the cell cycle.<sup>28</sup> *MYCN* can also function as a classic dominant oncogene that cooperates with activated *RAS* to transform normal cells.<sup>29</sup> Targeted expression of *MYCN* in transgenic mice results in the development of NBs.<sup>30</sup>

Overall, approximately 25% of primary NBs in children have *MYCN* amplification, with *MYCN* amplification being present in 40% with advanced disease but only 5% to 10% with low-stage disease.<sup>31</sup> The copy number, which can range from 5- to 500-fold amplification, is usually consistent among primary and metastatic sites and at different times during tumor evolution and treatment.<sup>32</sup> This finding suggests that

**Figure 68-3.** FISH analysis of a neuroblastoma. **A**, Chromosomes in metaphase. The bright spots are double-minute chromatin bodies. **B**, The metaphase chromosomes are again seen. An intact interphase nucleus is marked with an asterisk. The normal two copies of the *MYCN* gene are marked with solid arrows. Homogeneously staining regions (HSRs) are also seen. One is seen in the interphase nucleus, and the other is marked with a dotted arrow. (Courtesy of Marc Valentine, St. Jude Children's Research Hospital, Memphis, TN.)

*MYCN* amplification is an early event in the pathogenesis of NB. Amplification of *MYCN* is associated with advanced stages of disease, rapid tumor progression, and poor outcome. Therefore, it is a powerful prognostic indicator of biologically aggressive tumor behavior.<sup>31,33</sup> Amplification can be detected either by routine metaphase cytogenetics or fluorescent in situ hybridization (FISH). Current therapeutic NB protocols have incorporated the presence or absence of *MYCN* amplification into their risk stratification schema.

### Chromosomal Changes

Also noted on early karyotype analyses of NB-derived cell lines were frequent deletions of the short arm of chromosome 1.<sup>34</sup> Deletions of genetic material in tumors suggest the presence (and subsequent loss) of a tumor suppressor gene. Although no individual tumor suppressor gene has been confirmed on chromosome 1p, recent data have identified CHD-5 as the strongest candidate tumor suppressor gene that is deleted from 1p36.31 in NB.<sup>35</sup> Functional confirmation of the presence of a 1p tumor suppressor gene came from the demonstration that transfection of chromosome 1p into a NB cell line results in morphologic changes and ultimately cell senescence.<sup>36</sup> Twenty to 35 percent of primary NBs exhibit 1p deletion, as determined by FISH, with the smallest common region of loss located within region 1p36.<sup>37</sup> About 70% of advanced-stage NBs have 1p deletions.<sup>38</sup> Molecular studies have shown that there is a strong correlation between 1p deletion and *MYCN* amplification and other high-risk features such as age older than 1 year and advanced-stage disease.<sup>37</sup> In one study it was demonstrated that 1p deletions are independently associated with a worse outcome in patients with NB.<sup>39</sup> Deletions of the long arm of chromosome 11 (11q) and 14 (14q) also appear to be common in NBs. Both are inversely related to *MYCN* amplification.<sup>39,40</sup>

Comparative genomic hybridization (CGH) studies have shown that gain of genetic material on the

long arm of chromosome 17 (17q) is perhaps the most common genetic abnormality in NBs, occurring in approximately 75% of primary tumors.<sup>41</sup> Gain of 17q most often results from an unbalanced translocation of this region to other chromosomal sites, most frequently 1p or 11q. The term *unbalanced* implies that extra copies of 17q are present in addition to normal copies of chromosome 17. Currently, it is unclear how extra copies of 17q contribute to the malignant phenotype of NB and which genes on 17q are the critical ones. Gain of chromosome 17q is strongly associated with other known prognostic factors, but it may be a powerful independent predictor of adverse outcome.<sup>42</sup> Finally, more recently, a genome-wide association study has demonstrated that a common genetic variation at chromosome band 6p22 is associated with susceptibility to NB.<sup>43</sup>

### Other Molecular Abnormalities

Neurotrophins and their tyrosine kinase receptors are important in the development of the sympathetic nervous system and have been implicated in the pathogenesis of NB. Three receptor-ligand pairs have been identified: TrkA, the primary receptor for nerve growth factor (NGF); TrkB, the primary receptor of brain-derived neurotrophic factor (BDNF); and TrkC, the receptor for neurotrophin-3 (NT-3).<sup>44</sup> TrkA appears to mediate differentiation of developing neurons or NB in the presence of NGF ligand, and of apoptosis in the absence of NGF.<sup>45</sup> High TrkA expression is associated with favorable tumor biology and a good outcome<sup>46</sup> and is inversely correlated with *MYCN* amplification.<sup>47</sup> Conversely, the TrkB/BDNF pathway appears to promote NB survival through autocrine or paracrine signaling, especially in *MYCN*-amplified tumors.<sup>48</sup> TrkB is expressed in about 40% of NBs, usually advanced-stage disease. TrkC is expressed in approximately 25% of NBs and is strongly associated with TrkA expression.<sup>49</sup> Although the exact function of the

Trk receptors in the pathogenesis of NB is unknown, they remain attractive therapeutic targets.

Other molecular abnormalities frequently detected in NB include inactivation of caspase 8, expression of CD44, and overexpression of multidrug-resistance genes. Recent studies have demonstrated inactivation of caspase 8, a component of the Fas death-signaling complex, in *MYCN*-amplified NBs.<sup>50</sup> It has been proposed that inactivation of caspase 8 renders tumor cells resistant to apoptotic signals. CD44 is a cell surface glycoprotein that appears to play a role in tumor cell adhesion.<sup>51</sup> In NBs, CD44 expression is inversely correlated with *MYCN* amplification and is undetectable in most disseminated NBs.<sup>52</sup> Multidrug resistance-associated protein (MRP) is an efflux pump whose expression in NB appears to be correlated with *MYCN* amplification and poor prognosis.<sup>53,54</sup> The presence of MRP may explain the common clinical situation in which NBs initially respond well to chemotherapy but subsequently become resistant.

## CLINICAL PRESENTATION

Patients with NB usually present with signs and symptoms that reflect the primary site and extent of disease, although localized disease is often asymptomatic. Because 75% of NB occurs in the abdominal cavity (50% occur in the adrenal gland, 25% occur elsewhere in the retroperitoneum), an abdominal mass detected on physical examination is a common clinical feature, as is the complaint of abdominal pain. Other primary sites of NB include the posterior mediastinum (20%),

the cervical region (1%), and the pelvis (4%) (organ of Zuckerkandl) (Fig. 68-4). Respiratory distress or dysphagia may be a reflection of a thoracic tumor. Altered defecation or urination may be caused by mechanical compression of a pelvic tumor or by spinal cord compression from a paraspinal tumor. Spinal cord compression may also present as an altered gait. A tumor in the neck or upper thorax can produce Horner syndrome (ptosis, miosis, and anhidrosis), enophthalmos, and heterochromia of the iris. Acute cerebellar ataxia has also been observed, characterized by the dancing-eye syndrome, which includes opsoclonus, myoclonus, and chaotic nystagmus. Two thirds of these cases occur in infants with mediastinal primary tumors.<sup>55,56</sup> Additional signs and symptoms that reflect excessive catecholamine or vasoactive intestinal polypeptide secretion include diarrhea, weight loss, and hypertension.

The distribution of NB at presentation by age and stage is shown in Table 68-2. More than 40% of patients have metastatic disease at diagnosis. These patients are often quite ill and have systemic symptoms caused by widespread disease. In older patients, NB has a pattern of metastatic disease in which metastases to the bone marrow, lymph nodes, and bone predominate. The frequency of involvement of distant sites is shown in Table 68-3. These metastases may manifest as bone pain (bone metastases) or anemia (bone marrow infiltration). The brain, spinal cord, heart, and lungs are rare sites of metastases, except with advanced, end-stage disease. Metastatic disease may be also associated with “black eyes” (also referred to as “raccoon eyes”) as a result of retro-orbital venous plexus spread

**Figure 68-4.** Primary sites for neuroblastoma are depicted in this anatomic drawing. (Reprinted from Davidoff AM: Neuroblastoma. In Oldham KT, Colombani PM, Foglia RP, Skinner MA [eds]: Principles and Practice of Pediatric Surgery. Philadelphia, Lippincott Williams & Wilkins, 2005.)

Age	Stage					Total
	I	II	III	IV	IV-S	
<1 yr	10.5	9.5	5.1	9.5	7.5	42.2
≥1 yr	7.1	8.5	8.8	33.3	0	57.8
TOTAL	17.7	18.0	13.9	42.9	7.5

(Fig. 68-5A). This is an ominous physical sign, as is the presence of a limp in children without a history of head or extremity trauma. Infants with metastatic NB may have stage 4S disease, which, by definition, is a localized primary tumor in patients younger than 1 year, with dissemination limited to skin, liver, or bone marrow (<10% of nucleated cells). These patients may present with “blueberry muffin” cutaneous lesions (see Fig. 68-5B), respiratory distress secondary to massive hepatomegaly, and anemia secondary to bone marrow disease. The diagnosis of NB is generally made by histopathologic evaluation of primary or metastatic tumor tissue, or by the demonstration of tumor cells in the bone marrow, together with elevated levels of urinary catecholamines.

## DIAGNOSIS

### Laboratory Findings

#### Lactate Dehydrogenase

Despite its lack of specificity, serum lactate dehydrogenase (LDH) can have great prognostic significance. High serum levels of LDH reflect high proliferative activity or large tumor burden.<sup>57</sup>

**Figure 68-5.** Clinical evidence of metastatic neuroblastoma. **A**, “Raccoon eyes,” characteristic of metastatic neuroblastoma in the posterior orbital venous plexus, are seen in a child with stage 4 disease. **B**, “Blueberry muffin” spot (arrow) in the skin, characteristic of metastatic NB, is seen in the suprapubic region of an infant with a 4S NB. (Courtesy of Stephen Shochat, MD, St. Jude Children’s Research Hospital, Memphis, TN).

Moreover, an LDH level higher than 1500 IU/L appears to be associated with a poor prognosis.<sup>58</sup> Thus, LDH can be used to monitor disease activity or the response to therapy.

#### Ferritin

High levels of serum ferritin (>150 ng/mL) may also reflect a large tumor burden or rapid tumor progression. Elevated serum ferritin is often seen in

	Stage IV-S (%)	Stage IV < 1 year (%)	Stage IV ≥ 1 year (%)	Total (%)
Bone marrow	34.6	57.1	81.3	70.5
Bone	0	48.9	68.2	55.7
Lymph node	8.6	28.6	35.7	30.9
Liver	80.2	53.4	12.9	29.6
Intracranial/orbit	0	25.6	19.6	18.2
Adrenal	6.2	13.5	6.0	7.6
Skin	13.6	8.3	0.9	4.0
Pleura	0	4.5	3.7	3.4
Lung	0	2.3	4.1	3.2
Peritoneum	0	3.8	2.1	2.2
Other	0	3.8	1.6	1.9
Central nervous system	0	0	0.9	0.6

Adapted from Dubois SG, Kalika Y, Lukens JN, et al: Metastatic sites in stage IV and IVS NB correlate with age, tumor biology, and survival. *Pediatr Hematol Oncol* 21:181-189, 1999.

advanced-stage NBs and indicates a poor prognosis.<sup>59</sup> Levels often return to normal during clinical remission.

### Neuron-Specific Enolase

Neuron-specific enolase (NSE) is another useful prognostic marker of advanced-stage NB. The incidence of elevated NSE levels increases with stage.<sup>60</sup> A serum level of NSE greater than 100 ng/mL is associated with a poor outcome. NSE has been reported to correlate with tumor burden,<sup>61</sup> suggesting its reliability as a marker for treatment efficacy.

### Catecholamine Metabolites

NB is characterized by the relatively unique capacity for secretion of catecholamine products, the metabolites of which, vanillylmandelic acid and homovanillic acid can be detected in the urine of more than 90% of patients with NB. Thus, a urine specimen is of clinical value in diagnosing NB and determining the response to therapy. Documentation of elevated urinary catecholamines is required if the diagnosis of NB is being made solely by the identification of neuroblasts in the bone marrow. Urinary levels of these two catabolites can also be used as markers of tumor progression or relapse and can serve as a surrogate prognostic indicator. Random urine samples are preferable to 24-hour urine estimations for younger children.<sup>62</sup>

## Imaging

### Radiography

Chest radiography can be a useful tool for demonstrating the presence of a posterior mediastinal mass, which is usually a thoracic NB in a child. A Pediatric Oncology Group (POG) study demonstrated that a mediastinal mass was discovered on incidental chest radiographs in almost half of the patients with a thoracic NB who had symptoms seemingly unrelated to their tumors (Fig. 68-6A).<sup>63</sup> Abdominal radiography is less often the modality by which an NB is discovered. However, as many as half of abdominal NBs are detectable as a mass with fine calcification.

### Ultrasonography

Although ultrasonography is the modality most often used during the initial assessment of a suspected abdominal mass, its sensitivity and accuracy are less than that of computed tomography (CT) or magnetic resonance imaging (MRI) for diagnosing NB.<sup>64</sup> These latter modalities are generally used after screening with ultrasonography to assist in generating a differential diagnosis and for further anatomic definition once the presence of a mass has been confirmed. Ultrasonography can demonstrate tumor involvement with major vessels and organs. It can provide real-time three-dimensional information regarding their relation to the tumor. Color Doppler imaging can supply further information about vascular encasement within a tumor.<sup>65</sup>

### Computed Tomography

CT remains a useful, commonly used modality for the evaluation of NB (see Fig. 68-6B). It can demonstrate calcification in almost 85% of NBs, and intraspinal extension of the tumor can be determined on contrast-enhanced CT.<sup>66</sup> Overall, contrast-enhanced CT has been reported to be 82% accurate in defining NB extent, with the accuracy increasing to nearly 97% when performed with a bone scan.<sup>67</sup> Although some consider CT to have been supplanted by MRI, others still consider it to be the image modality of choice for patients with NB, especially when used in conjunction with bone scintigraphy.<sup>68</sup>

### Magnetic Resonance Imaging

MRI is becoming the most useful and most sensitive imaging modality for the diagnosis and staging of NB.<sup>69,70</sup> MRI appears to be more accurate than CT for detection of stage 4 disease. The sensitivity of MRI is 83%, and that of CT is 43%. The specificity of MRI is 97%, and that of CT is 88%.<sup>70</sup> Metastases to the bone and bone marrow, in particular, are better detected by MRI, as is intraspinal tumor extension (Fig. 68-7).<sup>70</sup> When considering skeletal metastases alone, MRI and bone scan have been shown to be equivalent.<sup>70</sup> Encasement of major vessels can be better defined by MRI than CT, especially with the use of MR angiography

**Figure 68-6.** A posterior mediastinal/thoracic neuroblastoma (arrows) is seen on chest radiograph (A) and chest CT scan (B).

**Figure 68-7.** These MR images highlight several characteristics of high-risk neuroblastoma. **A**, Bone metastasis in femur (*arrow*). **B**, Bone marrow metastases in the vertebral bodies. **C**, Intraspinal tumor extension (*dotted arrow*). Note displacement of spinal cord (*solid arrow*) from a large tumor (*asterisk*). **D**, Encasement of major intra-abdominal vessels (*arrow* points to the aorta and left renal artery).

(see Fig. 68-7D). MRI in the coronal plane is suitable for routine assessment of the whole body from the neck to the pelvis. Evaluating the utility of whole-body MRI, perhaps performed in conjunction with a functional imaging study such as positron-emission tomography (PET), is being considered for future clinical staging protocols. CT and MRI are not very accurate for staging localized disease. However, the sensitivity of T1- and T2-weighted MR images is 100% for detecting NBs in infants identified by mass screening.<sup>65</sup>

### Scintigraphy

Metaiodobenzylguanidine (MIBG) is transported to and stored in the distal storage granules of chromaffin cells in the same way as norepinephrine. MIBG has been used for scintigraphic imaging of NB. The MIBG scintiscan is the imaging study of choice in evaluating the involvement of bone and bone marrow by NB (Fig. 68-8). This imaging study has largely replaced technetium-99m methylene diphosphonate (<sup>99m</sup>Tc-MDP) bone scans, which are generally inferior to MIBG in detecting NBs with skeletal or extraskelatal involvement. In addition, monitoring MDP-avid NBs by bone scintigraphy often results in false-positive imaging for months after tumor remission. Thus, <sup>99m</sup>Tc-MDP

bone scanning is a second choice if MIBG imaging is not available or does not visualize known disease.<sup>71,72</sup> Iodine-131 (<sup>131</sup>I) or iodine-123 (<sup>123</sup>I) can be used to label MIBG. <sup>123</sup>I-MIBG provides a reduced absorbed radiation dosage and superior spatial resolution.<sup>73</sup> The reported sensitivity of MIBG in the detection of NB with metastases to the bone and bone marrow is 82%, and the specificity is 91%.<sup>74</sup> Primary tumors and lymph node metastases are also detectable. MIBG can demonstrate more sites of tumor involvement in the bone and bone marrow than either bone scintigraphy or standard radiography.<sup>74</sup> However, false-negative MIBG scans have been seen in cases in which the bone scintigraphy was positive.<sup>72</sup>

### Bone Marrow Examination

Bone marrow biopsy has been regarded as a routine and important method for detecting bone marrow involvement with NB. Both aspiration and biopsy should be performed, although the latter has better diagnostic value. To collect more accurate information, taking specimens from multiple sites is recommended. Immunohistochemical staining with antibodies such as antiganglioside G<sub>D2</sub>, S-100, NSE, and ferritin is also useful for reducing the number of false-negative

**Figure 68-8.** Imaging of neuroblastoma with MIBG scintigraphy. **A**, Scan obtained at presentation of a patient with metastatic NB. There is diffusely abnormal activity throughout much of the skeleton including the proximal right humerus, both proximal and distal femurs, and the proximal right tibia. There is also a focus of activity in the right upper retroperitoneum at the site of the primary tumor. **B**, Scan obtained of the same patient after completion of therapy shows no scintigraphic evidence of MIBG-avid NB.

cases.<sup>75</sup> Because a bone marrow biopsy is invasive and painful, noninvasive alternatives are being tested. Studies have suggested the superiority of MRI<sup>76</sup> and MIBG scintigraphy<sup>77</sup> over bone marrow biopsy in detecting bone marrow infiltration by NB. However, the specificity of these modalities requires further evaluation.

## Differential Diagnosis

Making a correct clinical diagnosis of NB can be difficult because patients present with such diverse symptoms. For example, acute cerebellar ataxia with opsoclonus-myoclonus can be mistaken for a primary neurologic disease. Widespread bone involvement may resemble non-neoplastic bone disease such as osteomyelitis or rheumatoid arthritis or be associated with systemic inflammatory changes. Symptoms referable to vasoactive intestinal polypeptide secretion (i.e., diarrhea) can be misinterpreted as symptoms of an enteric infection or inflammatory bowel disease.

Histologically, undifferentiated, small blue round cell NB may be hard to distinguish from rhabdomyosarcoma, primitive neuroectodermal tumors, Ewing sarcoma family of tumors, or non-Hodgkin lymphoma. Use of a panel of specific antibodies,<sup>76</sup> as mentioned previously, can facilitate histologic differentiation.

## Tumor Staging

In the past, two primary systems have been used to stage NB. These were the Evans classification, used by the former Children's Cancer Group (CCG) institutions,<sup>78</sup> and the St. Jude Children's Research Hospital classification, used by the former POG institutions.<sup>79</sup> The Evans classification emphasized tumor extent, as determined radiographically. In particular, it was important whether the tumor extended beyond the organ or structure of origin, and if it crossed the midline. The St. Jude classification relied on surgicopathologic staging, emphasizing lymph node involvement. Both staging systems had prognostic value, but differences and discrepancies between the two systems presented obstacles to population studies of NB. In an attempt to incorporate elements from both of these widely accepted systems and to have a single staging system, the International NB Staging System (INSS) was created (Table 68-4).<sup>71</sup> Evaluation of the primary tumor and involvement of metastatic sites in the INSS system depends largely on imaging studies (CT or MRI) (Table 68-5), although pathologic involvement of lymph nodes and bone marrow continue to be

**Table 68-4** International Neuroblastoma Staging System Criteria

Stage	Definition
1	Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (nodes attached to and removed with the primary tumor may be positive)
2A	Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically
2B	Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor. Enlarged contralateral lymph nodes must be negative microscopically.
3	Unresectable unilateral tumor infiltrating across the midline,* with or without regional lymph node involvement
	or
	Localized unilateral tumor with contralateral regional lymph node involvement
	or
	Midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement
4	Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, or other organs (except as defined for stage 4S).
4S	Localized primary tumor (as defined for stage 1, 2A, or 2B), with dissemination limited to skin, liver, and bone marrow† (limited to infants younger than 1 yr)

\*The midline is defined as the vertebral column. Tumors originating on one side and crossing the midline must infiltrate to or beyond the opposite side of the vertebral column.

†Marrow involvement in stage 4S should be minimal (i.e., <10% of total nucleated cells identified as malignant on bone marrow biopsy or on marrow aspirate). More extensive marrow involvement would be considered to be stage 4. The metaiodobenzylguanidine scan (if performed) should be negative in the marrow.

Table 68-5 International Neuroblastoma Staging System Staging Investigations	
Recommended Tests	
<b>Tumor Site</b>	
Primary tumor	CT or MRI with 3D measurements; MIBG scan, if available.
<b>Metastatic Sites</b>	
Bone marrow	Bilateral posterior iliac crest marrow aspirates and trephine (core) bone marrow biopsies required to exclude marrow involvement. A single positive site documents marrow involvement. Core biopsies must contain $\geq 1$ cm of marrow (excluding cartilage) to be considered adequate.
Bone	MIBG scan; $^{99m}\text{Tc}$ scan required if MIBG scan is negative or unavailable, and plain radiographs of positive lesions are recommended.
Lymph nodes	Clinical examination (palpable nodes), confirmed histologically CT scan for nonpalpable nodes (3D measurements)
Abdomen and liver	CT or MRI with 3D measurements
Chest	Anteroposterior and lateral chest radiographs CT and MRI necessary if chest radiograph is positive or if abdominal mass/nodes extend into chest

MIBG, metaiodobenzylguanidine.

important components. MIBG scanning is also recommended as part of the initial evaluation of new patients and, subsequently, for monitoring tumor response to therapy.

One drawback to the INSS is that the degree of initial surgical resection can have a significant impact on the staging of a tumor. Hence, the aggressiveness and skill of a surgeon can influence the stage and, ultimately, the therapy given to a particular patient. For example, disease in which there is a tumor that infiltrates across the midline (stage 3) but is completely resected, would be considered stage 1, and no further therapy would be given. In order to have a more uniform system for staging disease at presentation, children with localized NB who are enrolled on a COG protocol will have “image-defined risk factors” assessed by central review of diagnostic imaging studies. This will be performed to determine whether these factors are more prognostically relevant than INSS staging for patients with localized NB. These image-defined risk factors (Table 68-6) were proposed by the European International Society of Pediatric Oncology Neuroblastoma Group and generally reflect the presence of encasement of major vessels or nerves or the infiltration of adjacent organs/structures by locoregional tumor. In 2005, a report noted that the presence of one or more of these image-defined surgical risk factors was associated with a lower complete resection rate and a greater risk of surgery-related complications when attempting an initial resection of a localized NB.<sup>80</sup>

## BIOLOGICALLY BASED RISK GROUPS AND THERAPY

As previously mentioned, one of the notable characteristics of NB is the substantial heterogeneity of the disease, which ranges from spontaneous regression or maturation, even without therapy, to a highly malignant, aggressive phenotype poorly responsive to current intensive, multimodal therapy. Increasing evidence indicates that the biologic and molecular features of NB are highly predictive of clinical behavior. Therefore, NB has served as a paradigm for phenotypic risk assessment and treatment assignment.

Current treatment of children with NB is based not only on stage but also on risk stratification that takes into account both clinical and biologic variables predictive of disease relapse. The two most important clinical variables appear to be the child’s age at the time of diagnosis<sup>81</sup> and the stage<sup>82</sup> at diagnosis. The most powerful biologic factors at this time appear to be *MYCN* status,<sup>31,33</sup> ploidy<sup>83</sup> (for infants), and histopathologic classification.<sup>21</sup> However, additional biologic and molecular variables continue to be evaluated. Two variables, the allelic status at chromosomes 1p36 and 11q23, are currently being used to define the duration of therapy for certain patients. Taken together, these variables

Table 68-6 Image-Defined Risk Factors for Primary Resection of Localized Neuroblastoma

### Neck

1. Tumor encasing major vessel(s) (e.g., carotid artery, vertebral artery, internal jugular vein)
2. Tumor extending to base of skull
3. Tumor compressing the trachea
4. Tumor encasing the brachial plexus

### Thorax

1. Tumor encasing major vessel(s) (e.g., subclavian vessels, aorta, superior vena cava)
2. Tumor compressing the trachea or principal bronchi
3. Lower mediastinal tumor, infiltrating the costovertebral junction between T9 and T12 (may involve the artery of Adamkiewicz supplying the lower spinal cord)

### Abdomen

1. Tumor infiltrating the porta hepatis and/or the hepatoduodenal ligament
2. Tumor encasing the origin of the celiac axis and/or the superior mesenteric artery
3. Tumor invading one or both renal pedicles
4. Tumor encasing the aorta and/or vena cava
5. Tumor encasing the iliac vessels
6. Pelvic tumor crossing the sciatic notch

### Dumbbell tumors with symptoms of spinal cord compression: Any location

### Infiltration of adjacent organs/structures: Diaphragm, kidney, liver, duodenopancreatic block, and mesentery

**Table 68-7** Children's Oncology Group Risk Stratification for Children with Neuroblastoma

Risk Stratification	INSS Stage	Age	Biology
<i>Low</i>			
Group 1	1	Any	Any
	2A/2B (>50% resected)	Any	MYCN-NA, any histology/ploidy
	4S	<365 days	MYCN-NA, FH, DI > 1
<i>Intermediate</i>			
Group 2	2A/2B (<50% resected or biopsy only)	Birth-12 years	MYCN-NA, any histology/ploidy*
	3	<365 days	MYCN-NA, FH, DI > 1*
	3	>365 days to 12 years	MYCN-NA, FH*
Group 3	4S (symptomatic)	<365 days	MYCN-NA, FH, DI > 1*
	3	<365 days	MYCN-NA, either UH or DI = 1*
	4	<365 days	MYCN-NA, FH, DI > 1*
	4S	<365 days	MYCN-NA, either UH or DI = 1*; or unknown biology
Group 4	4	<365 days	MYCN-NA, either DI = 1 or UH
	3	365 to < 547 days	MYCN-NA, UH, any ploidy
	4	365 to < 547 days	MYCN-NA, FH, DI > 1
<i>High</i>			
	2A/2B, 3, 4, 4S	Any	MYCN-amplified, any histology/ploidy
	3	≥547 days	MYCN-NA, UH, any ploidy
	4	365 to > 547 days	MYCN-NA, UH or DI = 1
	4	>547 days	Any

\*If tumor contains chromosomal 1p LOH or unbalanced 11q LOH, or if data are missing, treatment assignment is upgraded to next group. MYCN-NA, MYCN not amplified; FH, favorable histology; UH, unfavorable histology; DI, DNA index.

currently define the COG risk stratification (Table 68-7) for therapeutic approach. On the basis of these clinical and biologic prognostic variables, infants and children with NB are categorized into three risk groups predictive of relapse: low, intermediate, and high risk. The probability of prolonged disease-free survival for patients in each group is more than 95%, more than 90%, and less than 30%, respectively. Other factors such as chromosome 17q gain, caspase 8 inactivation, and TrkA/B expression are still being evaluated and may help further refine risk assessment in the future.

### Low-Risk Disease

This classification includes all patients with stage 1 disease or patients with stage 2A/2B disease that is not MYCN amplified and in which the tumor has undergone a greater than 50% resection. Also included in the low-risk group are infants with stage 4S disease who have favorable histology, without MYCN amplification, and a DNA index greater than 1. The treatment of patients with low-risk disease is generally surgical resection alone, even in the presence of microscopic residual disease (stage 1), gross residual disease (stage 2A), or gross residual disease with ipsilateral lymph node involvement (stage 2B), if the tumor has favorable biologic characteristics (i.e., is without MYCN amplification). Infants with stage 4S disease who are not experiencing substantial symptoms may undergo an initial biopsy and observation only if the tumor has favorable biologic factors.

This “surgery alone” treatment plan for patients with low-risk disease was established on the basis

of the prior experiences of both CCG and POG. The POG 8104 study found that 2-year survival was 89% for patients with POG stage A (INSS stage 1) disease despite microscopic residual disease, when patients were treated with surgery alone.<sup>84,85</sup> In a similar cohort of patients, the CCG 3881 study found 3-year EFS and overall survival to be 94% and 99%, respectively, for patients with Evans stage I disease.<sup>86</sup> That study also found that although patients with Evans stage II disease (similar to INSS 2A/2B) had a 3-year EFS of 81% irrespective of the extent of surgical resection and subsequent treatment, the overall survival for these patients was 99%.<sup>86</sup> This finding suggests that even if these patients experience disease relapse, most can be salvaged with additional therapy. Therefore, neither adjuvant chemotherapy nor radiation therapy appears to be necessary for the initial management of most patients with low-risk disease.

On the basis of these data, a group-wide COG study (P9641) was conducted from 1998 to 2006 to evaluate primary surgical therapy for biologically defined low-risk NB. The overall strategy of this study was to treat patients with low-risk NB with surgery and supportive care only. Adjuvant therapy was given only when less than 50% of the tumor was resected or when symptoms that were life- or organ-threatening developed. A probability of 3-year survival more than 95% was predicted for these patients with low-risk disease. Although the final published results from this study are still pending, the current recommendation continues to be that patients with low-risk NB are treated with surgery alone.

## Intermediate-Risk Disease

This classification includes patients age birth to 12 years with stage 2A/2B disease that is not *MYCN* amplified and in whom the tumor has undergone less than 50% resection (or biopsy only), patients age birth to 1.5 years with stage 3 disease whose tumors are not *MYCN* amplified, patients age 1.5 to 12 years with stage 3 disease whose tumors are not *MYCN* amplified and are of favorable histology, infants with stage 4 disease whose tumors are not *MYCN* amplified, and patients age 1 to 1.5 years with stage 4 disease whose tumors are not *MYCN* amplified and have favorable histology and a DNA index greater than 1. Also included in this group are infants with stage 4S disease who are symptomatic from their tumor and the tumor biologic characteristics are either of unfavorable histology or the DNA index equals 1, or if no tissue was obtained at presentation for evaluation.

Intermediate-risk NB was initially defined through the analyses of CCG 3881 and POG 8742/9244 protocols. Based on these data, a group-wide COG study (A3961) was conducted from 1998 to 2006 to further refine therapy for patients with intermediate-risk disease. The overriding aim of this study was to maintain or improve survival while minimizing both acute and long-term morbidity in this group of patients. Patients received four of the most active agents for NB therapy: cyclophosphamide, doxorubicin, carboplatin, and etoposide, given for either four cycles (favorable biology) or eight cycles (unfavorable biology). Cycles were given every 3 weeks. This regimen was selected to maintain the dose intensity of CCG 3881 but to decrease therapy duration and cumulative doses, thereby reducing morbidity. Radiation therapy was not given unless there was progressive disease or an unresectable primary tumor with unfavorable prognostic features at the end of chemotherapy. Although the final published results from this study are still pending, 3-year event-free and overall survival appear excellent, at more than 85% and more than 95%, respectively.

The current COG protocol (ANBL0531), which opened in October 2007, seeks to further refine the minimal therapy needed to achieve these excellent outcomes (Fig. 68-9). As such, patients with favorable clinical and biologic factors will receive a further reduction in therapy. However, those patients in whom there is loss of heterozygosity (LOH—loss of one of the two normally paired chromosomal regions) at chromosome 1p or 11q (unbalanced) will not be eligible for this dose reduction because these events have been shown to be independently associated with decreased progression-free survival in patients with low- and intermediate-risk disease.<sup>39</sup> As with protocol A3961, patients will receive cycles of cyclophosphamide, doxorubicin, carboplatin, and etoposide given every 3 weeks. The duration of therapy (i.e., the number of cycles) will depend on which of three intermediate-risk groups the patient is enrolled, with group stratification again being based on clinical and biologic risk factors.<sup>87-89</sup> For almost all intermediate-risk patients, regardless of group (except group 4, stage 4 infants), this represents

a reduction in therapy,<sup>90,91</sup> either shortening the duration (groups 2 and 3) or downgrading from high-risk therapy (group 4) (see Table 68-7).

The overall surgical goal in intermediate-risk patients is to perform the most complete tumor resection possible, consistent with preservation of full organ and neurologic function. This may necessitate leaving residual disease adherent to critical anatomic structures. If a primary tumor is judged by the surgeon to be unresectable, a diagnostic biopsy is generally obtained and chemotherapy initiated. Delayed surgery is performed after the prescribed number of cycles, as dictated by the group assignment. A reduction in surgical therapy is being evaluated for infants with stage 4S disease because it is no longer required that they undergo resection of their primary tumor. In addition, if they are too unstable at presentation, it is no longer required that they undergo an initial biopsy to be eligible for enrollment in the current COG study.

Radiation will be administered only to symptomatic intermediate-risk patients when there is a risk of organ impairment due to tumor bulk that does not respond to initial chemotherapy. This will most often be encountered, albeit rarely, in infants with stage 4S disease, and in patients with epidural disease and symptoms of spinal cord compression.

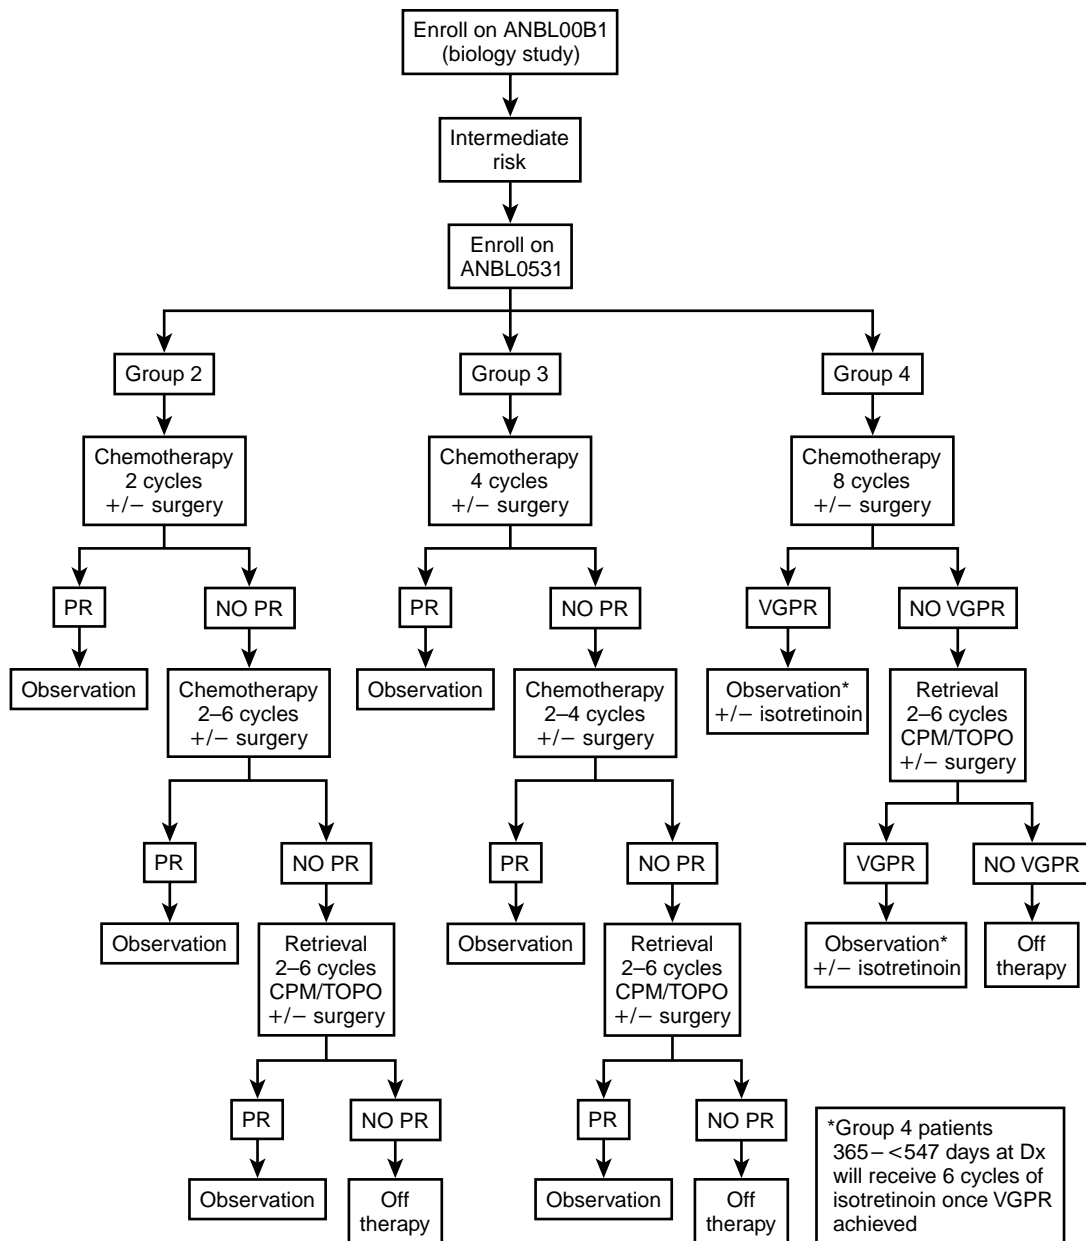

Patients older than 12 years of age are excluded from ANBL0531 because there is increasing evidence that adolescent patients with localized tumors have an indolent clinical course but ultimately have an unfavorable outcome.<sup>92,93</sup>

## High-Risk Disease

This classification includes patients of any age with *MYCN*-amplified tumors unless the tumor is localized and is grossly resected with ipsilateral lymph nodes being uninvolved (stage 1), patients older than 1.5 years with stage 3 tumors who have unfavorable histology, patients 1 to 1.5 years of age with stage 4 disease who have either unfavorable histology or a DNA index equal to 1, and patients older than 1.5 years with stage 4 disease regardless of tumor biology. Although not a part of the risk classification schema, the metastatic pattern of NB correlates not only with age but also with EFS.<sup>94</sup>

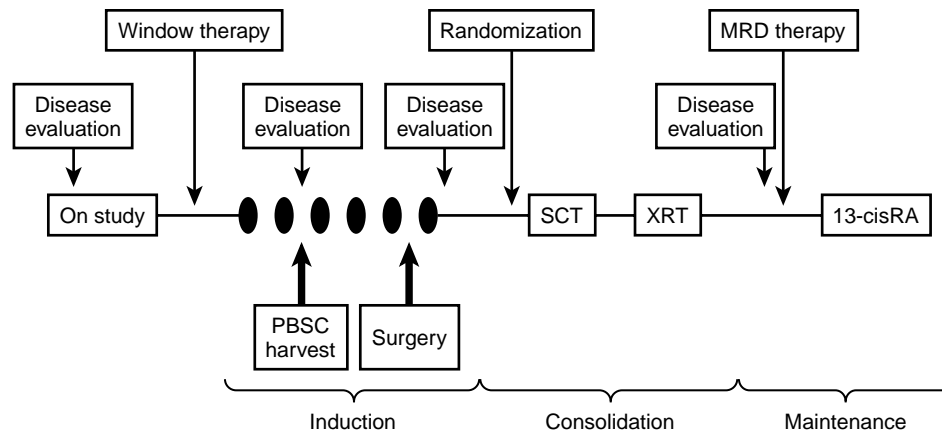

For patients with advanced NB, chemotherapy has been the mainstay of multimodality treatment. NB is generally a chemotherapy-sensitive tumor, and multiple-agent chemotherapy is usually effective in achieving a complete, or at least partial, response in older children with disseminated disease. However, this approach rarely effects a cure. The vast majority of these patients ultimately succumb to chemotherapy-resistant disease, despite the use of increasingly intensive chemotherapy. Several general principles of chemotherapy have been applied when treating patients with high-risk NB (as well as most of the other pediatric malignancies):

1. Combination chemotherapy is used to overcome drug resistance to individual agents and to achieve antitumor synergy using agents with different mechanisms of action.

**Figure 68-9.** Schema for intermediate-risk neuroblastoma chemotherapy on Children's Oncology Group trial ANBL0531. PR, partial response; VGPR, very good partial response; CPM, cyclophosphamide; TOPO, topotecan.

- Chemotherapeutic agents are administered at maximal dose intensity (the maximum tolerated dose [MTD] in the shortest time interval), because most of these drugs have a steep dose-response curve. This is why dose reduction due to organ dysfunction can have a potentially detrimental influence on disease outcome and why the risks and benefits of aggressive surgery should be carefully considered. The efficacy of MTD scheduling has been questioned recently, however, by the recognition of the importance of angiogenesis inhibition as an antitumor strategy. The recovery period that follows an MTD may permit recovery of the endothelial cells involved in the neovascularization required to support tumor growth and spread, whereas
  - continuous, low-dose therapy more effectively inhibits angiogenesis, which in turn inhibits tumor growth, even when the tumor cells are resistant to the direct effects of a chemotherapeutic agent.<sup>95</sup>
  - Chemotherapy appears to be most effective when administered in the adjuvant setting to patients who have minimal residual disease. This is an extension of the Goldie-Coldman hypothesis, which predicts that the development of drug resistance is the result of a random genetic event that is less likely to occur when treating minimal residual disease with simultaneous administration of all active drugs.<sup>96</sup>
- The general approach to treating patients with high-risk NB has included intensive induction chemotherapy,

**Figure 68-10.** General schema of multimodal therapy for treating children with high-risk neuroblastoma. Variations include the testing of new drugs or combinations during “window therapy,” the use of different “induction” regimens, randomizing patients to receive different consolidation therapy, and testing different approaches for treating minimal residual disease. Patients generally undergo PBSC harvest after two cycles of induction therapy and undergo delayed resection of the primary tumor (and locoregional disease) after five cycles of induction therapy. SCT, stem cell transplant; XRT, radiation therapy; MRD, minimal residual disease; RA, retinoic acid; PBSC, peripheral blood stem cell.

myeloablative consolidation therapy with stem cell rescue, and targeted therapy for minimal residual disease. Stem cell harvest is typically performed after the first two cycles of induction therapy, and resection of the primary tumor and bulky metastatic sites is attempted after the fifth cycle (Fig. 68-10). The CCG 3891 protocol enrolled patients with high-risk NB between 1991 and 1996. This study was designed to assess whether myeloablative therapy, in conjunction with autologous BMT, improved EFS when compared with chemotherapy alone, and whether subsequent treatment with 13-*cis*-retinoic acid, a differentiating agent, would further improve EFS.<sup>97</sup> The results from this double-randomization study demonstrated that the 3-year EFS was significantly better in patients who underwent BMT during the first randomization (34%) than in those who did not (22%;  $P = .034$ ). In the second randomization, those who received 13-*cis*-retinoic acid after BMT experienced a significantly better 3-year EFS (46%) than those who did not receive the retinoid (29%,  $P = .027$ ). Unfortunately, the long-term survival advantage for these patients is becoming less apparent. Nevertheless, autologous stem cell transplantation and 13-*cis*-retinoic acid are now part of most current high-risk NB protocols.

The first cooperative group high-risk NB protocol (COG A3973) opened in February 2001. It began with intensified induction therapy based on an analysis suggesting that increased dose intensity may improve remission rates and survival in these patients.<sup>98</sup> The induction therapy chosen, a dose-intensive combination of cyclophosphamide, vincristine, and doxorubicin alternating with cisplatin and etoposide, was based on the Memorial Sloan-Kettering Cancer Center (MSKCC) N7 protocol, which had a reported rate of remission of 90%.<sup>99</sup> Although the toxicity of the regimen was substantial, including the development of therapy-related myelodysplastic syndrome (MDS) and acute myelogenous leukemia (AML), the myelosuppression, fever, neutropenia, and mucositis were not

dose limiting. After the sixth cycle of induction chemotherapy, patients were re-evaluated. Those with at least a partial response continued on the protocol and received myeloablative consolidation therapy (based on the results of CCG-3891) with stem cell support. Those patients not eligible for myeloablative therapy received maintenance therapy using topotecan and cyclophosphamide. Patients eligible to receive myeloablative therapy were then randomized to receive either unpurged or purged autologous stem cells. The rationale for this randomization and primary study question was that, although there has been some evidence that tumor cells contaminating reinfused autologous stem cells contribute to tumor relapse in patients with NB, it is uncertain whether the removal of the tumor cells by purging the stem cell product would influence relapse rates.<sup>100,101</sup> This protocol was closed early (March 2006), however, because an interim analysis showed no difference in outcome for children who received either the purged or the unpurged stem cell product.

The current COG high-risk NB protocol (ANB0532) opened in November 2007. Its primary goal is to test whether further intensification of myeloablative therapy will improve the cure rate. Randomization to either one myeloablative consolidation with a carboplatin/etoposide/melphalan preparative regimen or two myeloablative consolidations, in which the initial regimen includes thiotepa and cyclophosphamide, will occur at the completion of induction chemotherapy.

Another aim of this study is to determine whether additional radiation therapy delivered to gross residual disease improves local control. Four to 6 weeks after stem cell transplantation, radiation therapy is administered to the region of the primary tumor site, including involved adjacent lymph nodes. The target volume is the area of residual disease, which is determined radiographically, after induction chemotherapy but prior to delayed surgical resection, with an additional 1.5-cm margin added, even if a complete resection

**Table 68-8** International Neuroblastoma Staging System Response Criteria

Response	Primary Tumor	Metastatic Sites*
CR	No tumor	No tumor; catecholamines normal
VGPR	Decreased by 90%-99%	No tumor; catecholamines normal; residual <sup>99m</sup> Tc bone changes allowed
PR	Decreased by > 50%	All measurable sites decreased by > 50% Bones and bone marrow: number of positive bone sites decreased by > 50%; no more than one positive bone marrow site allowed
MR	No new lesions	>50% reduction of any measurable lesion (primary or metastases) with < 50% reduction in any other; < 25% increase in any existing lesion
NR	No new lesions	<50% reduction but < 25% increase in any existing lesion
PD	Any new lesion	Increase of any measurable lesion by > 25%; previous negative marrow positive for tumor

\*One positive marrow aspirate or biopsy allowed for PR if this represents a decrease from the number of positive sites at diagnosis. CR, complete response; MR, minimal response; NR, no response; PD, progressive disease; PR, partial response; VGPR, very good partial response.

was ultimately achieved. Sites of persistent active metastatic disease prior to stem cell transplantation (i.e., positive sites on MIBG scan or those that do not show diminished enhancement on serial bone scans) are irradiated at the same time and with the same dose as the primary site.

Total-body irradiation is often used as part of the myeloablative therapy for bone marrow infusion.<sup>102</sup> In a review of CCG 3891, it was found that, in combination with external-beam radiation to the primary tumor site, the addition of 10 Gy of total-body irradiation as a component of high-dose chemotherapy with stem cell rescue improved local control compared with conventional chemotherapy without total-body irradiation.<sup>103</sup> Results from this study also suggested a dose-response relationship for local radiation therapy with limited short-term toxicity. Based on these results, patients treated on ANB0532 whose primary site has achieved a complete response at the end of induction therapy will receive 21.6 Gy to the site of primary locoregional disease while areas with gross residual disease will be treated with an additional boost of 14.4 Gy (36 Gy total).

A third aim of ANB0532 is to test the use of a dose-intensive topotecan-containing induction regimen, substituting two cycles of dose-intensive cyclophosphamide and topotecan for the first two cycles of induction used in COG A3973. Secondary surgical objectives embedded in this protocol include (1) a determination of whether resection completeness is predictive of local control rate or EPS, (2) a prospective tabulation of the complications related to efforts at local control, and (3) a description of the neurologic outcomes in patients with paraspinal primary tumors.

### Assessment of Therapeutic Response

Precise evaluation of the therapeutic response of primary and metastatic sites to treatment is essential for confirming the efficacy of therapy, predicting disease outcome, and planning the next therapeutic modality. The International NB Response Criteria<sup>71</sup> was presented in 1988 and has since been revised (Table 68-8).<sup>18</sup> The determination of response should be based on the

volume of the primary tumor and large metastases measured by three-dimensional imaging such as CT or MRI. Normalization of urinary catecholamines is included in the determination of the response of metastatic sites. Whether MIBG scans provide useful assessment of therapeutic response is currently being evaluated.

### Other Treatment Approaches to High-Risk Neuroblastoma

In addition to the group-wide COG protocol, other institutional protocols for treating patients with high-risk NB are being tested. In addition, several universities and children's hospitals have formed a consortium funded by the National Cancer Institute to test promising new therapies for NB. The New Approaches to NB Therapy (NANT) consortium was formed to organize closely collaborating investigators whose laboratory programs are developing novel therapies for high-risk NB. NANT currently conducts clinical trials that test new drugs and new combinations of drugs against high-risk NB. Those with promising results will be considered for more extensive national testing.

### Recurrent High-Risk Neuroblastoma

Patients with recurrent high-risk NB have a uniformly dismal outcome. Several group-wide, NANT, and institutional phase I and phase II trials are currently open and are testing new treatment strategies for these patients. However, although a few patients with relatively limited initial disease can be cured with salvage therapies at the time of relapse, disease recurrence portends a dismal outlook for most stage 4 patients (<5% survival). Radiation therapy can be used for the treatment of refractory sites of metastatic disease and for palliation of painful sites of metastatic disease, with some success in providing pain relief and disease control.<sup>104</sup>

### Future Approaches

In an attempt to improve the poor prognosis for patients with high-risk NB, newer chemotherapeutic agents continue to be tested as single agents in patients with

refractory or recurrent disease, or in phase II “upfront window” trials involving patients with previously untreated high-risk NB. This latter approach may give a more accurate assessment of a drug’s efficacy because these patients are not already chronically debilitated by extended treatment. It is important to note that, at present, there is no evidence of worsening response rates to standard multidrug induction chemotherapy in children treated with an initial phase II window designed to assess the anti-NB efficacy and toxicity of a new drug.<sup>105,106</sup> As more information regarding diagnostically and prognostically useful genetic markers for NB become available, therapeutic strategies will change accordingly. There may ultimately be individualized treatment regimens for children with NB based on the molecular biologic profile of a patient’s tumor. In addition, this profiling will not only identify patients whose tumors show a more aggressive biologic profile but also identify patients with tumors that do not have this aggressive biologic profile. Regimen toxicity, including late effects of therapy, is particularly important in the pediatric population. Therefore, treatment will be designed so that patients with biologically high-risk tumors receive intensified regimens and patients with biologically low-risk tumors benefit from the lower toxicity of less intensive therapy while maintaining cure rates.

## SURGICAL TREATMENT

Complete resection of a tumor offers definitive therapy with generally excellent outcome for patients with localized NB. The value of complete tumor removal may be overestimated, however, because of the possibility that localized NB may undergo spontaneous maturation or even regression. The role of surgery is even less clear in the curative treatment of patients with high-risk NBs. Unfortunately, more than half of patients with NB present with advanced local or metastatic disease, which requires intensive multimodal therapy in addition to surgery. It is crucial that surgeons consider the heterogeneous nature of NB and the molecular and biologic characteristics associated with good or bad prognoses when determining the role of surgery for any specific case.

### Localized Tumors

Most localized NBs have favorable biologic features and are successfully treated with operation alone.<sup>84,91,107-110</sup> In addition, studies suggest that a subset of localized tumors will spontaneously regress and that these patients can be observed without any treatment.<sup>111-114</sup> Local recurrences, when they rarely occur, can generally be managed surgically.<sup>115</sup> Thus, complete resection of a localized NB may be the only therapy required for some patients.<sup>116</sup> However, currently, biopsy of ipsilateral and contralateral lymph nodes is required for accurate staging, risk assessment, and therapy assignment for patients with an abdominal primary site. Lymph node evaluation is less important for patients with a thoracic primary site. Biopsy of contralateral lymph

nodes is rarely feasible in patients with a thoracic primary tumor. Moreover, evaluation of ipsilateral lymph nodes, which may potentially influence staging, rarely changes the risk classification and treatment. Regardless of the presence of microscopic or even gross residual disease with positive ipsilateral lymph nodes, no further therapy is given to patients with low-risk disease. Therefore, all patients with INSS stage 1 tumors, stage 2A/2B tumors without *MYCN* amplification (and > 50% resection), or stage 3 tumors of the midline that undergo gross total resection with negative lymph nodes are treated with surgical resection alone.

Several reports have indicated that the extent of surgery for localized disease is a significant predictor of outcome. One study reported a 2-year disease-free survival of 93% in patients with nonmetastatic disease and complete tumor resection, as compared with 54% for those undergoing a subtotal resection.<sup>117</sup> Another study reported a 77% long-term survival for patients with Evans stage III disease who had a complete resection at some point during therapy, compared with 28% long-term survival for those unable to have a complete resection.<sup>118</sup> The MSKCC experience suggests that for all patients with nonmetastatic disease and a single copy of *MYCN*, surgery alone is adequate treatment, even if residual disease is present or locoregional lymph nodes are positive.<sup>119</sup>

In most instances, performing a biopsy before resection is unnecessary in patients with localized tumors that are likely to be NB, appear to be easily resectable (based on diagnostic imaging), and have had a negative metastatic workup. This is especially true for those patients whose primary site is thoracic because the patients with low-risk disease will not receive adjuvant therapy. Even for patients with intermediate- or high-risk disease who will receive adjuvant chemotherapy, earlier removal of bulky disease may be feasible and may potentially decrease the likelihood of developing drug-resistant tumor clones.<sup>120</sup> However, primary resection in these patients should be attempted only if it can clearly be accomplished safely, without injury to adjacent organs or blood vessels and without delaying the initiation of chemotherapy. In all cases, if there is any question of resectability, a pre-resection risk determination should be performed because this may influence the surgical plan. An assessment of the *MYCN* status can be performed on a minimal amount of tumor tissue, including tumor cells in the bone marrow. *MYCN*-amplified tumors, unless stage 1, are all high risk. To determine the histopathologic status, the COG protocols currently require 1 cm<sup>3</sup> of tissue. Therefore, an “open” tumor biopsy (or potentially a laparoscopic biopsy) is recommended, as opposed to a percutaneous core biopsy, which generally provides smaller samples. However, the only situation in which histopathology is important for accurate determination of tumor biology in a patient with localized disease is in a child between 1.5 to 12 years of age with an unresectable tumor that infiltrates across the midline (stage 3). In this circumstance, the histopathology will distinguish between intermediate- and high-risk disease (if the tumor is not *MYCN* amplified).

As mentioned previously, an alternate approach to treating patients with localized NB is taken at MSKCC. At that institution, all patients with nonmetastatic disease are treated initially with operation alone. Adjuvant therapy is reserved for patients who suffer a relapse. This approach is supported by the high success rate of salvage therapy using intensive chemotherapy and antiganglioside G<sub>D2</sub> immunotherapy.<sup>121</sup>

### Locoregional Disease in Patients with Metastatic Disease

More than 80% of patients who are older than 1 year of age and have metastatic NB will have tumor in the bone marrow.<sup>122</sup> The presence of disseminated NB is often suggested by a patient's ill appearance, anemia, "raccoon eyes," bone pain, or a limp and can be confirmed by demonstrating neuroblasts in the bone marrow and elevated levels of catecholamines in the urine. Therefore, most of these patients can have the diagnosis of NB confirmed by bone marrow aspirate/biopsy and the demonstration of elevated catecholamines in the urine. A surgical biopsy is required only if there is no involvement of the bone marrow, if the histopathology of the tumor is important in determining the risk classification (the patient is between 1 and 1.5 years of age with disseminated disease, and tumor cells in the bone marrow are neither *MYCN* amplified or have a DNS index = 1), or to obtain sufficient tissue to support biologic studies. Most patients with disseminated disease should receive neoadjuvant chemotherapy before attempted resection of the primary tumor and involved locoregional lymphadenopathy.

### Delayed Surgical Intervention of Locoregional Disease

The role of surgery in the management of children with high-risk NB is controversial. Several reports have suggested that patients with INSS stage 3 or 4 disease who undergo gross total resection of their primary tumor and locoregional disease experience improved local tumor control and increased overall survival. However, other reports have not confirmed these observations. In one study, patients with stage 4 disease who were older than 1 year at the time of diagnosis had an improved outcome with gross total resection of the primary tumor, though the influence of resection was not independent of chemotherapy intensity.<sup>123</sup> A more recent paper from the same group provided further data suggesting that local control and overall survival are correlated with gross total resection of the primary tumor in high-risk NB and should be the goal in current clinical trials.<sup>124</sup> Similarly, another study supported the use of aggressive surgery for patients with metastatic disease in an attempt to improve outcome.<sup>118</sup> Also, improved survival in patients with metastatic disease who underwent complete resection of the primary tumor during delayed second-look procedures has been found.<sup>125</sup> Finally, a large meta-analysis of the outcomes for patients with stage 3 and 4 disease and a review of the impact of the extent of primary

site resection on EFS, overall survival, and local recurrence in high-risk NB for patients treated on COG A3973 were both presented at the recent Advances in Neuroblastoma Meeting (Chiba, Japan, 2008). A 90% or greater resection was found to be associated with a significant decrease in local recurrence, with a slight but sustained improvement in both event-free and overall survival, although this was not statistically significant.

In contrast, several studies have found that the extent of surgical resection does not affect the final outcome.<sup>126,127</sup> Another study found that the extent of surgical resection affected only certain subgroups of patients with high-risk disease.<sup>128</sup> In addition, substantial complication rates have also been reported after aggressive attempts at removing all gross tumor from the retroperitoneum.<sup>129</sup> Another report noted that the outcome for patients with stage 4 NB depended more on the biologic characteristics of the tumor than on the extent of surgical resection.<sup>130</sup> This conclusion is further highlighted by the results of the CCG 3881 study, which showed that, at least in infants with stage 4 disease and single-copy *MYCN* tumors, survival was excellent, regardless of whether gross total resection (3-year EFS, 91%) or incomplete resection (3-year EFS, 94%) was performed. However, survival was poor if the tumor was *MYCN* amplified, again, regardless of the extent of surgery. Three-year EFS after total resection was 14%, and 3-year EFS after incomplete resection was 10% ( $P = .18$ ).<sup>131</sup> The role of cytoreduction by surgical resection is unclear. However, resection of as much gross tumor as possible in patients who receive autologous or allogeneic BMT in combination with high-dose chemotherapy and total-body irradiation may be of some benefit.<sup>132</sup>

Despite the uncertainty of the role of surgery, the COG high-risk protocol currently recommends attempting gross total resection of the primary tumor and locoregional disease in patients with high-risk NB. Most children undergo delayed surgery after the completion of the fifth cycle of induction chemotherapy, even though tumor volume reduction plateaus after the second or third cycle of chemotherapy.<sup>133</sup> Other groups are performing surgery as soon as locoregional disease appears, radiographically, to be resectable.<sup>134</sup> Although initial surgical resection is often not appropriate for patients with NB, the principle of resection at the earliest feasible time should be considered. Because no prospective, randomized studies have been performed, the influence of the extent of surgical resection is unknown. However, in considering aggressive surgical resection, the risks involved, including vascular injury and significant bleeding, kidney or bowel infarction, infection, delay in chemotherapy, and long-term complications (e.g., renal atrophy and diarrhea) need to be weighed carefully against the uncertain benefits of extensive surgery. Certainly removal of kidneys or other organs is to be avoided because this may hinder or delay the ability to give potentially effective chemotherapy.

The age of the patient and the tumor biology are of critical importance when planning surgery. For example, survival of infants with stage 4, single-copy *MYCN* disease

is greater than 94%, regardless of the extent of surgical resection of locoregional disease. This favorable outcome for patients with stage 4, single-copy *MYCN* disease probably includes patients up to 18 months of age if the tumor's Shimada histology is also favorable. Clearly, the excellent prognosis for these patients should not be jeopardized by overly aggressive surgery. The extent of surgery also did not appear to significantly affect the survival of infants with *MYCN*-amplified tumors in this nonrandomized trial because the outcome for those patients was very poor (<15%). Perhaps, infants with stage 4 disease and *MYCN*-amplified tumors would benefit from more aggressive surgery despite the attendant risks, given that current adjuvant therapy is unlikely to provide a cure.

### Surgery for Recurrent Disease

Surgery may have a limited role in the management of patients with relapsed NB in whom the recurrence has been documented to be localized and refractory to available chemotherapeutic agents.

### Operative Principles

More than half of NBs arise in the abdominal cavity. Tumor size, the extent of vascular encasement, and the exact tumor location should be considered in selecting the approach for a retroperitoneal NB. Options available for the abdominal incision include a transverse incision, bilateral subcostal (chevron) incisions, or a midline incision. A transthoracic (intercostal), transdiaphragmatic extension can be added to either incision for excision of NBs with either thoracoabdominal extension or extensive periaortic or celiac axis encasement. The tumor and adjacent lymphadenopathy should be carefully exposed to determine the relation between the tumor and normal organs and vessels. If encasement of major vessels such as the aorta, vena cava, or their branches is found, tumor dissection must be performed to free the vessels completely. Use of the ultrasonic dissector in selected patients may

allow for better tumor dissection from the major vessels, with less blood loss and fewer complications.<sup>135</sup> Use of the argon beam coagulator and lasers<sup>132</sup> also helps to achieve complete or near-complete resection and reduces operative complications.<sup>136</sup>

For a major abdominal resection, several principles are helpful<sup>137</sup>:

1. Approach the operation as a vascular-type operation in which identification and skeletonization of the major intra-abdominal vessels is critical. Generally, the tumor can be separated from the vessel by dissecting in a subadventitial plane.
2. The tumor should be removed piecemeal. In particular, excessive torque on the renal artery in an effort to clear tumor from behind the renal hilum in one piece may result in injury to the intima of the artery with vessel spasm and/or thrombosis, leading to renal ischemia.
3. Dissection begins distal to the lower edge of the tumor, generally along the common or external iliac artery, and proceeds proximally to encounter the tumor along the aorta identifying the major arterial branches (and left renal vein). With deliberate dissection of the tumor from the mesenteric and renal vessels, injury to the liver, bowel, spleen, and kidneys can be avoided (Fig. 68-11), although this frequently results in piecemeal division and excision of the tumor.
4. Right-sided tumors are managed similarly and are generally less complicated unless intimately involved with the structures in the porta hepatis.

Pelvic tumors may involve the sacral plexus in addition to the iliac vessels. Thoracic tumors are usually more easily cleared of the vascular structures but often extend into the intervertebral foramina. Extraction of tumor from this location is of uncertain benefit and can be associated with significant complications. A standard posterolateral thoracotomy (with or without a muscle-sparing approach) can be used to expose tumors of the posterior mediastinum, and cervical incisions can be used to approach tumors of the neck.

**Figure 68-11.** Intraoperative photographs after resection of retroperitoneal neuroblastomas. **A**, Right-sided dissection: note the presence of two right renal arteries coming from the aorta (arrows). **B**, Left-sided dissection: seen are the skeletonized aorta, mesenteric arteries, and left renal artery and vein. IVC, inferior vena cava; SMA, superior mesenteric artery; IMA, inferior mesenteric artery.

**Figure 68-12.** This child presented with ptosis in his right eye. **A**, MRI revealed a neurogenic tumor (*arrow*) in the superior mediastinum on the right side. **B**, At thoracoscopy, the tumor (*asterisk*) is seen. This tumor was able to be removed completely, although the ptosis persisted.

A minimally invasive laparoscopic or thoracoscopic approach may be used for resection of selected NBs in the abdomen and thorax (Fig. 68-12).<sup>138,139</sup>

### Operative Complications

Because of the extensive surgery often required, intraoperative and postoperative complications are not uncommon.<sup>140-143</sup> As many as 80% of patients will experience significant blood loss during surgery that requires transfusion of blood and blood products either in the operating room or in the early postoperative period. Up to 10% will suffer an injury to a major vascular structure (aorta, vena cava, or renal vessels). Injury to other viscera (stomach, bowel, liver, spleen, or kidney) occurs in approximately 5% of cases. On occasion, this necessitates removal of injured organs, with the kidney being the most common. Postoperative complications vary widely. Wound complications and postoperative bowel obstruction occur in 1% to 5% of the patients. In addition, hypertension, chyle leak into the thorax or abdomen, pleural effusion, infection and sepsis, diarrhea, and a prolonged total parenteral nutrition requirement have been known to occur.

## SPECIAL MANAGEMENT SITUATIONS

### Screening for Neuroblastoma

Because the two most important clinical variables for predicting outcome in patients with NB are tumor stage and patient age at the time of diagnosis, it was hypothesized that earlier detection of NB through mass population screening might significantly impact NB-associated mortality. In Japan in the 1980s, mass screening of NB was performed in infants by quantitating urinary vanillylmandelic acid (VMA) and homovanillic acid (HVA). Initially, the mass screening showed very encouraging results.<sup>144</sup> However, subsequent population-based studies with concurrent control groups in Germany and North America found that although the incidence of NB increased, the additional cases were largely early-stage, favorable-biology, low-risk tumors.<sup>145,146</sup> Because the overall mortality of patients with NB was not affected, the implication

of these studies was that mass screening most likely detected tumors that would have undergone spontaneous regression and would not have been detected clinically. Thus, there currently appears to be no role for screening infants for NB.

Small, localized NBs in young infants tend to regress spontaneously. Based on this observation, the COG protocol ANBLOOP2 includes an arm of expectant observation in patients with these lesions to further define their natural history. This study is designed to prove the hypothesis that close biochemical and ultrasonographic observation can be used for safe clinical management of infants with small adrenal masses. Surgical resection is reserved for those rare cases in which there is evidence of continued growth. To be eligible, infants with an adrenal mass must be younger than 6 months of age when the mass is first identified. Also, the mass must be less than 16 mL in volume if solid or less than 65 mL if at least 25% cystic. Finally, disease must be limited to the adrenal gland.

### Stage 4S Disease

In 1971, D'Angio and colleagues reported a number of patients with a "special" variant of metastatic NB termed IV-S (now referred to as 4S).<sup>147</sup> These patients were infants who typically had a single, small primary tumor. However, these infants often had extensive metastatic disease in the liver, resulting in significant hepatomegaly, skin nodules ("blueberry muffin" lesions), and small amounts of disease in the bone marrow (<10% of the mononuclear cells). Patients with 4S NB were quite remarkable because the large amount of disease generally underwent spontaneous regression, even without treatment, and the infants ultimately were found to have no evidence of disease.

Only supportive therapy has been recommended for this stage of NB because of the high incidence of spontaneous regression and the resultant good prognosis.<sup>148</sup> Most of these patients have tumor with favorable biology (single-copy *MYCN*, favorable Shimada histology, and DNA index > 1). Therefore, they are assigned to the low-risk classification and receive no therapy. However, despite the generally benign course of their malignancy, these infants can die of complications caused by the initial bulk of their disease. Limited chemotherapy,

local irradiation, or minimal resection can be used to treat infants with life-threatening symptoms of hepatomegaly. Operative placement of a Silastic pouch as a temporary abdominal wall patch can be used for those with significant liver enlargement that causes either respiratory compromise secondary to diaphragmatic elevation or obstruction of the inferior vena cava. This procedure may help to avoid life-threatening events until shrinkage of the liver is achieved by either spontaneous regression or therapy. The rare infant with 4S disease and either unfavorable Shimada histology or a DNA index of 1 (or if the biology is not known) will be treated as for intermediate-risk disease (group 3). Those with 4S disease that is *MYCN* amplified will be treated as for high-risk disease.

### *Intraspinal Extension of Neuroblastoma*

In a subset of patients with paraspinal NB, tumor growth may extend into the spinal canal (“dumbbell” tumors). If neurologic symptoms result, urgent treatment is required to prevent permanent injury caused by compression of the cord. Each of the three main therapeutic modalities (surgery, radiation therapy, and chemotherapy) has been used in the past. A POG report showed similar rates of neurologic recovery in patients treated with surgery or chemotherapy, but significant orthopedic sequelae were seen more commonly in patients treated with surgery.<sup>149</sup> Although chemotherapy is probably considered most appropriate for the initial management of these patients, improvements in neurosurgical techniques, including the use of laminotomy instead of laminectomy to access the intraspinal tumor, may lead to reconsideration of this approach, especially in those patients with acutely progressive symptoms.

The appropriate approach for patients with asymptomatic intraspinal tumor extension is also uncertain. For patients with low- or intermediate-risk disease, the risks of attempting to remove the intraspinal component of a paraspinal tumor probably outweigh the benefits. This situation most commonly arises in patients with thoracic primary tumors. The intrathoracic component is resected, and gross residual disease remains in the spinal canal. Care should be taken to minimize surgical complications such as leakage of cerebrospinal fluid or uncontrollable intraspinal bleeding. Because residual foraminal disease rarely grows to a symptom-developing size, the importance of conservative therapy in this circumstance should be emphasized. In the absence of metastatic disease or unfavorable tumor biology, these patients’ disease will be classified as stage 2A/B, low risk, and they have a very favorable prognosis with no further therapy. For patients with high-risk disease, the importance of resecting gross intraspinal disease is uncertain.

### *Opsoclonus-Myoclonus Syndrome*

The opsoclonus-myoclonus syndrome (OMS) consists of myoclonic jerks and random eye movements or progressive cerebellar ataxia. OMS occurs in as many as

4% of patients, usually infants with thoracic primary tumors. Although the exact etiology of this syndrome is not known, the presence of cross-reactive autoantibodies to neural antigens in some of these patients suggests that it is mediated by the immune system.<sup>150</sup> Although patients generally have a good prognosis with regard to their tumor, neurologic symptoms often persist after successful removal of the tumor and can be quite debilitating.<sup>55,56</sup> Some symptomatic relief may be attained by high doses of corticosteroids or adrenocorticotrophic hormones. Some studies have suggested that chemotherapy, intravenous IgG therapy, or both may improve the long-term neurologic outcome for these patients.<sup>151,152</sup> COG is currently testing this approach in a prospective clinical trial.

## NEW TREATMENT STRATEGIES

### Differentiating Agents

Retinoids are derivatives of vitamin A. 13-*cis*-Retinoic acid (isotretinoin) is a synthetic derivative of the naturally occurring all-*trans* retinoic acid. These retinoids decrease the proliferation and expression of *MYCN* from NB cell lines in vitro and induce morphologic differentiation.<sup>153-156</sup> Because of these attractive characteristics and the observation that resistance to chemotherapy does not result in resistance to 13-*cis*-retinoic acid, retinoids have been tested clinically. The CCG 3891 clinical trial randomized patients with high-risk NB treated using chemotherapy or autologous BMT into two groups who received either 13-*cis*-retinoic acid for 6 months or no further therapy. The 3-year EFS of patients who received 13-*cis*-retinoic acid (46%) was significantly higher than that of patients who received no further therapy (29%;  $P = .027$ ) and was independent of the initial randomization to either chemotherapy or autologous BMT.<sup>97</sup> Because of this result, all patients on the current COG high-risk protocol receive oral 13-*cis*-retinoic acid twice daily for 2 weeks followed by 2 weeks without. This treatment is continued for six cycles (6 months total). Group 4 patients, age 365 to 574 days, being treated on the current COG intermediate-risk protocol will also receive 13-*cis*-retinoic acid.

### Targeted Therapy

As more information regarding diagnostically and prognostically useful genetic markers of NB become available, therapeutic strategies will change accordingly. In addition, molecular profiling will lead to new drug development designed to induce differentiation of tumor cells, block dysregulated growth pathways, or reactivate silenced apoptotic pathways. One of the most exciting prospects for improving the therapeutic index, as well as overcoming the problem of tumor resistance to therapy, involves targeted therapy. Information about the molecular profile of a given tumor type, specifically mechanisms of tumorigenesis and proliferation control, can be assembled using a variety

of molecular methods. This information can then be translated into new drug development designed to induce differentiation of tumor cells, block their growth pathways, and cause tumor cell death. These new agents can be used in concert with traditional regimens, and some may be used independently. Elucidation of the complex molecular pathways involved in tumorigenesis will also encourage the production of targeted anticancer agents with high specificity, efficacy, and therapeutic index. Two examples of this are the use of agents that act on impaired apoptosis pathways and neurotrophin receptor pathways in NB.

Caspase 8 is a cysteine protease that regulates programmed cell death. The gene that encodes caspase 8 is frequently inactivated in NB. DNA methylation and gene deletion mediate the complete inactivation of caspase 8, which occurs almost exclusively in NBs with *MYCN* amplification.<sup>50</sup> Caspase 8-deficient NB cells are resistant to death receptor- and doxorubicin-mediated apoptosis in vitro. These deficits are corrected by enforced expression of the enzyme. This finding suggests that caspase 8 acts as a tumor suppressor in NBs with *MYCN* amplification and may be of significant clinical importance.<sup>50</sup> Brief exposure of caspase 8-deficient NB cells to low levels of interferon- $\gamma$  results in the re-expression of caspase 8 and the resensitization of the cells to chemotherapeutic drug-induced apoptosis. This finding indicates that a targeted approach using interferon- $\gamma$ , perhaps in combination with doxorubicin, may be useful in patients with *MYCN*-amplified NB.

Different neurotrophin-receptor pathways probably mediate the signal for both cellular differentiation and malignant transformation of sympathetic neuroblasts to NB cells. As previously discussed, three tyrosine kinase receptors for these neurotrophins have been identified. Studies are ongoing to test agonists of TrkA in an attempt to induce cellular differentiation. Conversely, blocking the BDNF/TrkB signaling pathway with Trk-specific tyrosine kinase inhibitors, such as CEP-751, may induce apoptosis by blocking crucial survival pathways.<sup>48,157-159</sup> This targeted approach has the attractive potential for increased specificity and lower toxicity than conventional cytotoxic chemotherapy.

## Immunotherapy

Several characteristics of NB suggest that the immune system can be successfully recruited for the treatment of this tumor. For example, the incidence of NB in situ far exceeds that of the actual disease and the tumors in infants often spontaneously regress. Both occurrences are potentially mediated by the immune system. NB is derived from embryonic neuroectoderm and, therefore, expresses antigens not widely detected in normal tissues. In addition, a substantial amount of innate, IgM-mediated humoral anti-NB cytotoxicity has been detected in the sera of healthy adults.<sup>160</sup> Several studies have suggested that patients with NBs are likely to have lymphocytes with specific antitumor activity.<sup>161,162</sup>

## Cellular-Mediated Immunotherapy

Efforts to recruit T-cell-dependent and T-cell-independent cytotoxic effector mechanisms have focused largely on recombinant cytokines (e.g., interleukin-2 [IL-2]) that stimulate the immune system,<sup>163</sup> or on agents such as interferon- $\gamma$ , which may render NB cells more immunogenic to cytotoxic T cells by increasing their expression of class I MHC molecules.<sup>163-166</sup> Although these approaches increase cytotoxic effector function against NB cell lines in vitro, similar effects on tumor growth in vivo are uncertain.<sup>167-171</sup>

## Humoral-Mediated Immunotherapy

NB cells are sensitive to antibody-dependent cell-mediated cytotoxicity and to complement-dependent cytotoxicity.<sup>172</sup> Although a particular NB antigen has not been defined, monoclonal murine antibodies have been raised against the ganglioside  $G_{D2}$ , the predominant antigen in NB cells. Targeted immunotherapy using antiganglioside  $G_{D2}$  antibodies may be a promising approach for the treatment of advanced NBs. Therapeutic responses were initially obtained in phase I and phase II studies of the murine IgG<sub>3</sub> antibody 3F8<sup>173,174</sup> and the murine IgG<sub>2a</sub> antibody 14G2a.<sup>175-177</sup> In a phase II trial, the mouse monoclonal antibody 3F8 induced a tumor response in 40% of patients with NB resistant to chemotherapy.<sup>178</sup> Phase I studies of 14G2a have demonstrated significant responses in patients with refractory NBs.<sup>176</sup> To decrease the immunogenicity of murine antibodies, a chimeric antibody was constructed by combining the variable regions of murine IgG<sub>3</sub> antiganglioside  $G_{D2}$  antibody 14.18 and the constant regions of human IgG<sub>1</sub>- $\kappa$ . This chimera, ch14.18, binds the ganglioside  $G_{D2}$  antigen with exquisite specificity and alters both complement and cell-mediated cytotoxicity of NB cells by effector cells, such as peripheral blood mononuclear cells or granulocytes.<sup>179</sup> Superiority of ch14.18 over 14G2a in antibody-dependent cell-mediated cytotoxicity to NB cells in vitro was supported by a phase I trial of the chimeric antibody in which a durable response was achieved in children with refractory NB.<sup>180</sup> Ch14.18 was tested alone<sup>181</sup> and in combination with granulocyte-macrophage colony-stimulating factor (GM-CSF) in POG 9347. Some therapeutic efficacy in patients with refractory disease was found, although toxicity, particularly neuropathic pain, was substantial.<sup>182</sup> Because the induction of antibody-dependent cell-mediated cytotoxicity with antiganglioside  $G_{D2}$  antibodies is enhanced by cytokines such as GM-CSF<sup>182</sup> and IL-2,<sup>183</sup> the current phase III anti-NB antibody trial, COG ANBL0032, is designed to determine whether treatment with ch14.18 and cytokines (GM-CSF and IL-2) together with 13-*cis*-retinoic acid improves EFS and overall survival after autologous BMT as compared with treatment with 13-*cis*-retinoic acid alone.

## MIBG Therapy

Refractory NB has been treated with <sup>131</sup>I-MIBG because it is readily taken up by the tumor cells.<sup>184</sup> In an investigation of patients with advanced chemoresistant NBs,

response rates approached 33%.<sup>185</sup> Studies further suggest that this treatment can be used as front-line therapy, followed by chemotherapy, without significant hematologic toxicity.<sup>186</sup> In addition,<sup>130</sup> I-MIBG may have a potential role in the intraoperative identification of sites of active disease and in guiding the extent of surgical resection.<sup>124</sup> I-MIBG may be an even better treatment option for NBs with micrometastases or bone marrow infiltration<sup>187</sup> and is being tested for the treatment of patients with “ultra-high-risk” NB (expected survival of < 15%).

## Antiangiogenesis

Angiogenesis is the biologic process of blood vessel formation. In addition to occurring as part of several normal, physiologic processes, angiogenesis is an essential component of a number of pathologic conditions, including cancer. Compelling data suggest

that inhibition of angiogenesis not only prevents tumor-associated neovascularization but also affects tumor growth and spread. NB growth appears to be angiogenesis-dependent and is, therefore, likely to be susceptible to antiangiogenic therapy. Animals studies have demonstrated that NB is susceptible to a variety of angiogenesis inhibitors, including TNP-470 (a fumagillin derivative),<sup>188-190</sup> VEGF-Trap,<sup>191</sup> a truncated soluble form of the VEGF receptor-2,<sup>192,193</sup> and pigment epithelium-derived factor.<sup>194</sup> In addition, standard chemotherapeutic agents, when given using a low continuous dosing schedule, appear capable of treating tumors that had been previously resistant to them by destroying the neovascularity required by a progressing tumor.<sup>195</sup> By avoiding a “maximal tolerated dose” scheduling of these drugs, the patient can forego the recovery time required between cycles, thereby preventing recovery of the chemotherapy-sensitive endothelial cells.

# LESIONS OF THE LIVER

Walter S. Andrews, MD

**H**epatic tumors in children are relatively rare. The most common malignant neoplasms in the liver are not primary hepatic tumors but rather metastatic lesions such as Wilms' tumor, lymphoma, and neuroblastoma.<sup>1</sup> Primary liver tumors comprise between 1% and 4% of all solid tumors in children. Malignant hepatic tumors occur at a rate of about 1 to 1.5 per million children per year.<sup>1,2</sup> However, 10 primary liver masses occur with some frequency in the pediatric age group. Five of these occur only in children: infantile hemangioendotheliomas, hepatoblastoma, mesenchymal hamartoma, rhabdomyosarcoma of the biliary tract, and undifferentiated embryonal sarcoma (Table 69-1). Among these five tumors, the age distribution is distinctive, with hepatoblastoma and infantile hemangioendothelioma occurring most commonly in the first 2 years of life and hepatocellular carcinoma and focal nodular hyperplasia occurring most commonly after age 5 years (Table 69-2).<sup>1</sup>

Couinaud's elegant description of the segmental anatomy of the liver has allowed hepatic surgical procedures to evolve to a level at which they can be performed with an acceptable morbidity and mortality (Fig. 69-1).<sup>3,4</sup> The cumulative experience with hepatic resection and hepatic transplantation has allowed the development of techniques for both subsegmental and multisegmental resections of the liver in children. With the continued expansion of knowledge about these tumors, reasonable surgical and medical management plans can be devised.<sup>5</sup>

## BENIGN HEPATIC TUMORS

### Infantile Hemangioendothelioma

#### Incidence

Infantile hemangioendothelioma is the most common benign solid hepatic tumor in children, comprising about 16% of all pediatric liver tumors.<sup>1</sup> It also is the most common liver tumor in the first year of life. Almost all children with hepatic hemangioendotheliomas are seen initially before age 6 months, and the majority

are encountered in the first 2 months.<sup>6,7</sup> Historically, a slight female predominance has been found, but this finding has not been uniformly seen.<sup>8</sup>

#### Clinical Presentation

Hepatic hemangioendotheliomas can be either single lesions that can expand to a massive size or a multinodular infiltrative lesion. Occasionally these lesions are asymptomatic and present simply as an abdominal mass or abdominal distention. Hepatic vascular tumors can also be found in association with congenital syndromes such as Osler-Weber-Rendu, Klippel-Trénaunay-Weber, and Ehlers-Danlos. Infantile hemangioendotheliomas have also been reported in association with Beckwith-Wiedemann syndrome, diaphragmatic hernia, trisomy 21, transposition of the great arteries, and extraneous digits.<sup>9,10</sup> They frequently occur with hepatomegaly, high-output congestive heart failure, respiratory distress, and anemia. In addition, these patients may also have acute thrombocytopenia, a microangiopathic hemolytic anemia, and

a consumptive coagulopathy (Kasabach-Merritt syndrome).<sup>11</sup> The development of this syndrome is often life threatening and requires aggressive treatment, as well as treatment of the primary cause. Fortunately, the Kasabach-Merritt syndrome occurs infrequently and is usually associated with hemangioendotheliomas that have rapid growth to a diameter of 5 cm or more. No cases have been reported in association with smaller tumors.<sup>12</sup> Other associated symptoms can include jaundice, failure to thrive, respiratory difficulties, or poor feeding. It was recently found that some of these patients also have congenital hypothyroidism. The presence of severe hypothyroidism can significantly complicate the management of these patients if it is overlooked.<sup>13</sup>

As many as 50% to 60% of these patients will display symptoms of congestive heart failure.<sup>14,15</sup> Interestingly, neonates with a focal hemangioma tend to have high-output heart failure at birth, whereas infants with multifocal lesions tend to be initially seen between ages 1 and 16 weeks. A classic symptom-complex has been described in hepatic hemangioendotheliomas: hepatomegaly, congestive heart failure, and anemia or other cutaneous hemangiomas. This triad occurs in 80% of infants who have multiple hepatic hemangiomas.<sup>6</sup> Associated hemangiomas occur at multiple distant sites, including skin (45%), lung (10%), pancreas, lymph nodes, and bone.<sup>16,17</sup>

Hepatic transaminase levels and occasionally the  $\alpha$ -fetoprotein (AFP) level can be elevated. The cause of this elevation in AFP is unclear. The AFP level can be elevated in normal neonates and does not decrease to adult levels until about age 6 months.<sup>17</sup> In the presence of a significant elevation of AFP, however, hepatoblastoma must be excluded by either imaging studies or by biopsy of the lesion.<sup>18</sup>

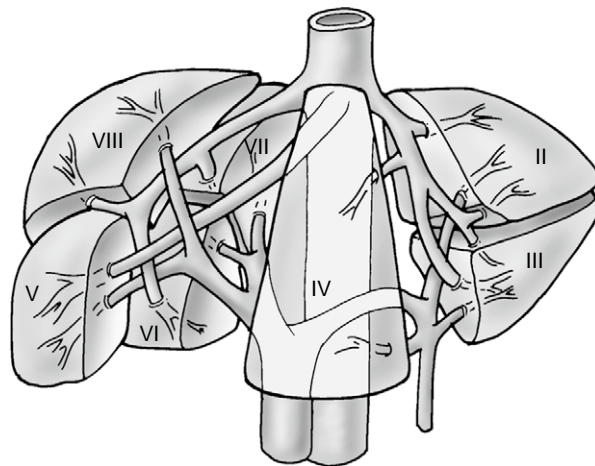

A significant incidence of placental abnormalities has recently been reported in very low birth weight infants (<1500 g) who presented with infantile

hemangiomas.<sup>19</sup> These researchers discovered a variety of placental anomalies that could lead to the shedding of placental cells into the fetal circulation along with fetal hypoxic stress. This hypoxic stress could then lead to increased production of angiogenic factors that could cause increased endothelial cell or placental cell proliferation in the postnatal period with the subsequent development of a hemangioendothelioma.

### Imaging

The ultrasonographic evaluation of hepatic hemangioendotheliomas can be highly variable. Solitary lesions can have a very heterogeneous echogenicity, and the Doppler spectral analysis can show a variety of flow patterns. Multifocal lesions, however, tend to be more uniform in their appearance and are seen as echolucent nodules associated with a high-flow vessel.<sup>20</sup> On computed tomography (CT) with intravenous contrast, classically the lesions either enhance diffusely or rim enhancement is followed by gradual filling of the center of the lesion (Fig. 69-2).<sup>15</sup>

Focal hemangiomas are most often described as showing the rim enhancement with an avascular center related to either hemorrhage or necrosis.<sup>21,22</sup> This enhancement pattern is not typical for a hemangioendothelioma and can lead to uncertainty in the diagnosis. Currently, magnetic resonance imaging (MRI) is thought to be the single most useful modality to show both the location of the hemangioma and its flow pattern and structure.<sup>23,24</sup> The addition of intravenous gadolinium and a gradient-recalled-echo sequence to the MRI enhances its utility in focal lesions. Recently, however, there has been a case report of a hypervascular hepatoblastoma that had a MRI pattern that was identical to a hemangioendothelioma.<sup>25</sup> Therefore, radiology alone cannot reliably distinguish between benign and malignant lesions.

**Figure 69-1.** The segmental hepatic anatomy as defined by Couinaud. A comprehensive understanding of the hepatic segmental division is necessary for successful hepatic resection. (From Couinaud C: *Surgical anatomy of the liver: Several new aspects*. *Chirurgie* 112:337-342, 1986; and Couinaud C: *The anatomy of the liver*. *Ann Ital Chir* 63:693-697, 1992.)

**Figure 69-2.** CT scan after intravenous administration of a contrast agent shows a large hemangioendothelioma with peripheral enhancement in the left lateral segment.

Another method for diagnosing hemangioendotheliomas is the use of a technetium-tagged red blood cell (RBC) blood pool scan. On delayed images (4 hours), an abnormal increase in activity is seen in the region of the hemangioendothelioma. This test is very specific and highly sensitive for hemangiomas.<sup>26</sup>

Hepatic hemangioendothelioma also has been seen in conjunction with focal nodular hyperplasia.<sup>27</sup> This association is important to remember during the radiologic evaluation of a child with multiple hepatic masses.

### Pathology

Microscopically, most of these lesions consist of a single layer or, occasionally, several layers of flat endothelial cells on a supporting fibrous stroma (type 1 lesion).<sup>28</sup> In the type 2 lesion, seen in about 20% of the cases, the endothelial cells are pleomorphic, larger, and more hyperchromatic than those seen in type 1 tumors. Also, they are present along poorly formed vascular spaces that often show tufting or branching. It is thought that the histologic picture of the type 2 lesion is more characteristic of a rapidly proliferating process. However, the differentiation between a type 2 lesion and an angiosarcoma can sometimes be difficult.<sup>16,29</sup> Pathologically, infantile hemangioendotheliomas will stain positive for the marker Glut 1.<sup>9</sup>

Well-preserved bile ducts can often be seen near the periphery of the type 1 lesion, whereas bile ducts are absent in the type 2 lesion.

### Treatment

The therapy for hemangioendotheliomas depends on the severity of the presenting symptoms and the size of the mass. In general, the natural history of these lesions is that they tend to grow over the first year of life and then begin to regress spontaneously.

Asymptomatic lesions are simply monitored, and no specific therapy is instituted until symptoms occur.<sup>11,30</sup>

As part of the evaluation in asymptomatic patients with multifocal hemangiomas, however, imaging studies of the brain and chest should be performed to make sure no associated intracranial or pulmonary lesions are present. In addition, all patients with hemangiomas should be screened for hypothyroidism.

Patients first seen with congestive heart failure, coagulopathy, or respiratory compromise will require intervention. Mortality rates in these patients have been reported to range from 17% to 35%, with some reports of death in as many as 90% of severely symptomatic patients.<sup>31-33</sup> Risk factors for death include congestive heart failure, jaundice, multiple tumor nodules, and the histologic absence of cavernous differentiation.

In patients with congestive heart failure, stabilization is initiated with digoxin and diuretics. Supportive measures may be necessary in patients with respiratory compromise either from the high-output cardiac failure or from restriction of diaphragmatic movement by the abdominal mass. Coagulation factors can be administered if a coagulopathy is present.

If hemodynamic or respiratory compromise or coagulopathy becomes a problem, therapy directed toward the hemangioma is needed. The usual initial treatment for a symptomatic lesion is prednisone or prednisolone at a dose of 2 to 3 mg/kg/day. The symptomatic response rate to corticosteroids is reported to be about 45%.<sup>34,35</sup> If this is not effective in relieving the symptoms after 1 to 2 weeks, a trial of interferon- $\alpha$  should be instituted. Prolonged administration may be necessary for a clinical response.<sup>36</sup> Interferon- $\alpha$  therapy is indicated in the presence of the Kasabach-Merritt syndrome.<sup>8</sup> A recent report described a reduction in levels of vascular endothelial growth factor (VEGF) after administration of interferon- $\alpha$ .<sup>37</sup> Three cases of steroid-resistant infantile hemangioendotheliomas showed resolution by using vincristine at a weekly dose of 1 to 2 mg/m<sup>2</sup> for 2 weeks.<sup>12</sup> Surgical resection of these lesions appears to be most effective when it is confined to a single lobe. In this situation, a survival rate of 92% has been reported, even if the clinical situation is complicated by congestive heart failure.<sup>29</sup>

Embolization is being used more frequently, especially in patients whose condition is thought to be too unstable for surgical intervention.<sup>38,39</sup> With this therapy, it is important to identify and occlude as distally as possible both the arterial and portal vascular supply.<sup>11,15</sup> After successful embolization, a rapid improvement in the clinical course usually occurs within 5 days.<sup>38,39</sup>

Finally, in patients in whom other modes of treatment have failed, liver transplantation has been used as successful therapy for severe congestive heart failure or unremitting coagulopathy (or both).<sup>40</sup>

Regardless of the treatment modality, if the hemangioendothelioma does not completely involute, malignant transformation of an infantile hemangioendothelioma to an angiosarcoma has been reported in older children.<sup>14,41</sup> For this reason, patients who are asymptomatic or who become asymptomatic after therapy must be monitored for complete resolution

of their hemangioendothelioma. Surgical resection of any residual lesion should be considered.

## Mesenchymal Hamartoma

### Incidence

Mesenchymal hamartoma is reported to be the third most common hepatic tumor and the second most common benign tumor in children.<sup>1</sup> Of the benign hepatic lesions that have been described, mesenchymal hamartomas account for between 18% and 29% of these tumors.<sup>42,43</sup> Approximately 120 cases of mesenchymal hamartomas have been described in the English literature.<sup>44</sup>

### Epidemiology

The reason for the development of a mesenchymal hamartoma is unclear. One theory is that it results from abnormal development of the primitive mesenchyme, which appears to occur at the level of the hepatic ductal plate, causing an abnormality of the bile ducts.<sup>45</sup> This postulate is supported by the histologic finding of a combination of cystic, anaplastic, and proliferating bile ducts, as well as the presence of multiple portal vein branches within the tumor. It is conjectured that the tumor then develops a cystic component as a result of obstruction and dilatation of lymphatics or from occluded bile ducts (or both). The tumor enlarges during infancy as the cystic areas increase in size. Most of the proliferative growth appears to occur before or just after birth because no observable mesenchymal mitotic activity is visible on histologic sections of the tumor.<sup>46</sup>

A second theory is that the lesions are reactive rather than developmental.<sup>47</sup> It is hypothesized that an abnormal blood supply to an otherwise normal hepatic parenchyma causes ischemic necrosis, leading to reactive cystic changes within that portion of the liver. This theory is supported by the findings that hamartomas often have a necrotic center, are often attached to the liver by only a thin pedicle, and rarely are found centrally in the liver.

The third theory suggests that a mesenchymal hamartoma is a proliferative lesion. This theory is supported by several findings. Increased fibroblast growth factor-2 (FGF-2) staining has been noted in the proliferating hepatic mesenchymal cells adjacent to the mesenchymal hamartoma.<sup>48</sup> Both the mesenchymal cells in the liver and the mesenchymal hamartoma tissue strongly express molecules of the FGF-receptor family. It is speculated that a local increase of FGF-2 secretion could stimulate the growth of mesenchymal cells to form the mesenchymal hamartoma. FGF-2 also is a potent angiogenic factor that could contribute to the intense vascularization seen within some of these lesions. Cytogenetic studies in these tumors have documented balanced translocation of chromosomes 11 and 19 and 15 and 19 as well as the presence of aneuploidy.<sup>49-52</sup> This cytogenetic abnormality along with aneuploidy

suggests that a mesenchymal hamartoma may be a proliferative lesion.

### Clinical Presentation

The widespread use of prenatal imaging has led to the detection of hepatic masses before birth.<sup>17</sup> Cases of hepatic mesenchymal hamartoma that were diagnosed or detected prenatally have been reported.<sup>53,54</sup> One of the unique characteristics of a neonatal mesenchymal hamartoma is that it can be solid as well as cystic. Unfortunately, the prognosis for these neonates is often poor. Of the reported cases mentioned earlier, five experienced very rapid tumor growth, with fetal hydrops occurring in three. Two of these five fetuses died. It was believed that the rapid growth of the liver cyst caused the development of fetal hydrops. Thus, it may be best to deliver these fetuses before fetal hydrops develops.<sup>54</sup> Another series reported the use of repeated intrauterine aspiration of the cysts until the infants could be delivered and definitive treatment initiated.<sup>55</sup>

In the neonate, these lesions can have a varying presentation. High-output cardiac failure with associated pulmonary hypertension has been reported in neonates with highly vascular mesenchymal hamartomas.<sup>56,57</sup> Respiratory distress secondary to a large hepatic mass impinging on the diaphragm has also been described.<sup>54</sup>

The presentation of a mesenchymal hamartoma in the older child is usually that of progressive abdominal distention or an abdominal mass (or both). A significant right-sided predilection exists for these masses, and they tend to be somewhat more common in male than female patients. Occasionally there are associated symptoms such as nausea and vomiting that are secondary to the compression of the stomach and intestine by the expanding mass.<sup>1</sup>

On physical examination, abdominal distention or a palpable abdominal mass is most common. The mass tends to be nontender and fixed. Laboratory studies almost always are normal, including liver function studies. The AFP level can be moderately elevated and it will return to normal after resection. This is important because patients have been treated with chemotherapy for hepatoblastoma until a tumor biopsy was obtained.<sup>58</sup>

### Imaging

CT, ultrasonography, and MRI have all been used for diagnosis. On CT and ultrasonography, usually a multiseptated, multicystic, anechoic mass is located in the periphery of the liver.<sup>59,60</sup> Occasionally the mass is pedunculated. Calcification is uncommon.<sup>61</sup> MR angiography has been proven useful both in the diagnosis and planning of the resection of these lesions.<sup>62</sup> The finding of a small round hyperechoic parietal nodule on ultrasonography is usually highly sensitive.<sup>63</sup>

### Pathology

Mesenchymal hamartomas typically are large, well-circumscribed tumors that measure at least 8 to 10 cm in diameter (Fig. 69-3). Three of four of these tumors

**Figure 69-3.** This young child presented with a palpable right upper abdominal mass. **A**, CT scan shows an anechoic mass (*asterisk*) in the periphery of the liver. **B**, At operation, the mass (*asterisk*) was found to be pedunculated and emanating from the right lobe of the liver. This hamartoma was easily removed.

occur in the right lobe of the liver, and only 3% are seen in both lobes of the liver. On cut section, multiple cysts measure from a few millimeters to 15 cm in diameter. These cysts are filled with either serous or viscous fluid separated by loose fibrous and myxoid tissue (Fig. 69-4). The surrounding tissue is yellow-tan to brown and is loose to moderately dense.

Microscopically, the tissue consists of a mixture of bile ducts, liver cell cysts, and mesenchyme. The cysts may simply be dilated bile ducts, dilated lymphatics, or amorphous fluid surrounded by mesenchyme. In older patients, the cysts may be lined with cuboidal epithelium (Fig. 69-5). Elongated or tortuous bile ducts surrounded by connective tissue are unevenly distributed throughout the mesenchyme. Typically the hepatocytes appear normal, and they are not a predominant part of the pathologic process. The bile ducts in the periphery of the lesion seem to be undergoing active proliferation.<sup>1</sup>

Despite the fact that the majority of these tumors are localized, there have been reports of these tumors being multifocal.<sup>52</sup> This may account for the occasional recurrences that are seen after resection of the primary tumor.

**Figure 69-4.** Cut surface of a mesenchymal hamartoma showing multiple cysts.

### Treatment

Various management strategies have been used for these lesions. Because they are sometimes encapsulated, simple surgical enucleation may be possible. Very large, bilobar tumors that are not amenable to resection can be marsupialized into the peritoneal cavity, but recurrence after marsupialization has been described.<sup>44</sup> If a patient is to have marsupialization alone, there needs to be very careful, long-term follow-up because of the risk of recurrence or the development of undifferentiated embryonal sarcoma. Complete excision of the lesion with a margin of normal liver is usually curative (including the use of liver transplantation for large, bilobar lesions) and is the recommended therapy.<sup>64</sup> Spontaneous involution of these lesions has been reported, but this is unusual.<sup>65</sup>

There is now strong evidence that an undifferentiated embryonal sarcoma of the liver can develop within a preexisting mesenchymal hamartoma.<sup>52,66-69</sup> This association has occurred both synchronously and metachronously (undifferentiated embryonal sarcoma in a 6-year-old who had undergone a resection at 18 months for mesenchymal hamartoma). The evidence for a direct link between a mesenchymal hamartoma and an undifferentiated embryonal sarcoma of

**Figure 69-5.** Light microscopy of mesenchymal hamartoma showing a cyst lined with cuboidal epithelium.

the liver comes from the simultaneous finding of both tumors arising within the same mass. Moreover, aneuploidy and similar chromosomal abnormalities involving chromosome 19q13 have been reported in both a mesenchymal hamartoma and an undifferentiated embryonal sarcoma of the liver.<sup>49,50,70,71</sup>

## Focal Nodular Hyperplasia

### Incidence

Focal nodular hyperplasia (FNH) accounts for about 10% of the hepatic tumors in children.<sup>1</sup> The reported age range is between 7 months and 16 years, with a mean of 7 years, and there is a slight female predominance.<sup>72</sup> The majority of these tumors are discovered incidentally.<sup>72,73</sup> The most common symptom is abdominal pain, but some patients describe decreased appetite, an abdominal mass, weight loss, or a combination of these. Hepatomegaly is a common finding, and liver function test abnormalities have been described.

FNH has been seen in association with a variety of different conditions and situations, including previous trauma to the liver, other liver tumors, hemochromatosis, Klinefelter's syndrome, the use of itraconazole, and cigarette smoking.<sup>74-79</sup>

The etiology of FNH is not certain, but the evidence suggests that it may be a congenital vascular abnormality. Pathologically, these lesions have a single feeding artery and there is an absence of bile ducts or veins in the lesion. The large artery causes a hyperperfused area of the parenchyma with subsequent growth of the liver tissue around the artery.<sup>80</sup> In addition, FNH has been associated with other vascular lesions such as hemangiomas, arteriovenous malformations, and hereditary hemorrhagic telangiectasia.<sup>81,82</sup> Further evidence that FNH is a reactive lesion secondary to vascular anomalies comes from a study in which an increase in the angiopoietin ratio (ANGPT1/ANGPT2) was seen.<sup>83</sup> The *ANGPT1* and *ANGPT2* genes are necessary for normal vascular development. In FNH, an overexpression of the *ANGPT1* gene and an absence of the antagonistic *ANGPT2* gene lead to uncontrolled and disorganized vascular development. Although it is not clear that this is the exact pathogenesis of FNH, it certainly suggests that this genetic imbalance may play a causative role.

Controversy exists about the relation between oral contraceptive use and the development of FNH. In a case-control study, it was noted that neither menstrual nor reproductive factors correlated with FNH risk. However, oral contraceptive use was a significant risk factor in the development of FNH.<sup>78</sup> Because the use of oral contraceptives also appears to be associated with hepatocellular adenomas, a history of oral contraceptive use does not help in distinguishing between these two entities.<sup>78</sup>

In children, an association has been noted between the congenital absence of the portal vein (Abernathy's syndrome) and FNH.<sup>84-86</sup> In addition, these patients have an increased incidence of other solid tumors

such as hepatoblastoma, hepatocellular carcinoma, and hepatocellular adenoma. FNH also has been seen, albeit less frequently than hepatocellular adenoma, in patients with glycogen storage disease (GSD) type I.<sup>86</sup> An especially interesting association was described with the development of FNH a number of years after treatment for either neuroblastoma or a variety of other small round cell tumors.<sup>87</sup> It was hypothesized that the chemotherapy caused microvascular alterations within the liver, resulting in the development of FNH.<sup>88</sup>

Therefore, it is important to remember that a liver lesion that occurs after treatment of a previous cancer does not always mean that there has been a recurrence of the primary tumor. A biopsy of the lesion should always be done before the initiation of any further therapy.<sup>89</sup>

### Imaging

The diagnosis of FNH by radiologic means often requires the use of multiple different imaging modalities. On CT, the classic findings are early enhancement of the lesion and the presence of a central scar (Fig. 69-6).<sup>90</sup> Unfortunately this pathognomonic association is not often seen.<sup>91,92</sup> Additional imaging modalities include single-photon emission CT (SPECT) radio-nuclide scans with either radiolabeled sulfur colloid or hepatoinodiacetic acid (HIDA) imaging, which demonstrates hypervascularization, increased tumor tracer uptake, and a central cold area.<sup>93-95</sup> Technetium-99m sulfur colloid scanning can also be useful in distinguishing between FNH and a hepatic adenoma. The colloid is taken up by the Kupffer cells in 80% of the FNH lesions but not by hepatic adenomas because they lack Kupffer cells.<sup>96</sup> MRI also has been useful when coupled with either gadolinium enhancement or the use of liver-specific contrast agents such as mangafodipir trisodium or iron oxide. These agents help to delineate the lesion better by specifically looking for the central scar.<sup>97,98</sup>

**Figure 69-6.** CT scan after intravenous administration of a contrast agent shows an early enhancing lesion in the right lobe of hypodense central scar consistent with focal nodular hyperplasia.

**Figure 69-7.** A large focal nodular hyperplasia lesion was resected. External scarring (*solid arrow*) is seen in the lesion. The *dotted arrow* points to normal liver.

### Pathology

FNH classically is characterized by nodular architecture, a central or eccentric scar containing malformed vessels that resemble an arteriovenous malformation, and a variable amount of bile duct proliferation (Figs. 69-7 and 69-8).<sup>99,100</sup> This entity develops in the setting of a noncirrhotic liver.

Histologically, the classic form of FNH with a central scar accounts for about 80% of the lesions. Twenty percent are nonclassic where the FNH lacks either the nodular architecture or the presence of the malformed blood vessels. These lesions are subdivided into three histologic categories: the telangiectatic form, the mixed hyperplastic and adenomatous form, and the atypical form.<sup>101</sup> These nonclassic categories always lack a macroscopic scar. The mixed hyperplastic and adenomatous form often can be difficult to distinguish from a hepatocellular adenoma. Hepatocellular adenomas have been reported to be present in association with FNH in about 4% of the cases.<sup>99</sup>

Recently, there has been a case report of what appears to be malignant transformation of an FNH to a fibrolamellar

**Figure 69-8.** Light microscopy of a focal nodular hyperplasia showing a central scar containing abnormal blood vessels.

hepatocellular carcinoma.<sup>102</sup> Also, FNH has been reported by several authors to occur in association with a well-differentiated fibrolamellar hepatocellular carcinoma.<sup>102,103</sup> This observation is important to remember in patients who have multiple hepatic nodules.<sup>104,105</sup>

### Treatment

The treatment of FNH depends on the clinical situation. If the diagnosis is certain, and the patient is asymptomatic, the consensus is that these patients can be followed with serial ultrasonography to make sure that no progression of the lesion occurs.<sup>72,91</sup> Percutaneous biopsy of these lesions has been helpful in their diagnosis.<sup>106</sup> However, if the patient is symptomatic, if the lesion is greater than 5 cm, if progression of the mass is seen, or if the diagnosis is unclear, then a biopsy or a resection of the lesion should be performed.<sup>107,108</sup> Because of the association of FNH with hepatocellular carcinoma, patients who are expectantly managed must have serial evaluations to ensure that no progression occurs. Moreover, they need to be monitored for the development of other hepatic lesions.

Several reports have noted a 40% to 50% regression rate in cases of FNH that have been monitored.<sup>109,110</sup> Regression of FNH is more likely if the use of oral contraceptives ceases.<sup>111,112</sup>

In two symptomatic patients in whom the FNH was in an area that was thought to be difficult for surgical resection, arterial embolization either with Lipiodol and absorbable gelatin foam (Gelfoam) or iodized oil and polyvinyl alcohol resulted in a significant regression in the size of the mass.<sup>113-115</sup>

## Hepatocellular Adenoma

### Incidence

Hepatocellular adenoma is a very rare hepatic tumor in children, comprising only about 4% of all solid liver tumors.<sup>1</sup> It is most commonly seen in women in their 20s and is associated with the use of oral contraceptives.

### Clinical Presentation

In children, these lesions are often asymptomatic and are discovered during the evaluation for other problems. Occasionally, they can produce intermittent abdominal pain and rarely can spontaneously rupture, resulting in hemoperitoneum and the clinical signs of acute volume depletion.

### Imaging

Hepatic adenomas are often solitary lesions in most cases, but occasionally two to three adenomas can be seen in one patient.<sup>114,116,117</sup> This finding carries the separate diagnosis of liver adenomatosis. On ultrasonography, these lesions can have a variable appearance, depending on the tumor composition. They can have a hyperechoic, hypoechoic, or a mixed echoic pattern depending on whether it is a simple adenoma,

an adenoma with fatty metamorphosis, or an adenoma with hemorrhagic necrosis.<sup>114</sup>

On CT, the adenoma can either be isoattenuating relative to the normal liver or hyperattenuating (due to the presence of fat). They are usually sharply marginated and nonlobular but can be encapsulated or calcified in some patients.<sup>118</sup> Hyperattenuated areas often correspond to recent hemorrhage. Occasionally, on CT scan with intravenous contrast, peripheral enhancement secondary to large subcapsular feeding vessels occurs. The finding of central hemorrhage or necrosis on CT scan helps differentiate hepatocellular adenoma from FNH.

### Associated Conditions

Hepatocellular adenomas were extremely rare prior to 1960, which corresponds to the year in which oral contraceptives were first introduced.<sup>119</sup> In women who have never used oral contraceptives, the annual incidence of hepatic adenoma is estimated to be about 1 per million. The duration of oral contraceptive use is directly related to the risk of developing a hepatic adenoma. The use of contraceptives for 5 to 7 years carries a 5-fold increased risk, and use for 9 or more years has a 25-fold increased risk.<sup>120-122</sup>

Hepatocellular adenomas also have been associated with galactosemia, hypothyroidism, polycythemia, diabetes, Fanconi's anemia, polycystic ovary syndrome, and the use of anabolic steroids.<sup>123-126</sup>

Hepatocellular adenomas can develop in patients with type 1A GSD from their teenage years into adulthood.<sup>127,128</sup> The estimated prevalence of adenomas in these patients is close to 50%.<sup>129,130</sup> These adenomas are often multiple rather than solitary lesions. Unfortunately, hepatocellular carcinoma can occur in association with hepatocellular adenomas in these patients as well. The youngest patient with GSD was 6 years old at the time of the diagnosis of hepatocellular carcinoma.<sup>131</sup> In several series, hepatocellular carcinoma has been found to develop in up to 18% of patients with a hepatocellular adenoma.<sup>132-136</sup> Direct evidence for malignant transformation of a hepatocellular adenoma into a carcinoma has been confirmed with the reporting of a hepatocellular carcinoma within a hepatic adenoma in patients with GSD.<sup>137</sup>

Adenomatosis (the occurrence of more than 10 simultaneous adenomas) is a rare disorder, with 38 cases reported in the literature through 2000.<sup>138</sup> The two forms are the massive form, characterized by multiple nodules measuring between 2 and 10 cm, and the multifocal form, in which most lesions are smaller than 1 cm, with only a few larger than 4 cm.<sup>139</sup> Oral contraceptive use has been seen in about half of the female patients. Interestingly, diabetes and hepatic steatosis has been noted in these patients but it is not clear whether a causative relation is present.<sup>139,140</sup>

### Pathology

Hepatocellular adenomas histologically consist of large plates or cords of cells that resemble normal hepatocytes. These plates are separated by dilated vascular

sinusoids, which are equivalent to thin-walled capillaries perfused by arterial pressure. Adenomas do not have a portal venous supply and are fed solely by peripheral arterial feeding vessels that account for the hypervascular nature of these lesions. Kupffer cells are found in reduced numbers and have little or no function. The absence of bile ducts serves as a key histologic feature that helps distinguish the hepatocellular adenoma from the FNH. Lipid accumulation is responsible for the characteristic yellow appearance on the cut surface.<sup>1</sup>

The exact reason for their development is unclear. Two reports have cited the mutations of the Wnt/ $\beta$ -catenin pathway in patients with hepatocellular adenoma.<sup>141,142</sup> This pathway mutation has been identified in many human hepatocellular neoplasms, although its direct contribution to carcinogenesis is not completely understood. A second mutation has been found in the *HNFI1A* gene that leads to the downregulation of hepatocyte nuclear factor-1 $\alpha$ . This downregulation has been linked to the development of hepatic steatosis and hepatic adenomas.<sup>143</sup> The significance of these findings in hepatocellular adenoma also is unknown.

Hepatocellular adenomas may be asymptomatic but also may be the site of hemorrhage. Larger lesions are more likely to bleed than are smaller lesions. Contained hemorrhage may result in rapid enlargement, but rupture with intraperitoneal hemorrhage may occur if the lesion is near the liver surface. Signs of blood loss or peritonitis (or both) may result.

### Treatment

The treatment approach for these lesions depends on a variety of factors. In patients who are receiving oral contraceptives or androgenic steroid therapy, the first step should be withdrawal of these medications. Multiple case reports mention regression of these adenomas after withdrawal of these compounds. However, in other multiple reports, withdrawal of these agents has resulted in persistence of the adenoma.<sup>144-146</sup> If discontinuation is not effective, then the adenoma should be surgically resected. This removes the potential for future hemorrhage or malignant degeneration (10% of lesions).<sup>147</sup> If the adenoma is larger than 5 cm or if the diagnosis of the hepatic lesion is uncertain, then surgical excision is immediately recommended.<sup>148,149</sup>

For patients with ruptured hepatocellular adenomas, the current suggested therapy in the hemodynamically stable patient is nonoperative monitoring and hemodynamic support. Once the hemorrhage has resolved and the patient has recovered, elective resection should be performed. In patients who continue to bleed actively, hepatic arterial embolization should be performed. This not only stops the hemorrhage but also can decrease the size of the adenoma.<sup>150</sup> After resolution of the hemorrhage, resection is indicated. This management plan results in a decrease in size of the lesion and allows a more limited hepatic resection under controlled conditions.<sup>151,152</sup>

In patients with type 1 GSD in whom multiple adenomas develop, hepatic transplantation should be considered because of the significant probability of the development of a concurrent hepatocellular carcinoma. Liver transplantation not only corrects the potential hemorrhagic problem but also removes the potential for development of hepatocellular carcinoma.

## MALIGNANT HEPATIC TUMORS

### Hepatoblastoma

Most hepatoblastomas develop before age 3 years, with a median age of about 18 months.<sup>153</sup> About 4% are present at the time of birth; 69% are present by the end of 2 years, and 90% develop by the end of 5 years. Only 3% of cases are noted in children older than 15 years.<sup>154</sup> A definite male predominance (1.7:1) is seen.<sup>5</sup>

#### Epidemiology

Hepatoblastomas are associated with a variety of clinical conditions, syndromes, and malformations (Table 69-3). Beckwith-Wiedemann syndrome is associated most commonly with Wilms' tumor, but other tumors such as hepatoblastomas, gonadoblastomas, and adrenal carcinomas are also seen.<sup>155,156</sup> The association with hepatoblastoma is so strong that patients with Beckwith-Wiedemann syndrome must be monitored with serial AFP levels every 3 months until the age of 4 years and an abdominal ultrasonogram every 3 months until they reach age 8 years.<sup>156-158</sup> Screening studies for hepatoblastoma are also recommended in patients with familial adenomatous polyposis. These patients should be screened for the *APC* tumor/suppressor gene. If this gene is present, then these patients are at increased risk for developing hepatoblastoma.<sup>159,160</sup>

Another interesting association exists between hepatoblastoma and extreme prematurity (<1000 g). In the Japanese Children's Cancer Registry (JCCR), it was noted that hepatoblastomas accounted for 58% of the malignancies diagnosed in extremely low birth weight children.<sup>161</sup> In a recent epidemiologic study, several factors were associated with an increased risk for the development of neonatal hepatoblastoma, including birth weight less than 1000 g, maternal age younger than 20 years, use of infertility treatment, maternal smoking, and a higher prepregnancy body mass index (BMI of 25-29).<sup>162</sup> The time from birth to onset of hepatoblastoma in this population ranges from 6 months to 6 years.<sup>163</sup> Unfortunately, the tumors that occurred in this group grew rapidly and had an unfavorable biologic behavior.<sup>164</sup> Although the etiology for the predilection of hepatoblastomas to develop in very low birth weight infants is not known, oxygen therapy, furosemide use, and a retarded growth rate all were noted to be risk factors.<sup>164</sup> The highest correlation was with the duration of oxygen therapy. The risk of hepatoblastoma increased by 20% if oxygen therapy was continued for 30 days, and the risk increased by 100% in children who were treated with oxygen for 4 months.

**Table 69-3** Conditions Associated with Hepatoblastoma

Beckwith-Wiedemann syndrome
Budd-Chiari syndrome
Gardner's syndrome
Hemihypertrophy
Heterozygous $\alpha_1$ -antitrypsin deficiency
Isosexual precocity
Polyposis coli families
Trisomy 18
Type 1a glycogen storage disease
Very low birth weight

Cysteine has also been implicated as a contributing factor. Cysteine is an amino acid that is necessary for the production of glutathione and taurine, both of which are intracellular antioxidants. In premature infant livers, there appears to be impaired production of cysteine.<sup>165</sup>

Because of the complexities of treating "micro-premies" through their first few months, multiple other interventions could influence the development of a hepatoblastoma.

#### Pathology

Hepatoblastomas tend to be unifocal lesions in most cases. Fifty percent are isolated to the right lobe, 15% are in the left lobe, and 27% are centrally located to involve both lobes (Fig. 69-9).

Histologically, the tumor can be divided into six different subtypes (Figs. 69-10 and 69-11) based on light microscopy (Table 69-4). A correlation between clinical outcome and the histologic subtypes has been suggested. The pure fetal subtype appears to be associated with the better prognosis, whereas the small cell undifferentiated subtype appears to have a very poor prognosis.<sup>166-169</sup> In several other studies, chemotherapy

**Figure 69-9.** CT scan after intravenous administration of a contrast agent shows a large right lobe hepatoblastoma extending into the left lateral segment.

**Figure 69-10.** Histology of a pure fetal hepatoblastoma. Note the hepatocytes have clear glycogen-rich cytoplasm and small, regular nuclei.

was initiated before surgical intervention and likely altered the accuracy of histologic definition of the resected tumor, making it difficult to correlate histology and outcome.<sup>170</sup>

### Biology and Cytogenetics

Thrombocytosis is common in patients with hepatoblastoma. This may be related to increased thrombopoietin levels, which have been reported in hepatoblastoma cell extracts.<sup>170</sup> Elevated interleukin-1b levels also have been noted in hepatoblastoma cell lines.<sup>171</sup> This results in an increased production of interleukin-6, which is known to stimulate thrombopoiesis and thrombocytosis.<sup>172</sup>

Chromosomal abnormalities have been documented in patients with hepatoblastoma.<sup>173</sup> The most common defects have been trisomy of chromosomes 20, 2, or 8, or a combination of these. Trisomy 18 also has been found.<sup>174</sup> As yet, however, no correlation has been noted between these cytogenetic abnormalities and either clinical outcome or tumor biology.

An association between hepatoblastoma and the *APC* gene was noted in patients with familial

**Figure 69-11.** Histology of a hepatoblastoma with mixed fetal and embryonal elements. Note the large solid nest (asterisk) of poorly differentiating cells (embryonal components). In contrast, note the surrounding trabeculae of the differentiating fetal hepatoblasts.

adenomatous polyposis and Gardner's syndrome.<sup>172,175</sup> A recent study has found an association between the activation of the Wnt/ $\beta$ -catenin signaling pathway and the development of carcinogenesis in hepatoblastoma and hepatocellular carcinoma.<sup>176</sup>

### Clinical Presentation

Patients with hepatoblastoma are most commonly seen with an asymptomatic right upper abdominal mass that is noted incidentally by either a parent or the pediatrician. Rarely these patients have tumor rupture, followed by significant hemorrhage and hypovolemia. Sexual precocity may be a presenting feature with hepatoblastoma, secondary to the tumor producing human chorionic gonadotropin. With large tumors, it is not unusual to see anorexia and failure to thrive. These lesions can become very large (15 cm) and can extend across the midline or down into the pelvis.

### Imaging

The first diagnostic test is usually an ultrasound examination. This usually differentiates between a renal mass and a hepatic mass. An abdominal CT scan is then usually performed. In half of patients, calcification is noted within the mass.<sup>177</sup> Spiral CT with an intravenous bolus of a contrast agent not only is helpful in the diagnosis but also is useful in the staging of the tumor and in determining its resectability. With three-dimensional reconstruction, the location of the mass with respect to the vena cava, the hepatic veins, and the portal venous system can often be precisely delineated (Fig. 69-12). MRI is becoming an increasingly helpful modality for determining the relation of the tumor to the hepatic anatomy and in differentiating hepatoblastomas from other childhood hepatic tumors.<sup>178</sup> A word of caution, however, is that no current noninvasive study can always differentiate between a benign or malignant liver lesion.<sup>25</sup> If there is any concern about the diagnosis, a tumor biopsy should be performed.

### Laboratory Studies

Anemia and thrombocytosis (platelet count  $>500,000/\text{mm}^3$ ) are often found in patients with hepatoblastoma.<sup>179</sup> However, the hallmark of hepatoblastoma is an elevated AFP level, which occurs in up to 90% of patients.<sup>180</sup> The serum levels of AFP can sometimes exceed 1 million ng/mL. This can lead to the

**Figure 69-12.** **A,** This CT scan obtained after intravenous administration of a contrast agent in a 1-year-old shows a large mass in the right hepatic lobe. On other images, the mass appears to invade or compress the medial segment of the left lobe. The middle hepatic vein (*dotted arrow*) is being compressed by the tumor. **B,** The inferior vena cava (*dotted arrow*) is being displaced medially and anteriorly by the mass, and the portal vein (*solid arrow*) is markedly displaced inferiorly.

“hook” effect in which the initially reported AFP level can be low despite the actual level being very high. If the lesion is suspicious for hepatoblastoma, a request should be made to dilute the AFP sample before retesting.<sup>181</sup> Serum AFP has a half-life of between 4 and 9 days, and the levels usually decrease to normal by 4 to 8 weeks after complete removal of the tumor.<sup>182</sup> It also is important to remember that neonates normally have an elevated AFP level (25 to 50,000 ng/mL) at birth that does not decrease to “adult” levels until age 6 months.<sup>17</sup> This becomes important when evaluating a neonate with a hepatic mass or when monitoring the AFP after liver resection in a neonate or infant.

AFP also has been used for monitoring purposes. In one case report, a radioimmunoassay method was used (technetium-labeled mouse antihuman monoclonal antibody to AFP).<sup>183</sup> After an initial decline in the AFP after liver resection, it began to increase, and an anti-AFP nuclear medicine study accurately located an active tumor in the remaining liver.

Recently, a new marker has been found for hepatoblastoma. Glypican 3 (GPC3) has been detected in hepatic stem cells and has been identified as being expressed by fetal, embryonal, and small cell undifferentiated hepatoblastomas. This marker is also shed by the tumor cells and has the potential to be used as a serum marker for hepatoblastoma.<sup>184</sup>

### Staging

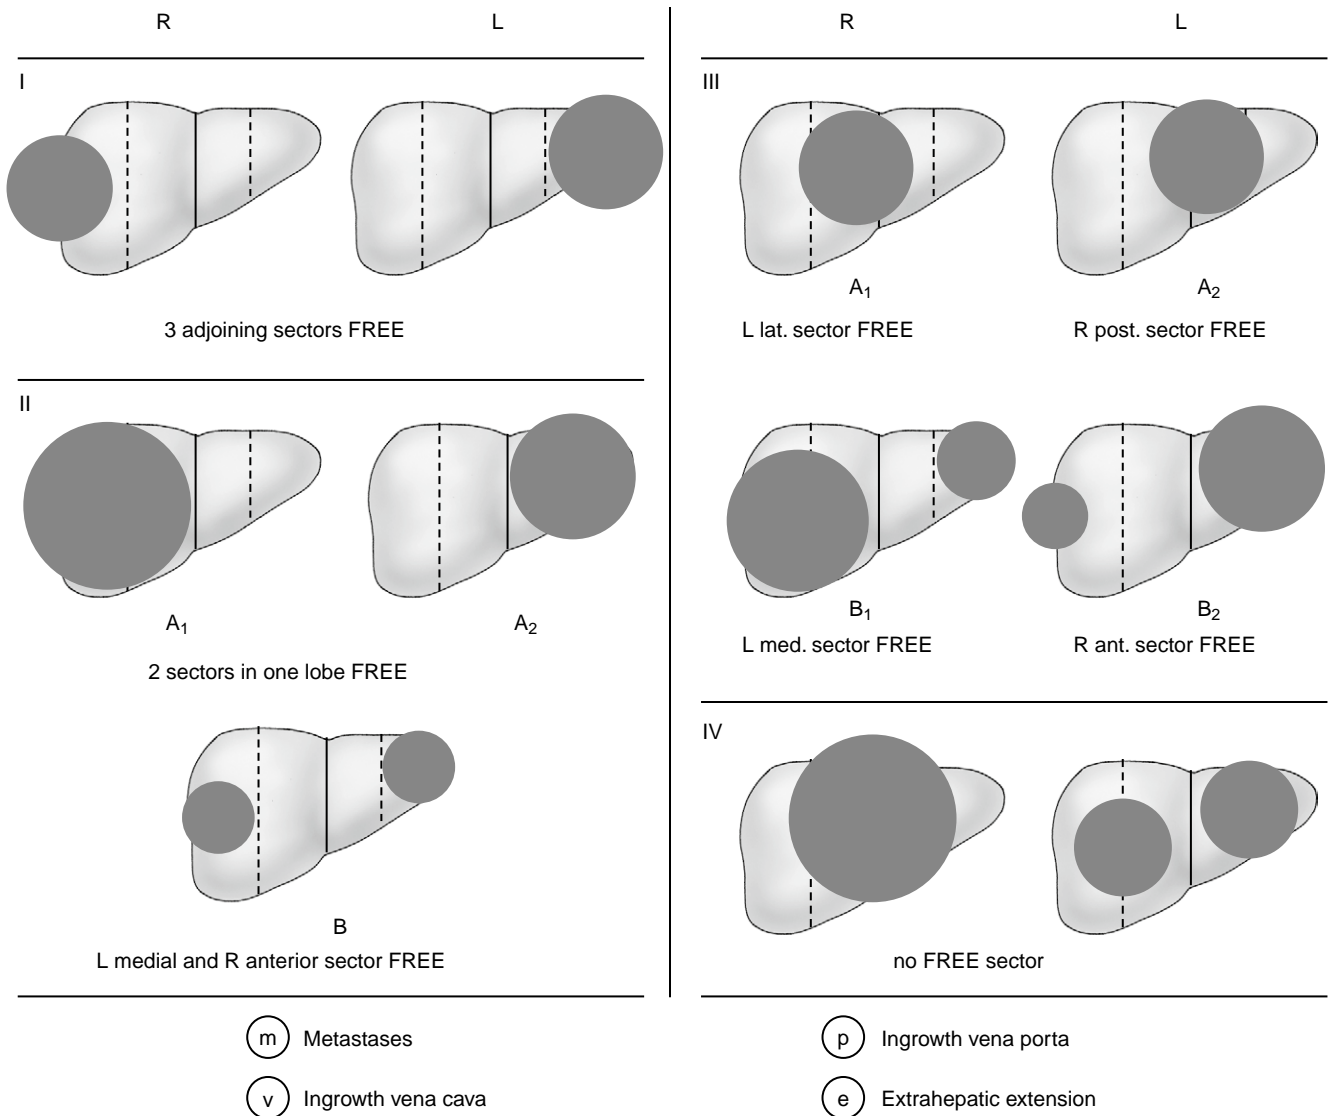

Two staging systems are currently used. In the United States, a combined histologic and surgical staging system is used by the Children’s Oncology Group (COG) (Table 69-5).<sup>185</sup> This tumor staging system is self-explanatory and is based on information gathered before any chemotherapy is started. The second staging system, used by the International Society of Pediatric Oncology (SIOP), is based on the radiologic location of

the tumor before treatment and is called the PRETEXT (Pretreatment Extent of Disease) Grouping System (Fig. 69-13).<sup>186</sup> Both of these staging systems are currently being used in ongoing studies so patient groups can be compared across different study groups.

In the PRETEXT system, the liver is divided into four sections: the anterior and posterior sectors on the right and the medial and lateral sectors on the left. Therefore, based on the extent of the tumor, the patient is classified as follows: PRETEXT 1, with three adjoining sectors free (tumor in only one sector); PRETEXT 2, with two adjoining sectors free (two sectors involved); PRETEXT 3, in which one sector but in two nonadjoining sectors is free (tumor involves two or three sectors); and PRETEXT 4, in which no sector is free (tumor in all four sectors). It is noted whether hepatic vein or portal vein involvement is present, if extrahepatic spread has occurred (enlargement of the hilar

Stage	Description	5-Year Survival
I	Complete resection, clear margin, pure fetal histology	100%
IU	Complete resection, clear margin, unfavorable histology	98%
II	Gross total resection with microscopic residual or perioperative rupture	100%
III	Unresectable or resection with gross residual or lymph node involvement	69%
IV	Metastatic disease	37%

**Figure 69-13.** PRETEXT (Pretreatment Extent of Disease) staging system. Stage is determined by the number of liver sectors free of tumor.

lymph nodes), or if metastases are found. Both staging systems have been shown to have direct correlations with ultimate patient survival (Table 69-6).

In addition to the staging systems, in upcoming protocols the patients will also be stratified according to risk. In the COG staging system, low-risk patients will be stage I/II without unfavorable biologic features, intermediate-risk patients will be stage III or stage I/II with small cell undifferentiated histology, and high-risk patients will be stage IV or stage I, II, III with an AFP less than 100 ng/mL at diagnosis. In the SIOPEL studies, the patients are stratified into standard risk (PRETEXT I, II, III) or high risk (PRETEXT IV or any tumor with metastases, vena cava or portal vein invasion, contiguous extrahepatic disease, or tumors with an AFP < 100 ng/mL at presentation).<sup>187</sup>

### Treatment

The treatment of hepatoblastoma requires a combined-modality approach. Except on very, very rare occasions, chemotherapy alone is unable to eradicate

the tumor. The only chance for a long-term cure is complete resection of the primary tumor. This goal can be achieved by the use of either traditional hepatic resections (right lobectomy: segments 5-8; left lobectomy: segments 2-4; or left lateral segmentectomy: segments 2-3) or extended resections (right trisegmentectomy: segments 4-8; or left trisegmentectomies: segments 2-4, 5, 8). The resection can be performed

**Table 69-6** SIOPEL PRETEXT Staging and Outcome

Stage	5-Year Survival

IV	57%

SIOPEL, International Society of Pediatric Oncology. From Brown J, Perilongo G, Shafford E, et al: Pretreatment prognostic factors for children with hepatoblastoma: Results from the International Society of Pediatric Oncology (SIOPEL) Study SIOPEL 1. *Eur J Cancer* 36:1418-1425, 2000.

using either open or laparoscopic techniques. There have been several case reports and two large series of laparoscopic liver resections in adults for both benign and malignant disease.<sup>188-191</sup> The outcomes of these laparoscopic series have been identical to the results of resections by an open approach. Obviously, a laparoscopic approach to a liver mass requires a team that has extensive expertise in both laparoscopic and hepatobiliary surgery. Unfortunately, due to the lower frequency of liver masses in children, it may be difficult to translate the excellent adult laparoscopic hepatic resection experience to the pediatric population.

The resection should be planned so that there is an anticipated margin of normal liver around the tumor. Fortunately, this margin does not need to be large (2-3 mm).<sup>192</sup> If it is doubtful that the tumor can be resected with a clear margin, then the patient should undergo preoperative chemotherapy to try to reduce the size of the tumor to the point where surgical resection is possible. In several studies, only between 30% and 50% of the patients were able to undergo either a complete or gross total resection of the tumor at the initial procedure.<sup>193,194</sup> In the COG trials, only 23% of the patients initially presented with stage I or stage II disease.<sup>195</sup>

If a difficult liver resection is elected, the conundrum exists as to what to do if the resection is unsuccessful and microscopic residual disease is left after a resection. The data from the COG studies, SIOPEL-1 and SIOPEL-2, indicate that microscopic residual disease after resection can be successfully treated with additional chemotherapy.<sup>168,196,197</sup> On the other hand, several series have reported that the most common reason for tumor recurrence is either a gross or microscopically incomplete resection.<sup>198-201</sup> If local recurrence of the tumor does occur, the prognosis is poor.<sup>182,202,203</sup> "Rescue" transplantation for local recurrence results in a survival rate of only 30%.<sup>204</sup> This would suggest that there must be multiple, yet to be defined, variables that determine if microscopic disease can be eradicated or if it will result in recurrent disease. In any case, there must be careful thought before undertaking a "difficult" liver resection when the possibility exists of leaving residual disease versus referring the patient directly for liver transplant evaluation.

If chemotherapy is necessary, it should be noted that there are two distinct approaches to its utilization in the treatment of hepatoblastoma. The COG approach is based on the premise that all patients who present with hepatoblastoma should be evaluated for a primary resection. If this is not possible, then the patient receives chemotherapy with the goal of shrinking the tumor to the point where it is resectable. The intent of this approach is to limit the patient's exposure to chemotherapeutic drugs that carry significant side effects (renal, cardiac, and ototoxicity). The SIOP approach is fundamentally different in that all their patients receive chemotherapy before any consideration for resection. The logic behind this approach is that chemotherapy will provide multiple benefits, such as shrinking the tumor, thereby potentially decreasing the size and risks of hepatic resection, decreasing the

**Figure 69-14.** After four cycles of chemotherapy, the CT scan showed marked diminution in the size of the mass (*asterisk*). Note the portal vein (*solid arrow*) has returned to its normal anatomic position. Compare with prechemotherapy CT scan in Figure 69-12.

viability of the tumor prior to surgical manipulation, and decreasing the vascularity of the tumor. The SIOP group uses the PRETEXT staging system, but the correlation between survival and PRETEXT stage is based on the fact that all PRETEXT staged tumors (regardless of stage) have received chemotherapy. It should be noted that neither approach has been proved to be superior to the other in multiple, multicenter trials.

Multiple chemotherapy regimens have been evaluated for hepatoblastoma.<sup>185,205</sup> The most active chemotherapy agent for hepatoblastoma is cisplatin. This drug is then combined with either vincristine, doxorubicin, or 5-fluorouracil and used in either an adjuvant or neoadjuvant fashion. The current recommended COG chemotherapy regimen for initially unresectable hepatoblastoma is cisplatin, 5-fluorouracil, and vincristine.<sup>206</sup> In the patients who have had complete resection of their tumor (without preoperative chemotherapy), either four to six postoperative courses of chemotherapy are given. In those children in whom the liver tumor was deemed unresectable at the initial operation, four rounds of chemotherapy are initially given, followed by repeat imaging (Fig. 69-14). With chemotherapy and delayed or second-look surgery, the resection rate has been reported to be increased to between 69% and 98%.<sup>5,207-209</sup> In patients with stage 3 disease whose tumor was initially unresectable and who underwent four cycles of chemotherapy, between 51% and 60% of the patients had their tumors rendered resectable (Fig. 69-15). In patients with stage 4 disease (initially unresectable), only 40% of these

**Figure 69-15.** Operative findings of the patient whose CT scans are seen in Figures 69-12 and 69-14. An umbilical tape has been used to encircle the middle hepatic vein. **A**, Note the residual tumor (asterisk) in the cephalad portion of the right hepatic lobe. **B**, The right hepatic lobe containing the lesion (asterisk) is seen. It was possible to obtain a normal margin of liver in the left lobe, but a trisegmentectomy was needed.

tumors were rendered resectable after four rounds of chemotherapy.

Resection is then performed if it is possible. If the tumor is not resectable, then the child is referred for evaluation for liver transplant. If the child is a transplant candidate (no evidence of active extrahepatic disease), additional rounds of chemotherapy are given until a donor is found. The time to transplantation, however, needs to be as short as possible. Preferably the time between the last round of chemotherapy and transplantation should be less than 4 weeks because it is now known that up to 80% of hepatoblastomas will develop drug resistance after four to five courses of chemotherapy.<sup>208,210</sup>

Some newer chemotherapy agents have been investigated for hepatoblastoma. Topotecan inhibits growth and neovascularization in a mouse model.<sup>211</sup> In addition, the suppressive effects of the topotecan lasted several weeks after discontinuation of the agent. Irinotecan appears to have some promise in salvaging patients who have recurrent disease. This drug could potentially be added to front-line chemotherapy regimens.<sup>212</sup> High-dose chemotherapy with stem cell rescue has been attempted but has not been successful.

Another approach to the unresectable hepatoblastoma is the use of preoperative chemoembolization.<sup>213</sup> Transarterial catheterization with selective tumor chemoembolization was able to shrink the tumor by an average of 26%, which allowed subsequent complete tumor resection in every case. Interestingly, the surgical specimens showed only minimally viable or no viable tumor. It was postulated that this technique may be useful not only as a therapeutic modality for unresectable hepatoblastomas but also potentially for resectable tumors that could be made minimally viable to nonviable before surgical intervention.<sup>214</sup>

Another therapeutic dilemma occurs in the child first seen with a ruptured tumor. In one review, all three patients who survived the initial rupture had no evidence of recurrent disease, with a mean survival of 36 months.<sup>215</sup> Even though rupture of the tumor and peritoneal soiling occurred, no peritoneal growths were subsequently identified in any patient.

### Outcome

Patient-outcome studies have been based on histologic type, the extent of the original tumor, or tumor response to chemotherapy.<sup>166</sup> Several studies have shown a good outcome with fetal histology and with complete resection of the tumor.<sup>41,155,169,216,217</sup> All the studies that have consistently shown a good outcome based on fetal histology have strictly limited this diagnosis to tumors with a mitotic activity less than 2 per 10 high-power fields. Conversely, several studies have consistently reported a poor outcome for those patients who have small cell undifferentiated hepatoblastoma.<sup>167</sup> Except for these data, no consistent correlation has been found with any of the other histologic patterns and patient outcome.

The AFP level also has been shown to have both prognostic and therapeutic implications. Patients with an AFP level less than 100 ng/mL or greater than 1 million ng/mL were found to have a worse prognosis.<sup>218</sup> The low-AFP group comprised patients with small cell undifferentiated tumors, suggesting that a low AFP level could be related to a very primitive and poorly differentiated tumor that was unable to make AFP.<sup>219</sup> Patients who had a slow decline in their AFP levels either after resection or chemotherapy had a poorer long-term prognosis than did those who had an early, very rapid decline (>99% drop in AFP levels).<sup>220</sup>

The best survival in patients with hepatoblastoma is in patients with stage 1 pure fetal histology who were treated with low-dose intravenous doxorubicin (100% survival). In the most recent COG study, the 3-year event = free survival (EFS) was 90% for stage I/II tumors, 50% for stage III tumors, and only 20% for stage IV tumors.<sup>221</sup> The European SIOPEL-2 study reported that the 3-year survival for standard risk tumors was 90% and for high-risk tumors it was 50%. These data compare favorably with those of a large German series that noted an EFS of 100% for stage 1, 80% for stage 2, and 68% for stage 3 disease.<sup>209</sup> None of the patients with stage 4 disease in the German trial survived. In another prospective study, the German group showed that the important prognostic factors

for survival appeared to be the tumor growth pattern, vascular invasion, and serum AFP levels.<sup>217,222</sup>

Because the patients in the high-risk PRETEXT or COG trials have poor outcomes, despite a complete surgical resection, additional or different chemotherapy regimens are necessary to improve patient survival in these groups.<sup>217</sup> Currently there are ongoing studies that are evaluating the possibility of modifying different cellular or gene targets in hepatoblastoma cells that will make them more susceptible to chemotherapy.<sup>223</sup>

### Transplantation

Once a patient has completed four rounds of chemotherapy to shrink the tumor, a decision is made to either perform a surgical resection with the goal of complete tumor excision or to refer the patient for liver transplantation. Several characteristics of hepatoblastoma have recently been reported as possible indicators of unresectability. Therefore, these patients need to be considered early for possible transplantation. Patients who were younger than 3 years of age at presentation tend to respond better to chemotherapy with greater reductions in tumor size when compared with older children.<sup>224</sup> Bilobar, multifocal tumors at presentation are candidates for transplantation. Despite apparent radiologic clearing of a lobe after chemotherapy, microscopic disease can persist in the liver leading to later recurrent disease.<sup>196,225,226</sup> Patients who present with low AFP levels (<100 ng/mL) tend not to respond to chemotherapy, so they should be considered for either upfront resection or transplantation. Patients who have tumor extension into the inferior vena cava, all three hepatic veins, or the bifurcation of the portal vein are unlikely to sufficiently shrink their tumor with chemotherapy to allow a surgical resection and therefore should be considered candidates for transplantation.<sup>204</sup>

Orthotopic liver transplantation is a successful treatment for unresectable hepatoblastoma.<sup>227</sup> A recurrence-free survival rate of between 79% and 92% has been reported.<sup>204,228,229</sup> In several series, an important prognostic factor that predicted good results after transplantation was a good initial response to chemotherapy. In one series, only 60% of the patients who were poor responders are currently alive, with a follow-up of less than 1 year.<sup>228</sup> As mentioned previously, liver transplantation for local tumor recurrence after resection is associated with a post-transplant recurrence rate of 30%. The utility of one to two post-transplant courses of chemotherapy in reducing this recurrence rate is controversial. Although post-transplant chemotherapy is frequently utilized, one multicenter review noted no significant difference in survival rates between those patients who received chemotherapy (77%) versus those who did not (70%).<sup>201,230-232</sup>

Patients with extrahepatic metastases found on initial evaluation can be successfully treated with liver transplantation if the metastatic disease is eradicated before the transplant. Hepatoblastoma commonly metastasizes to the lungs, and lung metastases are often present at diagnosis. Because this tumor tends

to be chemoresponsive, these metastases will often disappear after the first several rounds of chemotherapy. If the pulmonary metastases do not resolve, then current data would suggest that these patients should undergo a metastasectomy for any remaining disease, either before or shortly after resection and before consideration for transplantation. This approach has been successful in increasing patient survival.<sup>233,234</sup> Unfortunately the data on resection of pulmonary recurrences are less optimistic. There may be a role for resection of late pulmonary metastasis in patients who presented with stage I disease. However, pulmonary relapse in stage III and IV disease portends a poor prognosis that is not changed by lung resection.

## Undifferentiated Embryonal Sarcoma

### Incidence

Undifferentiated embryonal sarcoma of the liver makes up about 7% of the solid liver tumors in children.<sup>1</sup> Unfortunately, this is a very malignant tumor with a poor outcome.

### Clinical Presentation

Undifferentiated embryonal sarcoma most commonly affects children between the ages of 6 and 10 years but has been reported in a child as young as 19 months.<sup>235</sup> A slight male predominance has been noted. The most common clinical presentation is either right upper quadrant or epigastric pain with or without a palpable abdominal mass. Occasionally, marked hepatomegaly is seen without a definite mass. Rarely, this tumor can even masquerade as a hepatic abscess or infection.<sup>236</sup> Other nonspecific presenting complaints can include vomiting, anorexia, and lethargy. Laboratory studies, including AFP level, are usually normal.

### Imaging

On ultrasound examination, the lesion appears predominantly solid.<sup>237</sup> However, on CT and MRI, the lesion appears cystic without any significant solid component (Fig. 69-16). This same type of disparity has been reported only in Wilms' tumor metastatic to the liver. Thus, it appears that such a discrepancy between the two imaging techniques would be highly suggestive of an undifferentiated embryonal sarcoma.

### Pathology

Undifferentiated embryonal sarcoma is a neoplasm with a very primitive mesenchymal phenotype. These tumors tend to occur predominantly in the right lobe of the liver and to be large, with an average diameter of 14 to 21 cm.<sup>237</sup> In cross section, the tumors are often variegated, with white mucoid or gelatinous areas alternating with other areas of tumor necrosis and hemorrhage (Fig. 69-17). The tumor typically is well demarcated from the adjacent liver by a compressed, fibrous pseudocapsule.<sup>235</sup>

**Figure 69-16.** CT scan of an undifferentiated embryonal sarcoma after intravenous administration of a contrast agent shows a hypodense area (*arrow*) in the right lobe of the liver.

On microscopic section, these tumors are composed of medium to large spindle- to stellate-type cells in a variable amount of myxoid stroma (Fig. 69-18). The cells are usually densely arranged in a myxomatous background. In the periphery, entrapped bile ducts or hepatic cords have been noted.<sup>1,235</sup> Mitoses are frequent and usually bizarre.

No characteristic immunohistochemical stain pattern has been identified for embryonal sarcoma.<sup>238</sup> The only consistent cell markers have been vimentin and the “histiocytic” determinants  $\alpha_1$ -antitrypsin and  $\alpha$ -antichymotrypsin.<sup>239,240</sup>

In a cytogenetic study, extensive chromosomal rearrangements were noted to be very similar to other soft tissue sarcomas such as leiomyosarcoma, osteosarcoma, and malignant fibrous histiocytoma.<sup>241</sup> In only a few cytometric studies, the findings have ranged from diploidy to tetraploidy to aneuploidy.<sup>242,243</sup>

**Figure 69-17.** Note the variegated appearance on cut section of an undifferentiated embryonal sarcoma.

**Figure 69-18.** Histology of undifferentiated embryonal sarcoma shows large spindle cells with multiple mitoses.

### Treatment

In addition to the highly suggestive radiologic findings, these patients can be diagnosed by fine-needle aspiration. Two separate reports have noted that the cytologic features of undifferentiated embryonal sarcoma are distinctive and different from other childhood tumors.<sup>244,245</sup>

The initial experience with undifferentiated embryonal sarcoma of the liver was poor. In a review of patients treated from 1950 to 1988, only 37% of the patients were noted to be alive.<sup>243</sup> This tumor usually proves fatal because of massive upper abdominal growth with secondary involvement of the diaphragm, stomach, abdominal wall, ribs, or pancreas rather than by metastases. Occasionally, intra-abdominal dissemination of the tumor can occur, causing diffuse matting of the small bowel. Pulmonary and pleural metastases have been noted but are much less common than the secondary involvement of the extrahepatic tissue by direct extension.<sup>235</sup>

The only chance for cure is radical excision.<sup>246,247</sup> Unfortunately, despite complete surgical resection of the tumor, many patients have recurrent disease, which suggests the need for postoperative chemotherapy.<sup>248</sup>

The chemotherapy regimens that have been used are based on nonrhabdomyosarcomatous soft tissue sarcoma-type protocols.<sup>249</sup> With these regimens, survival rates have improved to 66%, because these tumors are very chemotherapy sensitive.<sup>250,251</sup> This finding has led to the use of preoperative chemotherapy to shrink an unresectable tumor to a size at which a radical hepatic resection is possible.<sup>252</sup> This is similar to the approach used to manage an initially nonresectable hepatoblastoma.

With the ongoing improvement in chemotherapy regimens for sarcomas, the previously bleak outlook for this tumor is now much more optimistic. The use of an aggressive chemotherapy regimen, along with complete resection of the primary tumor, has resulted in a 37% survival rate in patients whose tumors initially presented as free intraperitoneal rupture.<sup>251</sup>

In patients in whom complete resection of the tumor is not possible despite chemotherapy, liver transplantation has been advocated as another possible means

for complete excision. This aggressive approach is not completely unwarranted because these tumors are sensitive to chemotherapy. This approach is analogous to patients with hepatoblastoma who have chemotherapy-responsive tumors.

## Hepatocellular Carcinoma

Hepatocellular carcinoma is a relatively rare, highly malignant tumor that is more commonly seen in adults than in children. It is the second most common pediatric liver tumor, occurring about 19% of the time, but it still comprises less than 1% of all pediatric cancers.<sup>253</sup> Its peak incidence seems to be between 10 and 15 years, and it is more common in boys.<sup>254</sup>

The predisposing factors for hepatocellular carcinoma are distinctly different between the pediatric and the adult population. In the adult population, cirrhosis seems to be the primary etiology. The cirrhosis is usually seen in patients with either hepatitis B, hepatitis C, genetic hemochromatosis, alcohol-related cirrhosis, or cirrhosis due to primary biliary cirrhosis. In a recent review, it was noted that patients in these groups were at a significantly increased risk for developing hepatocellular carcinoma.<sup>255</sup> Hepatic ultrasonography and serum AFP evaluations every 6 months were recommended to detect this tumor at an early stage.

In contrast, cirrhosis is often not part of the antecedent process in children. Moreover, a previous congenital or acquired disorder of the liver may be found (Table 69-7).<sup>256</sup> Hepatocellular carcinoma in children has been associated with a variety of metabolic, familial, and infectious disorders. Some of these metabolic disorders include tyrosinemia,  $\alpha_1$ -antitrypsin deficiency, and hemochromatosis.<sup>257</sup> Patients with tyrosinemia seem to be at a particularly high risk for development of hepatocellular carcinoma. Because of this high prevalence rate, it has been suggested that liver transplantation be performed in this population before age 2 years.<sup>258,259</sup> Hepatocellular carcinoma also has been seen in patients with type 1 GSD. Most hepatic masses that develop in this population are hepatic adenomas, but carcinomas do present a real risk in this group.<sup>260</sup> A variety of other noncirrhotic liver diseases also have been associated with hepatocellular carcinoma, including familial polyposis, Gardner's syndrome, Sotos' syndrome, Blum's syndrome, neurofibromatosis, Abernathy's malformation, methotrexate therapy, and neonatal hepatitis. There is also an association with parenteral nutrition.<sup>261-266</sup>

Congenital and infectious disorders also are associated with this tumor, including extrahepatic biliary atresia, congenital hepatic fibrosis, Alagille syndrome, persistent familial intrahepatic cholestasis (PFIC),<sup>267</sup> hepatitis B, and hepatitis C. In areas where hepatitis B is endemic, it ranks fifth in the causes of childhood malignancies and outnumbers hepatoblastoma by 3:1.<sup>268</sup> The importance of hepatitis B and the subsequent development of hepatocellular carcinoma in children is highlighted by the aggressive hepatitis B vaccination program that began in 1984 in Taiwan.<sup>269</sup> When the mortality from liver carcinoma in the group

from birth to age 9 years was compared between the years 1984 and 1993, a substantial and statistically significant decrease in the mortality was seen by 1993. Another study from Gambia showed similar results.<sup>270</sup> Hepatitis C also has been linked to the development of hepatocellular carcinoma.<sup>271</sup> In contrast to hepatitis B, the cirrhosis and the subsequent development of hepatocellular carcinoma in the hepatitis C population usually takes several decades to develop.<sup>272</sup>

Of particular interest is the association between hepatocellular carcinoma and biliary atresia.<sup>254,273</sup> In a review, except for one patient first seen at age 5 months, all the other patients were older than 2 years with a mean of age 7.5 years when the hepatocellular carcinoma was discovered. These tumors were found either at autopsy or incidentally at the time of liver transplantation for biliary atresia. In those patients in whom hepatocellular carcinoma was identified at the time of transplantation, all of these patients are alive and well after transplant. This association between hepatocellular carcinoma and biliary atresia, or any other disease that would lead to hepatic cirrhosis, would suggest that a routine screening protocol every 6 months with hepatic ultrasonography and determination of AFP levels is warranted.<sup>274</sup>

### Clinical Presentation

Most patients are initially seen with either an abdominal mass or abdominal pain. Other associated symptoms include nausea and vomiting, anorexia, malaise, and a significant weight loss.<sup>268</sup> As many as 10% are seen primarily with tumor rupture and hemoperitoneum.<sup>275</sup> More than one third of hepatocellular

carcinomas appear as multiple nodules rather than a single tumor.<sup>276</sup>

Laboratory studies can show mild elevations in the serum glutamic oxaloacetic transaminase (SGOT) and lactic dehydrogenase (LDH) levels. The AFP is elevated in about 85% of patients but can be normal or only mildly elevated with the fibrolamellar variant.<sup>275,277</sup> An elevated AFP is associated with an increased risk for recurrence after resection and therefore reflects a poorer prognosis.<sup>278,279</sup>

### Imaging

CT and MRI are both helpful for delineating the mass and for determining resectability. With the advent of spiral CT with intravenous bolus contrast administration, the hepatic veins and portal venous system can be well delineated, and any tumor involvement can be adequately assessed. The American Association for the Study of Liver Diseases has published criteria for the noninvasive diagnosis of hepatocellular carcinoma. In nodules less than 2 cm in diameter in cirrhotic livers, the diagnosis of hepatocellular carcinoma can be made without biopsy of the lesion if two coincidental dynamic imaging studies (e.g., CT/MRI) reveal arterial-phase hypervascularity followed by wash-out in the portal venous phase.<sup>280</sup> The fibrolamellar variant is notable as a hypodense, single or multilobed mass on CT that tends to be hypervascular as well as sometimes showing a central scar.<sup>281</sup> This appearance could easily be confused with FNH, and care must be taken to distinguish between these two lesions.

### Pathology

Hepatocellular carcinoma can vary in size from 2 to 25 cm, and the surrounding liver can exhibit either micro- or macronodular cirrhosis in up to 60% of cases (Figs. 69-19 and 69-20).<sup>1</sup> Microscopically, trabeculae that are 2 to 10 cell layers in thickness are seen with the larger trabeculae sometimes displaying central necrosis. The individual cells are usually larger than normal hepatocytes, with nuclear hypochromasia and frequent and bizarre mitosis (Fig. 69-21). Vas-

**Figure 69-19.** Hepatocellular carcinoma in the setting of cirrhosis.

**Figure 69-20.** This histologic photomicrograph shows hepatocellular carcinoma with surrounding cirrhosis (arrow) and uninvolved liver (asterisk).

cular invasion may be prominent. Tumors less than 2 cm generally are well differentiated. Over time, as the tumor grows, the original tumor cells are replaced by poorly differentiated cell clones.<sup>282</sup> Moreover, as the tumor enlarges, its blood supply becomes more dependent on newly formed arterial vessels and less dependent on the portal circulation. This imbalance between the hepatic arterial and portal venous supply leads to the hypervascular pattern that is the radiologic hallmark for hepatocellular carcinoma.

In the fibrolamellar variant, the hepatocytes are large, deeply eosinophilic, and embedded within a lamellar fibrosis. Clusters of cells are often separated by broad bands of laminated collagen.<sup>1,283</sup> The presence of large amounts of fibrosis alone is not sufficient in itself for the diagnosis of fibrolamellar carcinoma.<sup>284</sup>

### Treatment

The treatment of hepatocellular carcinoma is surgical resection, varying from a simple anatomic resection to a liver transplant. Unfortunately, primary resection is not always possible because either the tumor is bilobar or the tumor is associated with cirrhosis. Because of the cirrhosis, concern may exist that the hepatic resection might leave the patient with insufficient functioning parenchyma.

In one pediatric report of 49 children, resection was possible in only 10%. Only 2 patients lived for more than 2 years.<sup>268</sup> If a complete, microscopically free, radical resection is possible, the prognosis can be good, with an 80% to 90% survival.<sup>285</sup> Unfortunately, the overall cure rate for this tumor in children is a dismal 15%. In the adult population, 3-year survival rates between 34% and 57% have been reported.<sup>286,287</sup> Multiple studies have looked at prognostic factors that influence outcome and recurrence after resection for hepatocellular carcinoma. Multiple staging systems have been proposed based on multivariate analyses of various prognostic factors. Three factors that have been repeatedly associated with improved survival and decreased recurrence rates are small tumor size

**Figure 69-21.** Histology of a hepatocellular carcinoma demonstrating enlarged hepatocytes and nuclear hyperchromasia.

(<2 cm), the number of tumor nodules, and a histologic increase in tumor microvascular density. These findings are highly predictive of tumor relapse after resection.<sup>288</sup> Unfortunately, it is rare to see patients initially with all three favorable variables. In most series, the tumors are usually larger than 5 cm in diameter at presentation.<sup>286,289</sup>

An important variant that should be mentioned is the fibrolamellar type. Only in the 1980s did this variant become established as a histologic and clinically distinct entity.<sup>290</sup> This lesion is characterized by relatively slow growth and occurs almost exclusively in a noncirrhotic liver.<sup>283</sup> The fibrolamellar variant usually occurs in adolescents and young adults, with a peak incidence in the second decade of life.<sup>291,292</sup> It accounts for between 16% and 50% of the hepatocellular carcinoma diagnosed in patients younger than 21 years of age.<sup>293</sup> In contrast to conventional hepatocellular carcinoma, fibrolamellar carcinoma is not associated with risk factors such as cirrhosis or chronic hepatitis B infection.<sup>294,295</sup> However, an association does exist between FNH and the fibrolamellar variant.

Radiologically, the fibrolamellar variant is often hypodense on noncontrast CT and can show a variable perfusion, including hypervascularity, on contrast CT. In addition, a central hypodense or hypervascular area can be seen that can mimic a central scar.<sup>296</sup> This can create confusion between the diagnosis of the fibrolamellar variant and FNH. MRI has been reported to be helpful in distinguishing between these two diagnoses.<sup>297</sup> The results after resection for fibrolamellar carcinoma in adults are very good, with 50% 5-year survivals. However, after apparent curative resections, recurrences or metastases can occur after very long disease-free intervals.<sup>298,299</sup> Unfortunately when the fibrolamellar variant was examined in children, there was no survival benefit to this diagnosis.<sup>221</sup>

### Transplantation for Hepatocellular Carcinoma

Liver transplantation has been used as curative therapy for the treatment of hepatocellular carcinoma. The early experience of liver transplantation in adults for hepatocellular carcinoma was discouraging.<sup>300</sup> However, in

a review of 344 patients who underwent liver transplantation for hepatocellular carcinoma (excluding the fibrolamellar type), three factors were associated with tumor-free survival: a unilobar tumor, a tumor smaller than 2 cm, and the absence of vascular invasion.<sup>301</sup> Two different pretransplant selection criteria are currently being utilized in adults (Table 69-8).

The Milan criteria are widely recognized as excellent predictors of a low recurrence rate after transplantation.<sup>302</sup> These criteria, however, have not been verified in the pediatric population, and their applicability in children has been questioned.<sup>303</sup> Because hepatocellular carcinoma can be a rapidly growing tumor, frequently by the time an organ becomes available the tumor has exceeded these criteria and the patient is no longer a candidate for transplant. The University of California at San Francisco criteria are an attempt to allow an increased pretransplant tumor burden and still have a low post-transplant recurrence rate. Several studies have supported this hypothesis.<sup>304,305</sup>

Currently there are two contraindications to transplantation for hepatocellular carcinoma in children: extrahepatic spread and macroscopic vascular invasion.<sup>231</sup> The SIOPEL-1 study reported no long-term survivors among those who failed to respond to chemotherapy.<sup>306</sup> Therefore, the lack of response to preoperative chemotherapy is a relative contraindication to transplantation. Despite these possible limitations, liver transplantation in children for hepatocellular carcinoma has a very good 5-year survival rate between 63% and 89%.<sup>231,307</sup> To transplant both adults and children quickly, patients are given additional points in the United Network for Organ Sharing (UNOS) matching system so they can be transplanted before the tumor progresses.

Interestingly, in contrast to patients with hepatoblastoma, several studies have shown that liver transplantation is an appropriate salvage procedure for patients with hepatocellular carcinoma who experience a recurrence after a resection. Their post-transplant survival is comparable to that of patients who underwent primary transplantation for hepatocellular carcinoma.<sup>308,309</sup>

Chemotherapy for hepatocellular carcinoma has not appeared to be beneficial in adults when given either before or after resection or transplant. Postresection chemotherapy has been uniformly ineffective in preventing or treating recurrences in the Pediatric Oncology Group (POG), SIOPEL, and German studies.<sup>306,310-312</sup>

**Table 69-8** Milan and UCSF Transplant Criteria for Hepatocellular Carcinoma

	Milan Criteria	UCSF Criteria
<b>Single Tumor Maximum Diameter</b>	≤5.0 cm	≤6.5 cm
<b>Maximum Number</b>	3	3
<b>Largest Tumor Size</b>	≤3.0 cm	≤4.5 cm
<b>Total Tumor Size</b>	NA	≤8.0 cm

NA, not applicable; UCSF, University of California at San Francisco.

New chemotherapeutic approaches are needed for this tumor, and currently studies are being planned that will combine chemotherapeutic agents with antiangiogenic agents. However, in two small series, chemotherapy was given to children with unresectable hepatocellular carcinomas before transplant. Eighty percent of these children had a dramatic decrease in their tumor size.<sup>253,313</sup> At the time of transplant, all tumors still had viable cells but only one patient after transplant had a recurrence and subsequently died.

Patients who are not surgical or transplant candidates, patients who demonstrate recurrences, or patients who are on the transplant list and their tumors have grown to the point that they exceed the Milan criteria can potentially benefit from several nonsurgical strategies, including percutaneous ethanol injection, radiofrequency ablation, or chemoembolization of the hepatic mass.<sup>314</sup> All of these therapies have proved efficacious in decreasing or eradicating localized tumors, treating recurrent tumors, or shrinking tumors so that the patient again falls within the transplant criteria.<sup>315</sup> These therapies also improved survival with this tumor, but unfortunately, none has been proved to be curative.<sup>255</sup>

A catastrophic presentation of hepatocellular carcinoma is spontaneous rupture. These patients present with acute right upper quadrant pain and hypovolemic shock. The diagnosis can be made with ultrasonography or abdominal CT. In the hemodynamically stable patient, the treatment is conservative with correction of volume status and correction of any coagulopathy. Then a careful assessment of the tumor needs to be made with the goal of primary resection of the tumor. If the patient is hemodynamically unstable, then transarterial embolization of the tumor should be done to control the hemorrhage. After the patient's condition has stabilized, he or she needs to be evaluated for a resection.<sup>316</sup>

The outcome for patients with hepatocellular carcinoma, regardless of the treatment modality, is still not as good as the outcome for hepatoblastoma. Further improvements in survival for hepatocellular carcinoma will come from advances in chemotherapy regimens that will prevent tumor recurrences.

## Rhabdomyosarcoma of the Biliary Tree

### *Incidence and Clinical Presentation*

Even though rhabdomyosarcoma is the most common sarcoma in children, it accounts for only 1% of all liver tumors and only 0.8% of all rhabdomyosarcomas in children.<sup>1,317</sup> Hepatobiliary rhabdomyosarcoma tends to be a disease of the young, with a median age of 3 years. It is rarely seen in children older than 15 years.<sup>318,319</sup> This tumor most commonly arises in the intrahepatic biliary system and then extends into the liver parenchyma itself. It also has been reported to arise from a variety of other sites, including an intrahepatic cyst, the gallbladder, the cystic duct, the ampulla of Vater, a choledochal cyst, and the hepatic parenchyma itself.<sup>318-324</sup>

Because it arises most commonly from the bile ducts, the most common presenting symptom is jaundice. Because the median tumor diameter at diagnosis is 8 cm, an abdominal mass is a common finding.<sup>317</sup>

### *Laboratory Findings and Differential Diagnosis*

Because jaundice is a common presenting symptom, elevated direct bilirubin, alkaline phosphatase, and  $\gamma$ -glutamyltransferase (GGT) levels are common. The differential diagnosis for an intraductal lesion in a child would include either an inflammatory pseudotumor or a cholangiocarcinoma, but these are extraordinarily rare.<sup>325</sup> If the rhabdomyosarcoma is a predominantly hepatic mass with minimal bile duct involvement, then the differential diagnosis would be more dependent on the patient's age, as noted in the previous sections.

The pathology of the intraductal lesions is similar to that of rhabdomyosarcoma at extrabiliary sites. The intraductal tumor is usually either the botryoid or embryonal subtype, unless the lesion involves predominantly the hepatic parenchyma, in which the alveolar subtype predominates.<sup>326</sup>

### *Imaging*

Multiple imaging modalities have been used for diagnosis. Ultrasonography typically reveals biliary dilatation and possibly a mass in the biliary system. Larger lesions may have cystic areas within them, possibly reflecting areas of partial tumor necrosis.<sup>177</sup> CT will often show an intraductal mass in association with areas of low attenuation within the tumor. MRI may have an advantage over CT in that it not only can show the anatomic source and location of the mass but, with the advent of MR cholangiography, also can evaluate the bile ducts by demonstrating biliary dilatation and intraductal irregularity.<sup>327</sup> Percutaneous transhepatic cholangiography (PTC) also can be useful in patients who have a dilated biliary system. PTC can demonstrate multiple filling defects that correspond to the intraductal tumor.<sup>328</sup> PTC also has the advantage of providing external drainage of the biliary system in those patients with obstructive jaundice.

### *Treatment and Prognosis*

The best treatment for biliary rhabdomyosarcoma is a multidisciplinary approach using surgical procedures, chemotherapy, and, potentially, radiation therapy. Unfortunately, surgical resection alone is not usually possible because of spread of the tumor into the liver parenchyma or direct local extension into the duodenum, stomach, or pancreas. It is common to find lymphatic spread at the initial operation. Because of these problems, adequate resection is usually possible in only 20% to 40% of the patients.<sup>317-319</sup> In patients in whom primary resection is not possible, the initial approach should be biopsy and lymph node sampling, followed by standard rhabdomyosarcoma chemotherapy protocols and a second-look procedure. In a study of biliary rhabdomyosarcoma that used

# TERATOMAS, DERMoids, AND OTHER SOFT TISSUE TUMORS

Jean-Martin Laberge, MD • Pramod S. Puligandla, MD • Kenneth Shaw, MD

## TERATOMAS

Teratomas are generally divided into gonadal and extragonadal types. The focus of this discussion is on those in extragonadal locations, the most common being sacrococcygeal teratomas.

### Embryology and Pathology

Teratoma, from the Greek *teras* (“of the monster”) and *onkoma* (“swelling”), is a term first applied by Virchow in 1869 to “sacrococcygeal growths.”<sup>1</sup> Teratomas are composed of multiple tissues foreign to the organ or site from which they arise.<sup>2</sup> Although teratomas are sometimes defined as having the three embryonic layers (endoderm, mesoderm, and ectoderm), recent classifications also include monodermal types.<sup>2,3</sup>

Teratomas are thought by some to arise from totipotent primordial germ cells.<sup>3,4</sup> These cells develop among the endodermal cells of the yolk sac near the origin of the allantois and migrate to the gonadal ridges during weeks 4 and 5 of gestation (Fig. 70-1).<sup>5</sup> Some cells may miss their target destination and give rise to a teratoma anywhere from the brain to the coccygeal area, usually in the midline. Another theory has teratomas arising from remnants of the primitive streak or primitive node.<sup>5-7</sup> During week 3 of development, midline cells at the caudal end of the embryo divide rapidly and, in a process called gastrulation, give rise to all three germ layers of the embryo (Fig. 70-2).<sup>5</sup> By the end of week 3, the primitive streak shortens and disappears. This theory would explain the more common occurrence of teratomas in the sacrococcygeal region. With either theory, the totipotent cells could give rise to monoclonal neoplasms. Recent evidence shows that, whereas immature teratomas may be monoclonal, mature teratomas can be polyclonal, more like a hamartoma than a neoplasm.<sup>8</sup> This finding is compatible with the third theory that teratomas are a form of incomplete twinning.<sup>2,3</sup>

The primordial germ cell is the principal but probably not the exclusive progenitor of a teratoma.<sup>2</sup> The recent trend is to include teratomas under the classification of germ cell tumors.<sup>2-4</sup> This histologic classification also includes germinomas (formerly dysgerminomas), embryonal carcinomas, yolk sac tumors, choriocarcinomas, gonadoblastomas, and mixed germ cell tumors. Gonadal and extragonadal teratomas may have a different origin, explaining the different behavior according to tumor site.

Teratomas are fascinating tumors owing to the diversity of tissues they may contain and the varying degree of organization of these tissues. Many tumors contain skin elements, neural tissue, teeth, fat, cartilage, and intestinal mucosa, often with normal ganglion cells. These tissues are usually present as disorganized islands of cells with cystic spaces. The tumor sometimes consists of more organized tissue, such as small bowel, limbs, and even a beating heart. These have been called fetiform teratomas (Fig. 70-3).<sup>2,3,6,9,10</sup> When the mass includes vertebrae or notochord and a high degree of structural organization, the term *fetus-in-fetu* is used. This is viewed by some as a variant of conjoined twinning but is classified as a teratoma by others, owing to the absence of a recognizable umbilical cord in its vascular pedicle.<sup>3,11</sup> Whether teratomas are at one end of a spectrum that includes fetus-in-fetu, parasitic twins, conjoined twins, and normal twins is the subject of controversy.<sup>3</sup> One certainly cannot dismiss the many reports of teratomas associated with fetus-in-fetu in the same patient and with a twin pregnancy.<sup>2,3,12-14</sup>

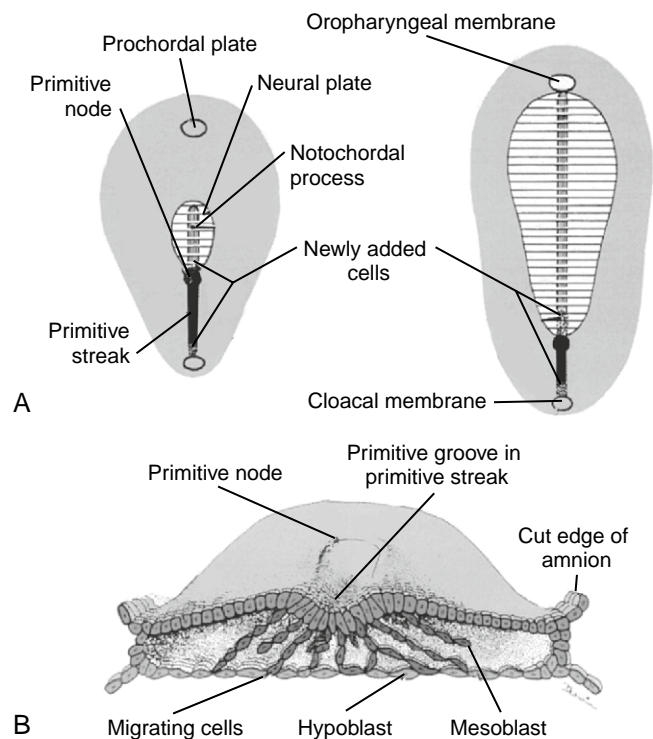

The overall tissue architecture is variable in teratomas. Moreover, a spectrum of cellular differentiation exists. Most benign teratomas are composed of mature cells, but 20% to 25% also contain immature elements, most often neuroepithelium.<sup>2-4</sup> The degree of histologic immaturity is of proven prognostic significance only in ovarian teratomas.<sup>3,15</sup> Even this concept is being questioned since one large cooperative study demonstrated that overlooked microscopic foci

**Figure 70-1.** Commonly cited theory on the origin of teratomas. **A**, Drawing of embryo during week 4 (longitudinal section), showing primordial germ cells at the base of the yolk sac. **B** and **C**, During week 5, these cells migrate toward the gonadal ridges. According to this theory, some cells could miss their intended destination. (Modified from Moore KL, Persaud TVN: *The Developing Human*. Philadelphia, WB Saunders, 1993, pp 71, 181.)

of yolk sac tumor, rather than the grade of immaturity, was predictive of recurrence.<sup>16</sup> In neonatal teratoma, immature tissue is considered normal and without any influence on prognosis.<sup>2,6</sup> Spontaneous maturation of malignant tumors has been reported after partial excision of giant sacrococcygeal teratomas in two fetuses at 23 and 27 weeks of gestation.<sup>17</sup>

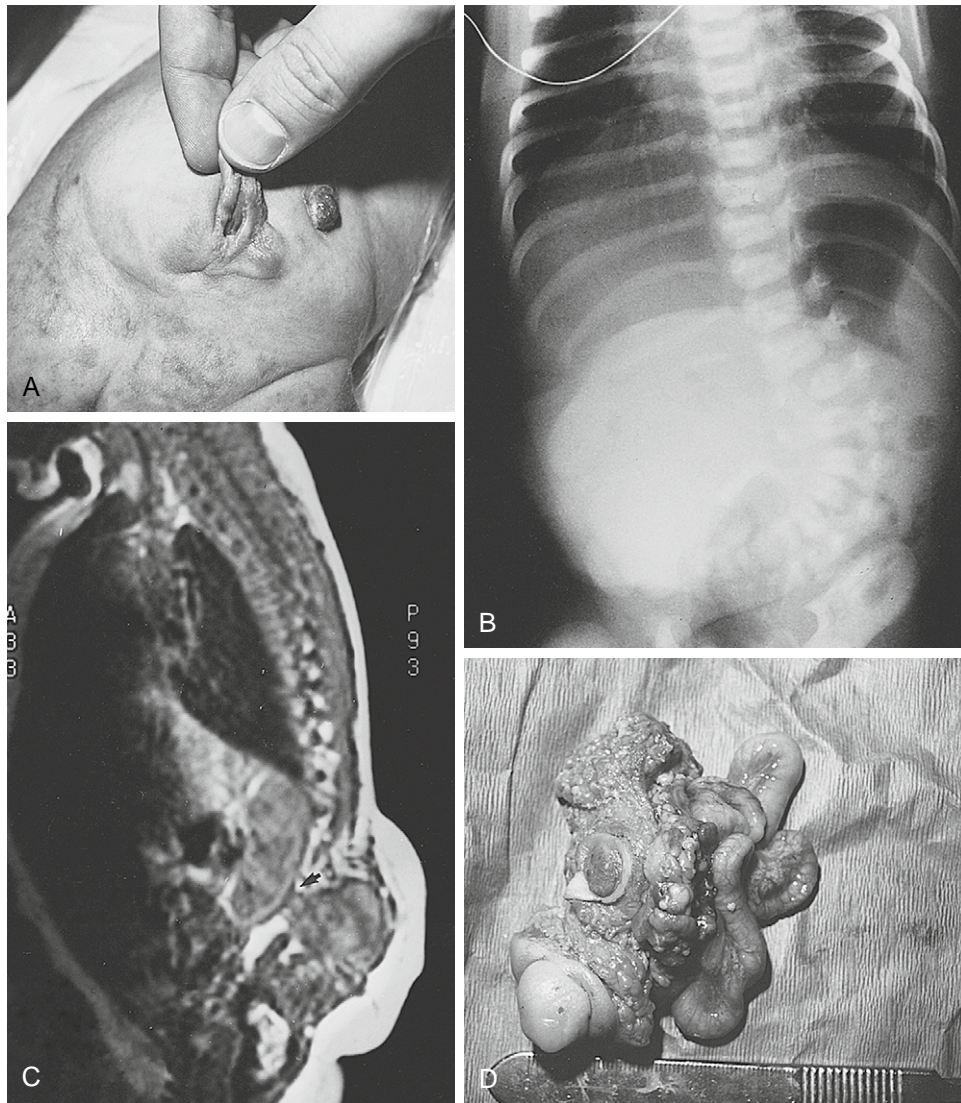

Teratomas may also contain or develop foci of malignancy. A malignant germ cell tumor may be found in sites typical for teratomas, such as the mediastinum or sacrococcygeal area. Whether the lesion was malignant from the onset or the malignant cells destroyed and replaced the benign teratoma component is often difficult to differentiate. The most common malignant

**Figure 70-2.** Alternate theory on embryogenesis of teratomas. **A**, Sketches of dorsal views of the embryonic disk on days 17 and 18, showing the primitive streak and primitive node. **B**, Drawing of a transverse cut of the embryonic disk during week 3. This shows that cells from the primitive streak migrate to form the mesoblast (the origin of all mesenchymal tissues) and also displace the hypoblast to form the endoderm. Hence, remnants of these pluripotent primitive streak cells could give rise to teratomas and could account for the more frequent sacrococcygeal location. (From Moore KL, Persaud TVN: *The Developing Human*. Philadelphia, WB Saunders, 1993, pp 55-56.)

component within a teratoma is a yolk sac tumor, also called an endodermal sinus tumor. Other malignant germ cell tumors can occur, and, rarely, malignancy of other tissues composing the teratoma, such as neuroblastoma,<sup>18,19</sup> squamous cell carcinoma,<sup>20</sup> carcinoid,<sup>21</sup> and others can develop. Malignancy at birth is uncommon but increases with age and with incomplete resection. An apparently mature teratoma may recur several months or years after resection as a malignant yolk sac tumor, illustrating the difficulties in histologic sampling of large tumors and the need for close follow-up.<sup>2,3</sup>

Most yolk sac tumors and some embryonal carcinomas secrete  $\alpha$ -fetoprotein (AFP), which can be measured in the serum and demonstrated in the cells by immunohistochemistry.<sup>22</sup> This marker is particularly useful for assessing the presence of residual or recurrent disease. AFP levels are normally very high in neonates and decrease with time.<sup>22,23</sup> The post-operative half-life is about 6 days. Persistently high levels may be an indication for the need for further surgical procedures or chemotherapy. Other markers that may be elevated are  $\beta$ -human chorionic gonadotropin ( $\beta$ -hCG), produced by choriocarcinomas, and, rarely, carcinoembryonic antigen. Secretion of  $\beta$ -hCG

**Figure 70-3.** **A**, This child had a large fluctuant lumbar mass at birth. A family history of myelomeningocele existed in a great aunt. She also had an atrophic right leg with neurologic impairment below the L3 root and clubbing of the right foot. Note the ulcerated, arachnoid-looking area cranially and the pedunculated skin caudally, which had the appearance of a vulva and was oozing serous fluid. **B**, Plain radiograph shows a severe lumbosacral scoliosis with vertebral anomalies. CT confirmed the vertebral anomalies with spina bifida and demonstrated a pattern of intestine with inspissated or calcified meconium in the teratoma. **C**, MR image reveals that the mass extended into the retroperitoneum, where it was contiguous with the lower pole of the right kidney (*arrow*). **D**, At operation, normal-looking blind bowel loops were found deep to the vulva-like structure. Part of the mass extended along the spinal cord, which required dissection and untethering by a neurosurgeon. The pathologic diagnosis was a mature fetiform teratoma that contained, among many other things, two adrenals, two ovaries, renal tissue with some glomeruli and tubules, bone with bone marrow, and portions of stomach and small and large bowel. The child recovered well neurologically but required spinal instrumentation owing to progressive scoliosis at age 2 years.

by the tumor may be sufficient to cause precocious puberty.<sup>24</sup>

The genetic basis of teratomas is not yet understood. Most germ cell tumors appear to have an amplification, or isochromosome, in a region of the short arm of chromosome 12, designated *i*(12p).<sup>3,4,25</sup> This has been well described in adults but was not confirmed in one pediatric series in which deletions on chromosomes 1 and 6 were found instead.<sup>26</sup> Similarly, oncogenes and tumor suppressor genes did not appear to correlate with prognosis in one study.<sup>27</sup> *MYCN* gene amplification was present in immature teratomas but absent in mature teratomas in another report.<sup>28</sup> *BAX* mutation

and overexpression correlated with survival in childhood germ cell tumors.<sup>29</sup> The clinical usefulness of these findings remains unclear.

### Associated Anomalies

Teratomas are usually isolated lesions. A well-recognized association is the Currarino triad of ano-rectal malformation, sacral anomaly, and a presacral mass.<sup>30,31</sup> The presacral mass is usually a teratoma or an anterior meningocele. However, hamartomas, duplication cysts, and dermoid cysts have been described, as have combinations of these lesions.

An extensive review of the English and German literature published in 1989<sup>32</sup> found 51 cases of infants with the Currarino triad and highlighted several important facts. Twenty percent of patients were older than 12 years at the time of diagnosis, yet no reports of malignancy were found. This contrasts to a 75% malignancy rate in patients older than 1 year who had the usual sacrococcygeal teratoma.<sup>33</sup> Later, a case report of a child with severe anal stenosis and a presacral teratoma without a sacral bony defect described a malignant recurrence that subsequently resulted in the patient's demise at 4 years of age despite chemotherapy.<sup>34</sup> Subsequently, more reports of malignant transformation of a presacral teratoma in the context of the Currarino triad have appeared, and the risk of malignant transformation has been estimated at 1%.<sup>35,36</sup> Hence, one should not dismiss the presacral mass as always benign in these patients. The female preponderance for patients with this triad is only 1.5:1, which is less than the 3:1 ratio noted in isolated sacrococcygeal teratomas. A familial predisposition, first recognized in 1974,<sup>37</sup> is noted in 57% of cases and has an autosomal dominant inheritance pattern. Although all variants of anorectal malformations have been described, by far the most common is anal or anorectal stenosis. In one report, this triad was present in 38% of all patients with anorectal stenosis and in 1.6% of patients with low imperforate anus.<sup>38</sup>

Anal anomalies also have been reported in conjunction with a presacral mass, but in the absence of sacral defects. Hirschsprung's disease has been incorrectly diagnosed in some cases,<sup>4,39,40</sup> indicating the need to eliminate the presence of a presacral mass by digital rectal examination, by a metal sound when the anus is too tight, or by imaging techniques. In the screening of family members, normal plain radiographs of the sacrum are not adequate, because a presacral mass may exist in the absence of a bony defect.<sup>41</sup> The low incidence of malignancy has led one author to conclude that the presacral lesion in this context is a hamartoma rather than a teratoma.<sup>42</sup> This is supported by the demonstration of deletions or mutations of the homeobox gene *HLXB9*, located at 7q36, in several affected families.<sup>43</sup> In one recently reported family, no deletions of 7q could be detected, but the authors did not comment about *HLXB9* mutations.<sup>44</sup> However, in another family with proven *HLXB9* mutation, one affected member died at 22 years-of-age from a metastatic neuroendocrine tumor, likely originating from the presacral teratoma.<sup>35</sup>

Urogenital anomalies, such as hypospadias, vesicoureteral reflux, vaginal or uterine duplications, and other anomalies are associated with teratomas.<sup>31,33,45</sup> Congenital dislocation of the hip has been found in 7% of patients with sacrococcygeal teratomas, drawing attention to vertebral anomalies and late orthopedic sequelae (see Fig. 70-3).<sup>46</sup> Central nervous system lesions, such as anencephaly, trigonocephaly, Dandy-Walker malformations, spina bifida, and myelomeningocele, may occur.<sup>2,3,47-49</sup> Another peculiar association with sacrococcygeal teratomas is a family history of

twins in as many as 10% of the patients.<sup>37,50,51</sup> Although not confirmed in all series, this finding, combined with reports of simultaneous twin pregnancy or sequential familial occurrences of fetus-in-fetu and teratoma, supports the theory that teratomas are just one end of the spectrum of conjoint twinning.<sup>2,3,10,12,14</sup>

Klinefelter's syndrome is strongly associated with mediastinal teratoma<sup>52</sup> and has been reported in patients with intracranial<sup>53</sup> or retroperitoneal tumors.<sup>54,55</sup> It is estimated that 8% of male patients with primary mediastinal germ cell tumors have Klinefelter's syndrome, which is 50 times the expected frequency.<sup>52</sup> These tumors are often malignant, are of the choriocarcinoma type, secrete  $\beta$ -hCG, and produce precocious puberty. Histiocytosis is also associated with mediastinal teratoma, both with<sup>56,57</sup> and without Klinefelter's syndrome.<sup>58</sup> Other hematologic malignancies, such as acute leukemias<sup>59,60</sup> and Hodgkin's disease,<sup>61,62</sup> occur rarely.

The following rare associations have been reported, most often with nonsacrococcygeal lesions: trisomy 13,<sup>63</sup> trisomy 21, Morgagni hernia,<sup>64</sup> congenital heart defects,<sup>47,48</sup> Beckwith-Wiedemann syndrome,<sup>65</sup> pterygium,<sup>66</sup> cleft lip and palate,<sup>47</sup> and rare syndromes, such as Proteus<sup>67</sup> and Schinzel-Giedion syndromes.<sup>68</sup>

## Diagnosis and Management by Tumor Site

### Sacrococcygeal Teratoma

Sacrococcygeal teratomas account for 35% to 60% of teratomas (gonadal included) in large series (Table 70-1).<sup>69-71</sup> This is the most common tumor in the newborn, even when stillbirths are considered.<sup>47</sup> The estimated incidence is 1 per 35,000 to 40,000 live births.<sup>3,4</sup>

**Table 70-1** Relative Frequency of Teratomas by Site

Site	No. of Cases (%)
Sacrococcygeal	290 (45)
Gonadal	
Ovary	176 (27)
Testis	31 (5)
Mediastinal	41 (6)
Central nervous system	30 (5)
Retroperitoneal	28 (4)
Cervical	20 (3)
Head	20 (3)
Gastric	3 (<1)
Hepatic	2 (<1)
Pericardial	1 (<1)
Umbilical cord	1 (<1)
TOTAL	643 (100)

Modified from Dehner LP: Gonadal and extragonadal germ cell neoplasms: Teratomas in childhood. In Finegold M (ed): Pathology of Neoplasia in Children and Adolescents. Philadelphia, WB Saunders, 1986, pp 282-312.

Data are from five series of teratomas in children.

**Figure 70-4.** This infant has a large sacrococcygeal teratoma. The infant and attached teratoma weighed 2363 g. The teratoma weighed 675 g. After surgical excision of the tumor, the infant weighed 1688 g. The external size of such a teratoma is not a deterrent to surgical excision because the attachment in large and small teratomas is similar.

## DIAGNOSIS

In countries where prenatal ultrasonography is not readily available, most sacrococcygeal teratomas are seen as a visible mass at birth, making the diagnosis obvious (Fig. 70-4). Prenatal diagnosis has important implications and will be discussed further.

There is an unexplained female preponderance of 3:1.<sup>33,69</sup> The main differential diagnosis is meningocele. Typically, meningoceles occur cephalad to the sacrum and are covered by dura, but sometimes they are covered by skin. Examination of the child reveals bulging of the fontanelle with gentle pressure on a sacral meningocele, helping to establish the diagnosis before plain radiography, ultrasonography, and magnetic resonance imaging (MRI) confirm it. The co-existence of meningocele with teratoma is well recognized in the familial form, but these are usually presacral. Rarely, a typical exophytic teratoma may have an intradural extension.<sup>72</sup> Other lesions in the differential diagnosis of neonatal sacrococcygeal masses include lymphangiomas, lipomas, tail-like remnants (Fig. 70-5), meconium pseudocysts, and several other rare conditions.<sup>33,73,74</sup>

Although many neonates with sacrococcygeal teratomas do not have symptoms, some require intensive care because of prematurity, high-output cardiac failure, disseminated intravascular coagulation,<sup>75</sup> and tumor rupture or bleeding within the tumor.<sup>76-78</sup> Lethal hyperkalemia from tumor necrosis has been

described.<sup>79</sup> Lesions with a large intrapelvic component may cause urinary obstruction. Besides looking for signs of a myelomeningocele, the physical examination should always include a rectal examination to evaluate any intrapelvic component. The most helpful imaging studies consist of plain anteroposterior and lateral radiographs of the pelvis and spine, looking for calcifications in the tumor and for spinal defects, and ultrasonography of the abdomen, pelvis, and spine. Further preoperative studies are unnecessary in most newborns.

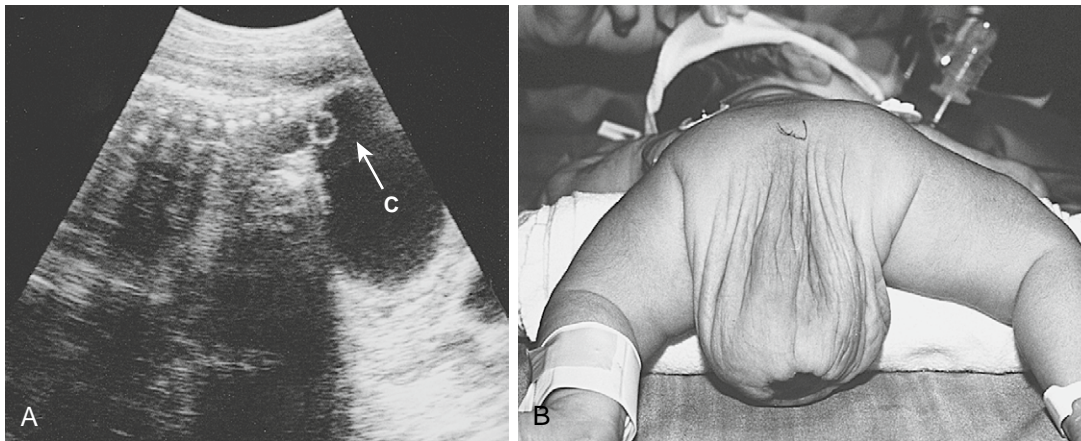

The diagnosis of purely intrapelvic teratomas is often delayed.<sup>33</sup> Children develop constipation, urinary retention, an abdominal mass, or symptoms of malignancy, such as failure to thrive. Age is a predictor of malignancy in patients with testicular, mediastinal, and sacrococcygeal teratomas.<sup>2</sup> The risk of malignancy is less than 10% at birth but more than 75% after age 1 year for sacrococcygeal teratomas, with the exception of familial presacral teratomas. The risk of malignancy also is high for incompletely excised lesions. Complete excision of the tumor should be carried out as soon as the neonate is stable enough to undergo the operation. Serum markers should be determined before the operation for later comparison.

In recent decades, the diagnosis has often been made on prenatal ultrasonography, especially when this examination is routinely performed in the second trimester. The site of the lesion, its complex appearance, and intrapelvic extension with or without urinary tract obstruction are easily recognized. Although most small teratomas do not adversely affect the fetus in utero, the presence of a large solid vascular tumor is associated with a significant mortality rate, both in utero and perinatally.<sup>76,77,80,81</sup> Perinatal mortality is usually related to prematurity or tumor rupture with exsanguination (or both). Premature delivery may

**Figure 70-5.** This patient had a scrotum-like perianal mass with anal stenosis at birth. Anoplasty was done with removal of the mass, which was not attached to the coccyx. Pathology showed only fibroadipose tissue with smooth muscle, vascular structures, and cartilage, consistent with a hamartomatous process or caudal vestige (also called a tail remnant).

**Figure 70-6.** A, Ultrasound image of a female fetus at 38 weeks of gestation, showing a large cystic mass (C) attached to the coccyx, with tiny cysts anterior to the sacrum (arrow). An ultrasound evaluation at 18 weeks was normal. The cyst was gradually enlarging from an initial diameter of 9.5 cm at 31 weeks of gestation. The cyst was aspirated for 650 mL of fluid, permitting external rotation from breech to the vertex position. Two days later, when labor was induced, another 200 mL of fluid was removed to permit an uncomplicated vaginal delivery. B, Twenty-four hours postnatally, the lesion remained floppy with an area of skin ulceration, likely a consequence of excessive in utero distention. A mature cystic teratoma was confirmed histologically.

occur spontaneously from polyhydramnios or may be induced urgently because of fetal distress.

Repeated ultrasound assessment of tumor size is important because the fetus should be delivered by cesarean section if the tumor is larger than 5 cm or larger than the fetal biparietal diameter.<sup>80</sup> Dystocia during vaginal delivery is associated with tumor rupture and hemorrhage and is an avoidable obstetric nightmare. The options in managing unexpected cases with dystocia include emergency cesarean completion of the partially delivered fetus who has been intubated and ventilated after vaginal presentation of the head.<sup>80</sup>

Polyhydramnios with larger tumors may lead to premature labor. Tumors that are larger than the fetal biparietal diameter at diagnosis, or that grow faster than the fetus, are associated with a poor prognosis.<sup>82</sup> As the tumor enlarges, the fetus may develop placentomegaly or hydrops. This is a harbinger of impending fetal death and should lead to urgent cesarean delivery, especially when the maternal mirror syndrome is present.<sup>83</sup> Open fetal surgical excision has been performed with success in three of four cases considered too premature to deliver in one center and in two of four cases in another.<sup>17,77</sup> Others have reported survival after emergency delivery as early as 26 weeks of gestation.<sup>84</sup> Successful intrauterine endoscopic laser ablation was reported in one case.<sup>85</sup> Attempts at interrupting the high vascular flow have also been described by using radiofrequency ablation, with two survivors in four attempts.<sup>86</sup> One survivor had significant perineal damage.<sup>87</sup> Purely cystic teratomas occur in 10% to 15% of cases. Prenatal diagnosis allows percutaneous aspiration to facilitate delivery (Fig. 70-6),<sup>81,88</sup> to eradicate uterine irritability, or to prevent tumor rupture at delivery.<sup>77</sup> In other reports, prenatal decompression using a cyst-amniotic shunt was successfully performed to relieve the obstructive uropathy caused by the cystic teratoma.<sup>89,90</sup> Fetal MRI is a useful adjunct to the prenatal evaluation, providing additional information that helps in counseling and

preoperative planning.<sup>91</sup> It also helps in the differential diagnosis when the teratoma is entirely presacral.<sup>92</sup>

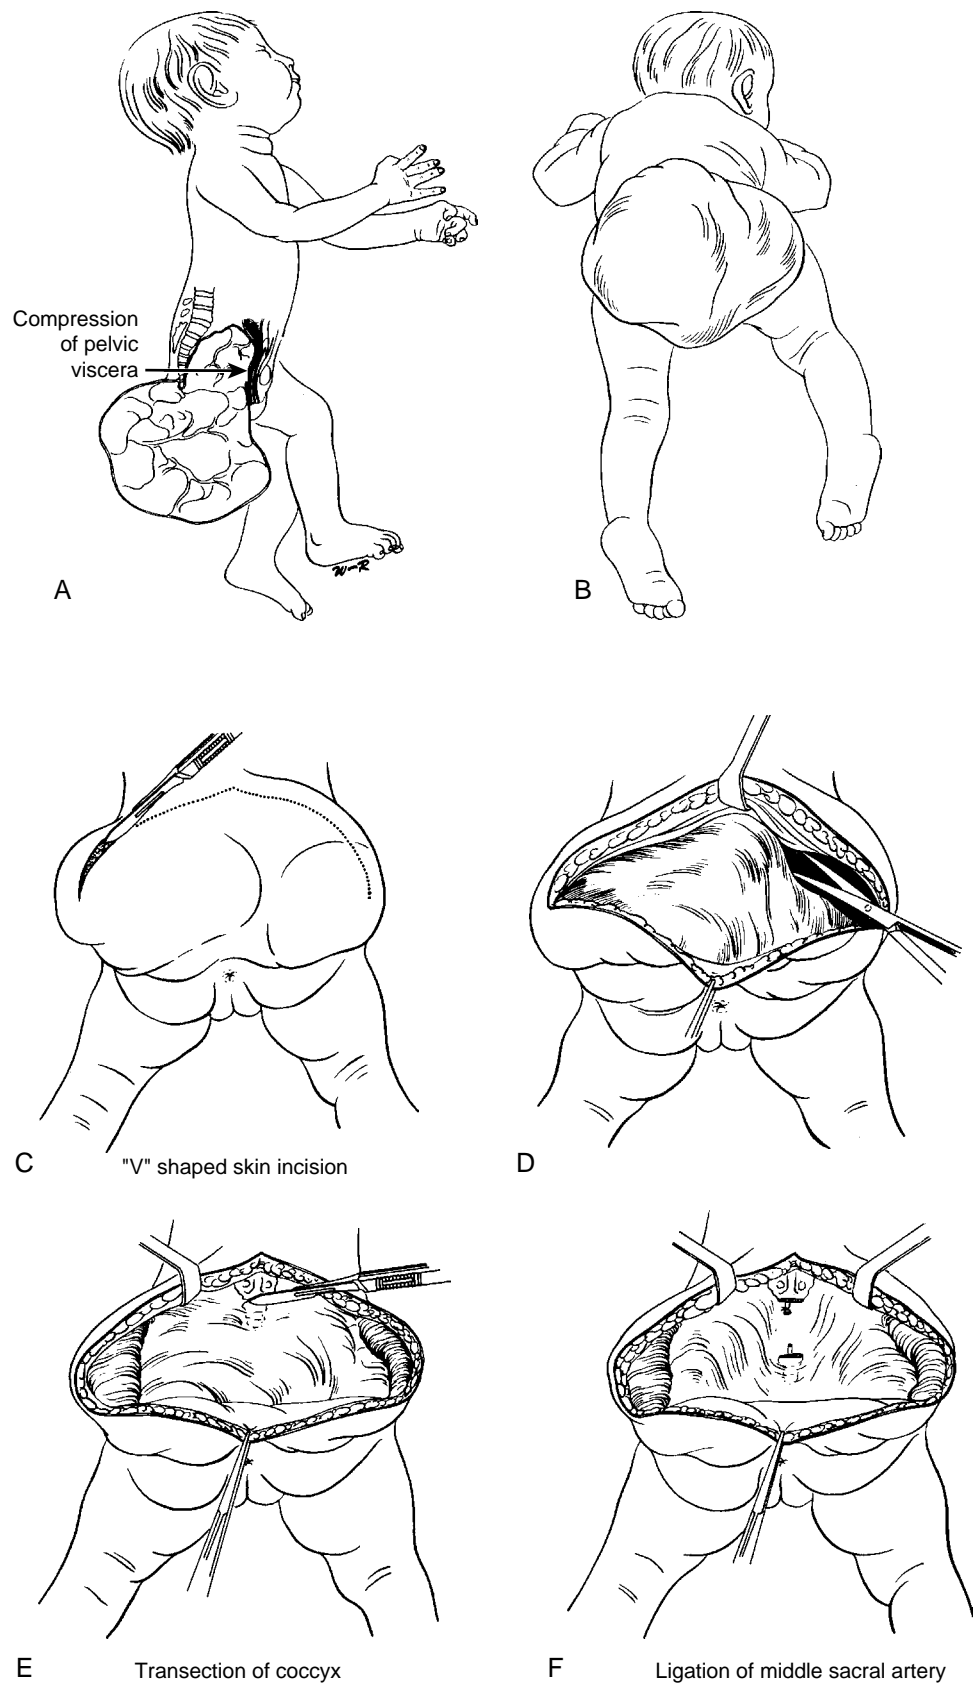

#### OPERATIVE PROCEDURE

Adequate intravenous access and the availability of blood products should be ascertained before starting the operation, especially with large tumors.

For most tumors, the major component is extrapelvic and the patient is placed in the prone position. If a significant intrapelvic or intra-abdominal component is present, it may be wise to begin with a laparotomy or laparoscopy. In our experience, most resections can be achieved completely in the prone position, especially if the internal portion is cystic. When in doubt, a safe approach is to prepare the skin from the lower chest to the toes, allowing the infant to be turned to the supine position without having to re-drape. Vaseline packing in the rectum facilitates its identification throughout the procedure (Fig. 70-7). En-bloc excision, including the coccyx, is preferable. Failure to remove the coccyx is associated with a high recurrence rate.<sup>2-4</sup> An acceptable gluteal crease and perineum is formed by the appropriate positioning of the perianal musculature. The use of plastic surgical principles to close the skin improves the cosmetic appearance of the scar (see Fig. 70-7, inset).<sup>93</sup>

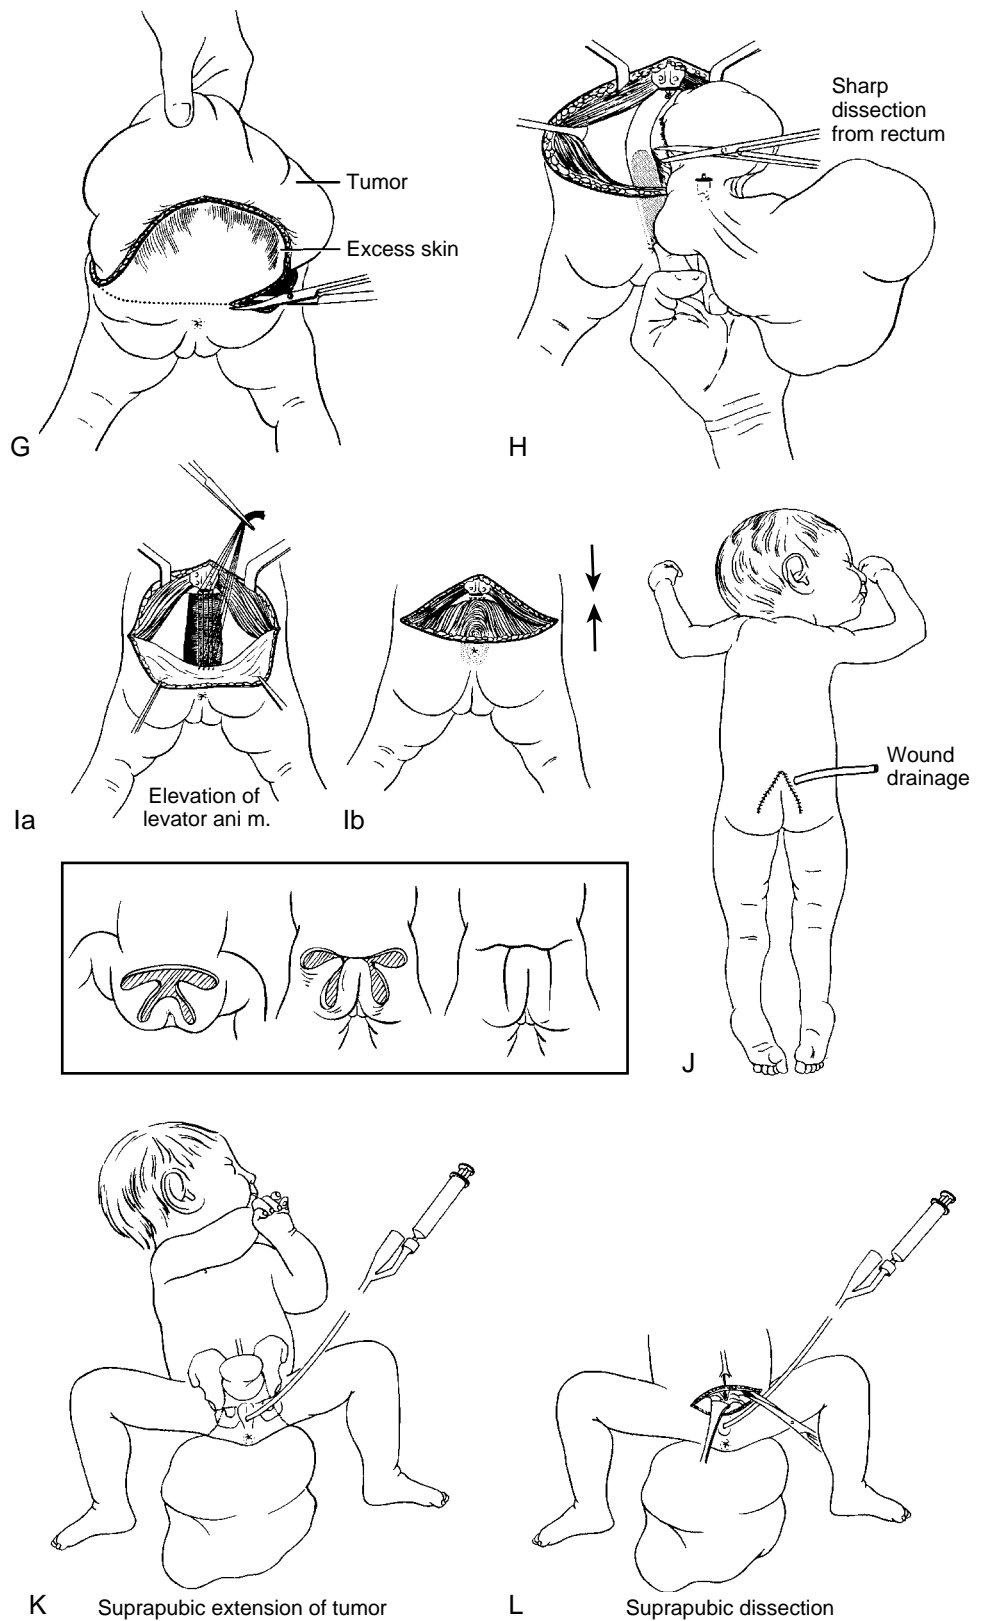

Although the chevron incision has been used by most surgeons, a vertical incision is sometimes possible. It is preferred for smaller teratomas because it leaves a nearly normal-looking median raphe (Fig. 70-8). Resection of the excess skin at the closure gives an optimal cosmetic result.

Several techniques have been described to help in the management of giant sacrococcygeal teratomas. These include intraoperative snaring of the aorta,<sup>78,94</sup> laparoscopic clipping of the median sacral artery,<sup>95</sup> the use of extracorporeal membrane oxygenation and hypothermic perfusion,<sup>96</sup> devascularization and staged resection,<sup>84</sup> preoperative embolization, and radiofrequency ablation.<sup>97</sup> Autologous cord blood transfusion is a useful adjunct recently described.<sup>98</sup>

**Figure 70-7.** A, The teratomatous attachment may compress the rectum, vagina, and bladder anteriorly. B, The patient is placed on the operating table in a prone jackknife position, with general endotracheal anesthesia. An appropriate intravenous cannula should be placed in an arm vein. C, The incision is an inverted-"V" shape to allow excision of the tumor and to facilitate an eventually satisfactory cosmetic closure. The amount of skin excised is dependent on the size and shape of the tumor. D, The tumor is dissected from the gluteus maximus muscle. E, The coccyx is transected and removed in continuity with the tumor. F, The middle sacral artery is the major blood supply to the tumor and is ligated after transection of the coccyx.

(continued)

**Figure 70-7, cont'd G,** Excess skin is excised to facilitate closure. **H,** Because the tumor is adherent to the rectum, sharp dissection can be directed by placing a finger in the rectum. **I,** Placement of sutures between the anal sphincter and the presacral fascia (a). When the sutures are tied, the anal sphincter is pulled upward to the sacrum to form a gluteal crease (b). **J,** A drain is left in the surgical site for drainage of postoperative sero-sanguineous fluid. **Inset,** Recently described technique for closure after excision of large teratomas. Using plastic surgery principles, this avoids "dog ears" and places the scars along natural skin lines for a much-improved long-term cosmetic result. **K,** If the tumor extends through the bony pelvis into the retroperitoneum, a urinary bladder catheter is inserted to facilitate suprapubic dissection. **L,** Lower abdominal transverse incision allows interruption of the middle sacral artery and dissection of the tumor from the sacrum and pelvis, which is eventually removed from the perineum. (Inset redrawn from Fishman SJ, Jennings RW, Johnson SM, et al: Contouring buttock reconstruction after sacrococcygeal teratoma resection. *J Pediatr Surg* 39: 439-441, 2004; with permission.)

**Figure 70-8.** Smaller cystic teratoma at age 1 month, initially mistaken for a hemangioma owing to its soft compressible nature and bluish skin discoloration. This tumor lends itself well to a longitudinal elliptical excision with midline closure, as in a posterior sagittal anorectoplasty.

## PROGNOSIS

Fetuses with tumors diagnosed in utero have a survival rate in excess of 90% if the tumors are small and discovered by routine prenatal ultrasonography. If a complicated pregnancy is the indication for ultrasound evaluation, the mortality increases to 60%. Nearly 100% of patients die when hydrops or placentomegaly occurs.<sup>77,80,81</sup> Dystocia or tumor rupture during delivery are likely underreported as a cause of mortality.<sup>99</sup> In one series, 10% of patients died during transfer, all before the widespread use of antenatal ultrasonography.<sup>100</sup> In a report of 24 patients with sacrococcygeal teratoma diagnosed on routine obstetric ultrasonography, 3 were aborted electively, 4 died in utero at 20 to 27 weeks of gestation, and 3 died of tumor rupture during delivery at 29 to 35 weeks of gestation (1 after vaginal and 2 after cesarean delivery).<sup>76</sup> The incidence of placentomegaly (none), hydrops (5%), and polyhydramnios (19%) was lower than in series in which ultrasonography was performed for an obstetric reason.<sup>77,80,101</sup> Tumor size, vascularity, and content were used to develop a prognostic classification from a cohort of 44 fetal sacrococcygeal teratomas. Fifty percent of infants with tumors 10 cm or greater that were highly vascular or fast growing died, whereas none died if these features were absent or if the tumor was predominantly cystic.<sup>102</sup>

In the absence of severe prematurity and intrapartum complications, the prognosis is dependent on the presence of malignancy and is therefore related to age at operation and completeness of resection.<sup>103,104</sup> When the tumor is benign and completely excised, recurrence is less common than when the tumor is large and mostly solid.<sup>105</sup> The recurrent tumor may be benign or malignant, and benign metastatic tissue may become evident in lymph nodes.<sup>106</sup> Although

immature or fetal elements in gonadal teratomas are associated with a higher risk of aggressive behavior,<sup>107</sup> this is not considered true for sacrococcygeal teratomas.<sup>2,6</sup> However, a recent multicenter study identified immature histology and incomplete resection as risk factors for recurrence.<sup>108</sup> Although malignant recurrence of a “benign” teratoma may be as high as 10% to 15%,<sup>7,108</sup> the original benign diagnosis may have been due to sampling error,<sup>16</sup> an undetected residual microscopic focus of malignant tumor,<sup>109</sup> or secondary to incomplete coccygectomy at the initial operation.<sup>34</sup> Patients whose tumors are resected after the newborn period have a higher risk of malignant recurrence, especially when an elevated AFP level is present at diagnosis. The elevated AFP likely signifies the presence of malignancy in the original tumor.<sup>16,110</sup> It is important to monitor all patients with physical examination, including rectal examination and serum markers, every 2 or 3 months for at least 3 years, because most recurrences occur within 3 years of operation.<sup>111</sup>

Recurrent disease is usually local, but metastases to inguinal nodes, lung, liver, brain, and peritoneum can occur, including pseudomyxoma peritonei.<sup>112</sup> The prognosis of a malignant tumor or a malignant recurrence was dismal until the advent of platinum-based chemotherapy.<sup>109</sup> Survival rates higher than 80% are now achieved, but the risk of late recurrences or second malignancies persists.<sup>110,111,113,114</sup>

A Children’s Cancer Group (CCG) review illustrates the revised prognosis.<sup>114</sup> The mortality was 10% in 126 patients treated in 15 institutions from 1972 to 1994. Three patients died of severe associated anomalies. Two died of hemorrhagic shock postoperatively and 6 due to combinations of severe prematurity, birth asphyxia due to failed vaginal delivery, or preoperative tumor rupture. Death from metastatic yolk sac tumor occurred in 1 patient. A second patient with metastatic disease was lost to follow-up and is presumed dead. Thus, only two deaths occurred from malignancy, despite a total of 20 yolk sac tumors (13 malignant at initial operation, 7 malignant recurrences after resection of “benign” teratomas). Owing to the effectiveness of current chemotherapy in treating recurrent disease, as well as its toxicity in young infants, it appears that a completely excised malignant yolk sac tumor does not require adjuvant therapy. These patients should be closely monitored clinically and with serial AFP measurements.<sup>115</sup> Similar encouraging results were seen in the German Cooperative Studies.<sup>116</sup>

In older patients, treatment of malignant tumors involves excision, chemotherapy, and monitoring with imaging studies and serum markers. For unresectable tumors, biopsy and chemotherapy are followed by excision of the primary tumor after adequate reduction has been obtained.<sup>113</sup> Radiation therapy is usually reserved for local recurrence of malignant tumors. Patients with malignant tumors should be enrolled in a pediatric cooperative study or treated according to their guidelines.

In the current era of the rather routine use of ultrasonography in pregnancy, the prognosis for patients with a sacrococcygeal teratoma is not dependent on Altman’s

classification<sup>33</sup> but rather on tumor size, physiologic consequences, histology, and associated anomalies. The prognosis of malignant tumors depends on tumor type, stage,<sup>114</sup> location, and patient age. Functional results in survivors have been reported as excellent in most series.<sup>69,71,105,117</sup> However, several reports draw attention to fecal and urinary continence problems, as well as lower limb weakness.<sup>103,118-123</sup> Some of these problems are clearly related to associated anomalies<sup>100</sup> or to the presence of large presacral or intra-abdominal tumors,<sup>117</sup> but they can occur after excision of purely extrapelvic benign tumors. A good outcome requires meticulous dissection along the tumor capsule, preservation and reconstruction of muscular structures, and long-term follow-up. One group advocates earlier cesarean delivery to minimize urologic sequelae in patients with large tumors causing urinary tract dilatation.<sup>121</sup> A poor cosmetic result was noted in more than half of the patients in another review.<sup>124</sup> These authors advocate early assessment of bladder, anorectal, and sexual function along with cosmetic results within a structured oncology follow-up program. The technique described by the Boston Children's group is a major step to improve cosmesis (see Fig. 70-7).<sup>93</sup>

### Thoracic Teratomas

The anterior mediastinum is the most common site of thoracic teratomas, which account for 7% to 10% of all teratomas (see Table 70-1).<sup>2,3</sup>

### MEDIASTINAL TERATOMAS

Mediastinal teratomas are diagnosed from the fetal period to adolescence and even adulthood.<sup>2,125,126</sup> Most are located in the anterior mediastinum, but a few have been described in the posterior mediastinum,<sup>127</sup> some with epidural extension.<sup>128</sup> In infants, respiratory distress is a common presenting manifestation,<sup>129</sup> but in older children the teratoma is often an incidental finding on chest radiography (Fig. 70-9).<sup>2</sup> Mediastinal

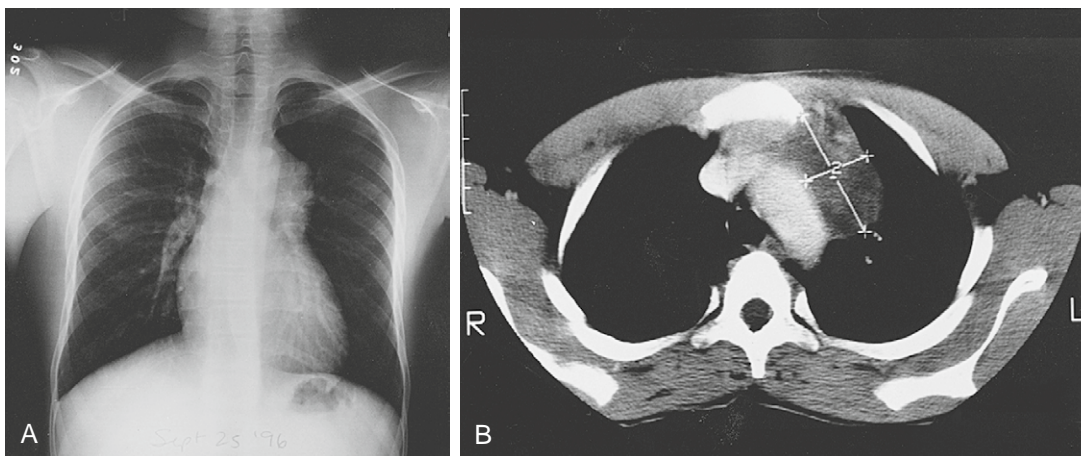

teratomas may be first seen as a chest wall tumor and may even erode through the skin (Fig. 70-10). They also can erode into a bronchus, with hemoptysis as the initial manifestation, or rupture into the pleural cavity.<sup>130</sup> Secondary pericardial effusion and tamponade have also been described.<sup>131</sup> A strong association is found with Klinefelter's syndrome. In these cases, choriocarcinoma within the teratoma often leads to precocious puberty.<sup>2,24,132</sup> Histiocytosis also has been reported with mediastinal teratoma, both with and without Klinefelter's syndrome.<sup>50,57,58,132</sup>

Histologically, the presence of immature tissue does not affect the prognosis in children younger than 15 years.<sup>2</sup> After age 15 years, mediastinal teratomas have a high incidence of malignant behavior, which is usually indicated by elevated levels of AFP or  $\beta$ -hCG (or both).<sup>133</sup> The tumor should be excised through either a median sternotomy or a thoracotomy.<sup>2,132</sup> Smaller tumors may be approached through an anterior mediastinotomy (see Fig. 70-9) or by thoracoscopy.<sup>134</sup> Chemotherapy is required for malignant lesions as adjuvant therapy or preoperatively for unresectable tumors. Complete resection correlates best with event-free survival and is more often achieved with a strategy of delayed resection after preoperative chemotherapy.<sup>133</sup>

### INTRAPERICARDIAL TERATOMAS

Intrapericardial teratomas are most commonly seen in the newborn period or in utero, with evidence of cardiorespiratory distress or nonimmune fetal hydrops.<sup>2,3,135</sup> They are a leading cause of massive pericardial effusion in the neonate.<sup>3</sup> Delay in diagnosis can be fatal. A fetal diagnosis allows early postnatal treatment in most patients<sup>136</sup> or early delivery for emergency surgical excision if the infant develops signs of cardiac tamponade.<sup>137</sup>

On ultrasonography, a cystic or solid teratoma is located anterior to the right atrium and ventricle with attachments to the great vessels.<sup>135</sup> In older infants,

**Figure 70-9.** A, A 13-year-old African boy has an asymptomatic anterior mediastinal mass that was discovered on routine immigration chest radiograph. B, The CT scan shows a heterogeneous mass adjacent to the aorta, suggestive of a neoplasm (thymoma or lymphoma). During consideration of a fine-needle aspiration biopsy, ultrasonography was done and suggested the presence of cysts with debris (not shown). MRI (not shown) confirmed the presence of the cystic components as well as fat. A mature teratoma was excised through a small left anterior mediastinotomy, removing the left second costal cartilage.

**Figure 70-10.** This 2-year-old was referred for a 5 × 5-cm, hard, fixed, right chest wall mass that appeared suddenly during an upper respiratory tract infection. The CT scan shows a bilobed lesion that extends through the chest wall and contains a small area of calcification. An incisional biopsy revealed pus-like material, containing ghost cells and calcified debris. Serum markers were normal. Complete excision of the mass required a right anterior thoracotomy and partial resection of an adherent right middle lobe. Pathologic examination revealed a ruptured mature teratoma with marked inflammatory reaction, containing foci of enteric, respiratory, and squamous mucosa; smooth muscle; salivary glands; pancreas; neuroglial tissue; and bone.

it may present as respiratory distress or poor feeding. Often, the tumor may be found incidentally on a chest radiograph. The only treatment is surgical excision. On histologic examination, these teratomas are usually composed of mature tissue with or without neuroglial components.<sup>2,3</sup>

### INTRACARDIAC TERATOMAS

Intracardiac teratomas are rare and arise from the atrium or ventricle. Many can be cured by surgical resection.<sup>2</sup>

### PULMONARY TERATOMAS

Few cases of intrapulmonary teratoma have been described.<sup>138,139</sup> Symptoms included trichoptysis or hemoptysis. Lobectomy is the usual treatment.

### Abdominal Teratomas

The most frequent abdominal teratomas are the gonadal teratomas, which are discussed in Chapters 52 and 76.

### RETROPERITONEAL TERATOMAS

Retroperitoneal teratomas occur outside the pelvis, often in a suprarenal location. They represent about 5% of all childhood teratomas, and 75% occur in children younger than 5 years of age.<sup>2,3</sup> An association with Klinefelter's syndrome has been described.<sup>55</sup> Usually the tumor is discovered as an abdominal mass that can compress the gastrointestinal tract, causing symptoms such as vomiting and constipation.<sup>140</sup> Presentation with an acute abdomen from infection has also been described.<sup>141</sup>

Abdominal radiographs may show calcifications or bony structures within the tumor (Fig. 70-11). Ultrasonography and computed tomography (CT) are the investigations used, and assessment of serum markers is important. Surgical excision is usually straightforward, but occasionally the tumor may encase major vessels, making resection difficult.<sup>142</sup> Malignancy is uncommon,<sup>2,140</sup> but sometimes differentiation from a teratoid Wilms' tumor can be difficult.<sup>143</sup> The retroperitoneum is the most common location for the

**Figure 70-11.** This 7-month-old girl was found to have an abdominal mass on physical examination. **A**, Plain films showed a large calcified left upper quadrant mass, which can be seen to displace the kidney inferiorly after injection of intravenous contrast. Ultrasonography (not shown) revealed multiple cystic areas. **B**, This was confirmed by CT, which also revealed areas of fat density, making teratoma much more likely than neuroblastoma. The mature teratoma contained all types of cerebral and cerebellar tissues; respiratory, transitional, and squamous epithelium; sebaceous and salivary glands; smooth muscle; cartilage; and fat. Serum markers were normal.

fetus-in-fetu malformations and intermediate fetiform teratomas.<sup>2,3,144,145</sup>

### GASTRIC TERATOMAS

Gastric teratomas are rare lesions seen most commonly in male infants.<sup>2,50,146,147</sup> They account for 1% of all teratomas. Clinically, the tumors present as hematemesis or vomiting due to gastric outlet obstruction.<sup>2,3,50,147,148</sup> A palpable mass is common. The tumor is an exophytic mass in the lesser curvature or posterior wall of the stomach, and the whole stomach may be involved.

Most gastric teratomas are benign with primarily mature and immature neuroglial tissue. Benign peritoneal gliomatosis has been found incidentally in hernia sacs 10 months after resection of a gastric teratoma in the newborn period, illustrating the unusual behavior of some of these tumors.<sup>149</sup> Surgical excision is curative. Recurrence and malignancy are rare, despite local infiltration or nodal metastasis.<sup>146,150</sup> Regardless, periodic follow-up including AFP measurements is important.<sup>151</sup>

Other rare sites of abdominal teratomas include liver, gallbladder, pancreas, kidney, intestine, bladder, prostate, uterus, mesentery, omentum, abdominal wall, and diaphragm.<sup>2,3,152-159</sup>

### Head and Neck Teratomas

More than 10% of teratomas in children originate from the neck, head, and central nervous system.<sup>2,3,160,161</sup> Most of these tumors are recognized at or shortly after birth and are associated with an increased incidence of stillbirth. They also can be diagnosed with prenatal ultrasonography (Fig. 70-12).<sup>162,163</sup>

### CERVICAL TERATOMAS

Cervical teratomas represent up to 8% of all teratomas.<sup>18,163</sup> Large tumors can be seen in utero with ultrasonography.<sup>162</sup> These tumors are initially seen as a partial or completely cystic neck mass, which may compromise the airway and require immediate intubation or tracheostomy.<sup>164,165</sup> Large teratomas often lead to severe polyhydramnios, presumably because of esophageal compression. In turn, this may lead to premature labor. Serial amnioreduction may be required to prevent this complication. At birth, death may result from tracheal compression or deviation and the inability to intubate.<sup>18,166-168</sup> Prenatal diagnosis permits cesarean section and establishment of an airway by the surgical team before the cord is clamped.<sup>167</sup> Refinements of this technique, called the EXIT procedure (EX-utero Intrapartum Treatment), have been documented in a series of 31 patients, 7 of whom had a large cervical teratoma.<sup>169</sup> Extension of the tumor to the mediastinum or displacement of the trachea and carina may cause pulmonary hypoplasia, which increases respiratory morbidity and mortality.<sup>2,3,169</sup> The tumor is usually well defined and may contain calcifications. The differential diagnosis includes lymphangioma, congenital goiter, foregut duplication cyst, and branchial cleft cyst (see Fig. 70-12).<sup>166,169</sup> Investigation should

include plain radiographs, ultrasonography, and measurement of AFP and  $\beta$ -hCG, as well as urinary catecholamine metabolites. CT and MRI may be useful to establish the diagnosis and to define the anatomic relations.

Complete excision is accomplished through a wide collar incision. The tumor is usually not difficult to separate from the strap muscles and the fascial planes, but the pretracheal fascia is sometimes very adherent. Often, the site of origin cannot be identified. In many instances, however, the tumor is firmly attached to and appears to originate from the thyroid gland. In such cases, a thyroid lobectomy should be performed. The terms *thyrocervical* and *cervicothyroidal* are often used to describe cervical teratomas.<sup>2,3</sup> In other instances, the tumor is adherent to the pharynx. In these cases, meticulous dissection and pharyngotomy, if necessary, are important to prevent tumor recurrence. Giant teratomas may distort the anatomy, leading to permanent sequelae (see Fig. 70-12E, F). Generally, the tumor is composed of both mature and immature neuroglial tissue, but cartilage and bronchial epithelium can also be found.<sup>18,166,170</sup> In 35% of cases, the tumor contains thyroid tissue.<sup>171</sup> Hypothyroidism can be a well-known postoperative complication.<sup>172</sup>

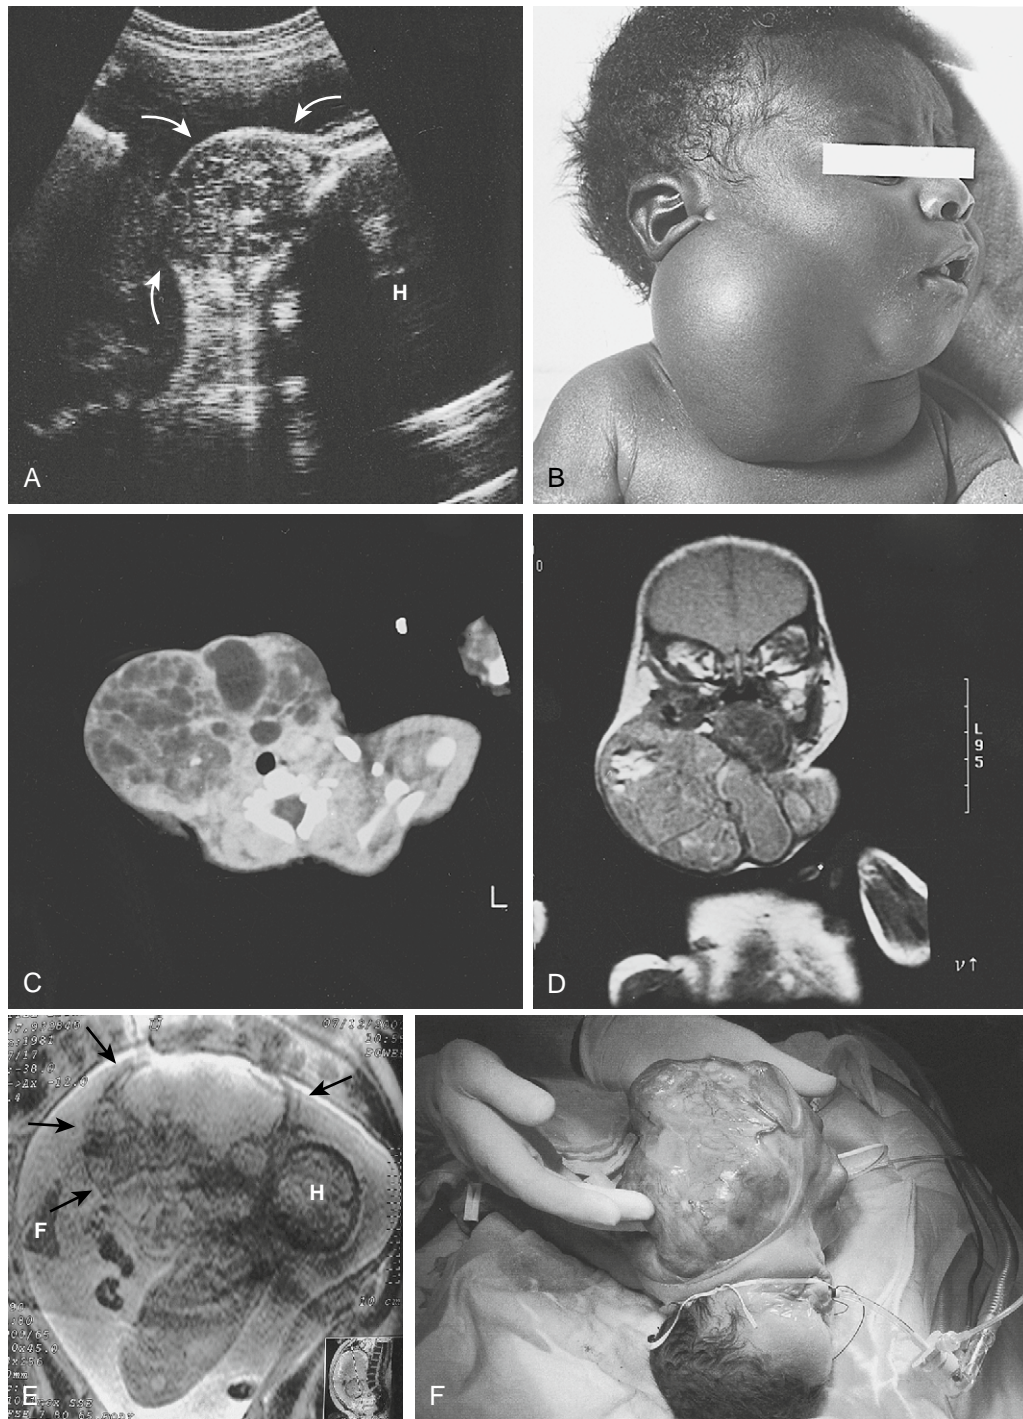

Cervical teratomas are usually benign, but malignancy has been reported, even in infants. A CCG report showed that 20% of tumors clearly contained malignant elements, most often neuroblastoma, but also teratocarcinoma, neuroblastoma-like tumor, and neuroectodermal tumor.<sup>18</sup> Complete excision in the neonatal period results in a survival rate of 80% to 90%. As for teratomas in other sites, one neonate was reported with a benign thyroid teratoma accompanied by neuroglial tissue deposits in cervical nodes.<sup>173</sup> A prognostic classification for cervical teratomas takes into account birth status, age at diagnosis, and the presence of respiratory distress.<sup>170</sup> In neonates without respiratory distress, the mortality rate was 2.7%, compared with 43.4% in those with respiratory compromise. Prenatal diagnosis and delivery by using the EXIT procedure can undoubtedly increase survival.<sup>167-169</sup>

Thyroid teratomas may be present in older children and adults and are often malignant in the latter.<sup>174,175</sup> Spindle epithelial tumor with thymus-like elements (SETTLE) is a malignant thyroid neoplasm that can sometimes be confused with thyroid teratomas due to their spindle cell and epithelial components.<sup>176</sup> These unique neoplasms have a propensity for delayed metastases, particularly to the lungs, kidney, mediastinum, lymph nodes, liver, and vertebrae.<sup>177</sup> Adjuvant chemotherapy and radiotherapy do not seem to have a significant impact on overall outcome for metastatic disease. In these patients, survival is poor.<sup>176</sup>

### CRANIOFACIAL TERATOMAS

Craniofacial teratomas include a spectrum of lesions that may be life threatening.

**Epignathus.** *Epignathus* is a term used to describe teratomas protruding from the mouth (Fig. 70-13). These tumors arise from the soft or hard palate in the

**Figure 70-12.** **A**, Fetal ultrasound image at 34 weeks of gestation shows a 7-cm cervical mass of mixed echogenicity, containing blood flow by Doppler (*arrows* point to the mass; H, head). **B**, After birth by cesarean section, the neonate had only mild tachypnea despite the large right cervical mass extending to the left side. Parts of the mass transilluminated, suggesting the diagnosis of a lymphangioma. **C**, CT scan of the lower cervical area shows an intact trachea and multiple cysts in the mass. **D**, MRI confirmed the presence of fat, which appears bright on T1-weighted images as well as on the proton density-weighted imaging sequence shown here. At operation, the mass appeared to originate from the right lobe of the thyroid gland. It contained epithelium-lined cysts, cartilage, bone, glandular tissue, and complex papillary structures; A predominance of neuroepithelial tissue was found with a few small areas of immature, neuroblastoma-like tissue. Preoperative vanillylmandelic acid levels were normal. The patient required postoperative thyroid hormone supplementation because of subclinical hypothyroidism (elevated thyroid-stimulating hormone with normal thyroxine and triiodothyronine levels). **E**, Another patient, with a giant cervical teratoma, seen on magnetic resonance at 30 weeks of gestation. The lesion was first diagnosed on routine ultrasonography at 18 weeks and grew much faster than the fetus. Several amnioreductions were required because of polyhydramnios, and an EXIT procedure was performed at 34 weeks of gestation (H, head; F, foot; *arrows* outline the tumor). **F**, After securing the airway during the EXIT procedure and stabilizing the neonate, resection was completed successfully. Notice the displacement of the ear. During resection, it became obvious that the left carotid artery and jugular vein entered the tumor. The left vagus nerve (hence the left recurrent nerve) was never seen, and the left glossopharyngeal nerve also was sacrificed. The tumor originated from the left pharyngeal wall. Including the fluid within the cystic parts, the teratoma weighed 1.4 kg, and the neonate weighed 1.6 kg postoperatively.

**Figure 70-13.** This baby was born with the epignathus protruding from his mouth.

region of Rathke's pouch.<sup>178,179</sup> They generally fill the oral cavity and extend out through the mouth. They can prevent fetal swallowing, which leads to polyhydramnios. Surgical excision is mandatory. They are usually benign, and recurrence is rare. A high degree of organization often gives them the appearance of a parasitic fetus.

**Pharyngeal Teratomas.** Pharyngeal teratomas arise from the posterior aspect of the nasopharynx. Large tumors can interfere with fetal swallowing and produce polyhydramnios, cause severe respiratory distress at birth, and lead to stillbirth.<sup>2,180</sup> Most pharyngeal teratomas are benign. Their treatment is surgical excision.<sup>164</sup>

**Oropharyngeal Teratomas.** Oropharyngeal teratomas represent 2% of all teratomas.<sup>181</sup> These tumors can originate from the tongue, sinuses, mandible, and tonsils. Airway compromise requires immediate care at the time of delivery. For oropharyngeal and nasopharyngeal teratomas, the EXIT procedure may be indicated when a large tumor detected prenatally appears to obstruct the airway. Most tumors are benign, and recurrence is uncommon after complete resection.<sup>181</sup> Separate tumors may occur in the same infant, and intracranial extension has been described.<sup>182,183</sup>

**Orbital Teratomas.** Orbital teratomas usually present at birth with unilateral proptosis in a normal, term neonate.<sup>184</sup> They grow rapidly, but the eye is intact. Occasionally, the tumor extends intracranially. The proptotic eye may rupture because of prolonged

exposure. Histologically, these tumors are benign and contain mature tissue and immature neuroglial elements. Surgical resection is the treatment of choice, and the eye can usually be preserved.<sup>2,184</sup>

**Middle Ear Teratomas.** Middle ear teratomas may be difficult to differentiate from hereditary cholesteatoma. They are benign tumors, but surgical resection is difficult owing to the location of the tumor and the deformation of the middle ear. Ossiculoplasty is sometimes necessary.<sup>185,186</sup>

### *Intracranial Teratomas*

Intracranial teratomas generally present with symptoms of space-occupying lesions. These lesions account for only 2% to 4% of all teratomas, but they represent nearly 50% of brain tumors in the first 2 months of life.<sup>2,3,50,187</sup> Most are benign in neonates, but malignancy dominates in older children and young adults.<sup>50,187-190</sup> These teratomas can appear in utero and cause massive hydrocephalus. A massive teratoma, causing skull rupture at delivery, has been reported.<sup>188</sup> The pineal gland is the most common site of origin, but intracranial teratomas may be seen in other areas, including the hypothalamus, ventricles, cavernous sinus, cerebellum, and suprasellar region.<sup>50,189-191</sup>

Pineal gland teratomas can secrete chorionic gonadotropin hormone, causing precocious puberty. In infants younger than 2 years, obstructive hydrocephalus is the most common clinical finding. In older children, symptoms of increased intracranial pressure are most common. The diagnosis can be made by using skull radiographs, ultrasonography, CT, or MRI.

Treatment of intracranial teratomas is difficult, and many are unresectable. The only long-term survivors are those who have the mass completely resected. Palliative shunting to reduce intracranial pressure is of little long-term benefit.<sup>50</sup> Perinatal mortality is high, with only a 6% survival when diagnosed in the fetus or newborn.<sup>3,192</sup>

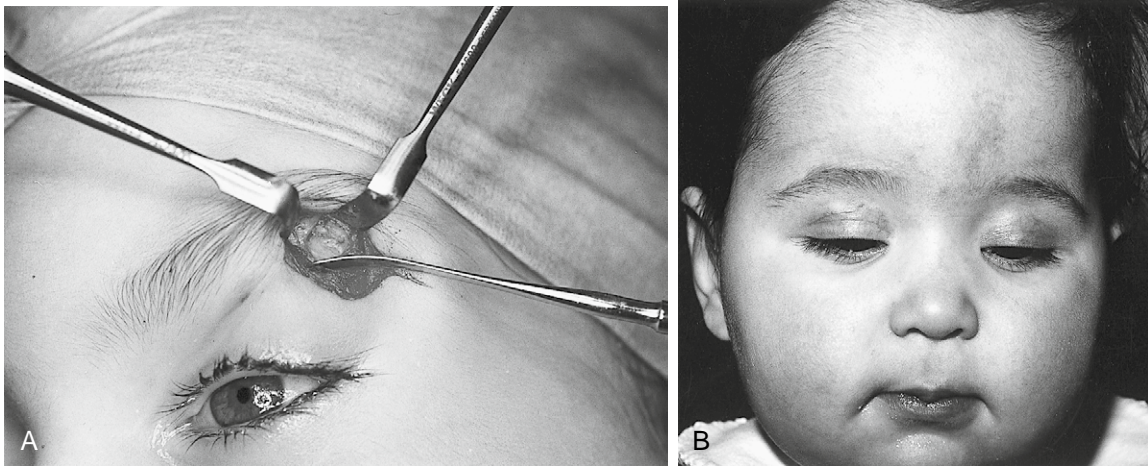

### *Miscellaneous Sites*

Teratomas have been reported in other sites, such as skin, parotid, vulva, perianal region well away from the coccyx, spinal canal, umbilical cord (possibly associated with omphalocele), and placenta.<sup>2,3,193-197</sup> Some of the spinal teratomas are now considered as enterogenous cysts.<sup>198</sup>

## **DERMOID, EPIDERMOID, AND RELATED CYSTS**

### **Dermoid Cysts**

Dermoid cysts are congenital cysts that are lined by skin with fully mature pilosebaceous structures.<sup>199,200</sup> They are the result of sequestration of skin along lines of embryonic closure. The head and neck are the sites

**Figure 70-14.** **A**, A dermoid cyst deep to the lateral part of the left eyebrow is approached through an incision made in the palpebral crease, taken through the muscle, which is then retracted upward, exposing the cyst lying on the periosteum. **B**, A different patient shown 1 month after excision of a right eyebrow dermoid through a palpebral skin incision. (A courtesy of Patricia Bortoluzzi, MD.)

of predilection, but these lesions have been described in other midline sites, including the sacral area, perineal raphe, scrotum, and presternal area.<sup>200</sup> The so-called dermoids of the ovary are, in fact, cystic teratomas and are discussed in Chapter 76.

Typical locations on the head are under the lateral part of the eyebrow, the scalp, the glabella, the tip of the nose, the orbit, and the palate, where they are associated with a cleft.<sup>201</sup> They also occur intracranially and in the spinal canal.<sup>202</sup>

Dermoids are usually round, soft, and often fixed to deep tissues or to bone. They usually present as a painless mass of 1 or 2 cm in diameter but can grow up to 4 cm or more if untreated. Some are associated with a sinus tract, especially those on the nose. This site is also typical for intracranial extension and a familial occurrence.<sup>202</sup> Dermoids in the head area are usually deep to muscles and often cause an indentation in the outer table of the skull. They can even erode through both bony tables and extend intracranially. A skull radiograph may show the defect, but it may be normal if the cyst is situated over a fontanelle or an unfused suture. CT is essential in those cases, and neurosurgical consultation is advisable.<sup>202</sup>

Dermoids deep to the lateral part of the eyebrow are usually approached through an incision just above the eyebrow because an incision within the eyebrow leaves a more visible scar. We have been impressed with an alternative incision through the palpebral crease (Fig. 70-14). This requires a slightly longer incision and more retraction but leaves an invisible scar (see Fig. 70-14). This approach also has the advantage of allowing access to the orbit for the rare cases in which the cyst penetrates through the orbital bone in a dumbbell fashion.

Dermoids in the cervical area are usually midline, mostly suprahyoid or submental. Because they are deep within muscles, they tend to move with swallowing, just as thyroglossal duct cysts do. On ultrasonography, they usually appear echogenic and are often misinterpreted as being solid rather than cystic. They

can be differentiated intraoperatively by their yellowish appearance and their soft, buttery content with sebaceous material and hair (Fig. 70-15). This appearance alleviates the need for a hyoidectomy.

Dermoid cysts should be excised because they tend to grow and may rupture or become infected, resulting in a more difficult excision and a higher risk of recurrence.

## Epidermal Cysts

Epidermal or epidermoid cysts have a wall composed of true epidermis, as seen on the skin surface and in the infundibulum of hair follicles (hence, they also are called infundibular cysts).<sup>199</sup> They do not contain pilosebaceous units or hair. Some have a congenital origin like dermoid cysts, whereas others are acquired, either spontaneously arising from hair

**Figure 70-15.** Dermoid cysts in the cervical region are found in the midline. They are usually suprahyoid or submental. This operative photograph shows a midline cervical dermoid cyst with its characteristic yellowish appearance. The cyst consists of a soft, buttery, cheesy content with sebaceous material. Preoperatively, these lesions are usually confused with a thyroglossal duct cyst. However, removal of the hyoid bone is not needed if a dermoid cyst is found.

follicles or secondary to trauma with implantation of epidermis into the dermis or subcutaneous tissue.

Epidermal cysts are slow growing and are formed by the desquamation of epithelial cells. They are round, intradermal, or subcutaneous lesions that stop growing after having reached 1 to 5 cm in diameter. They occur most commonly on the face, scalp, neck, and trunk (i.e., hair-bearing areas). They may be associated with a small sinus tract or dimpling of the skin. In the neck and infraclavicular area, they may be confused with branchial cleft remnants. Preauricular sinuses and cysts are often considered epidermal cysts. Epidermoid cysts of the spleen are discussed in Chapter 47.

Some patients may have more than one cyst, but the presence of multiple cysts, especially on the scalp and face, should raise the possibility of Gardner syndrome.<sup>199,200</sup> The cysts contain dry cheesy or horny material and lack skin appendages on histology. Treatment is excision, which often can be achieved under local anesthesia, even in young children.

Preauricular cysts are better excised under general anesthesia, owing to their deep attachment to the helix cartilage.<sup>201</sup> Spontaneous rupture of any epidermal cyst leads to an intense foreign-body reaction, and the child presents with an abscess-like mass. This may require incision and drainage but often can be treated with antibiotics and local warm compresses. This mode of presentation increases the risk of cyst recurrence after excision and often results in a wider scar than would have occurred with earlier excision. Infection of the cyst also may be caused by bacteria tracking along the small sinus tract that is sometimes present. These lesions rarely degenerate to epidermoid or basal cell carcinomas.<sup>202</sup> The treatment of asymptomatic preauricular sinuses is controversial, but certainly excision should be carried out in the presence of a palpable cyst or discharge of material from the sinus tract.

Epidermoid cysts of the skull and central nervous system share some similarities with dermoids, but they usually become symptomatic at an older age, between 20 and 40 years.<sup>203</sup> Most are thought to have a congenital origin, although iatrogenic and inflammatory mechanisms are likely for intraspinal epidermoids

(caused by multiple lumbar punctures, especially when using a needle without stylet) and middle ear epidermoids (cholesteatomas), respectively.

## Trichilemmal Cysts

Trichilemmal cysts, also called pilar or sebaceous cysts, are thought to arise from hair follicles.<sup>199</sup> Most are acquired and appear in adulthood. They often show an autosomal dominant inheritance pattern and are solitary in only 30% of the cases.<sup>199</sup> Some authors classify these as epidermoid or epidermal cysts.<sup>202</sup>

## SOFT TISSUE TUMORS

Numerous soft tissue tumors have been described and are of mainly ectodermal and mesodermal origin. Some of these pediatric neoplasms are classified in Table 70-2. Only those soft tissue tumors likely to be encountered by pediatric surgeons are discussed here. More extensive discussions of soft tissue tumors are available.<sup>204,205</sup> Many soft tissue tumors are cutaneous or subcutaneous and are amenable to excision under local anesthesia.

## Epidermal Tumors

### Pyogenic Granulomas

Pyogenic granulomas are solitary polypoid capillary lesions often associated with trauma or local irritation. They are commonly found on the skin as red, raised, occasionally bleeding lesions or in the mouth in association with pregnancy.<sup>206</sup> They are easily treated with topical silver nitrate or liquid nitrogen or ligation of the polyp neck. Rarely, excision or electrocautery is needed.

### Skin Papillomas

Skin papillomas resemble skin tags of the mucous membrane and occur at birth or in childhood.<sup>207</sup> Sessile variants may be called *verrucae*, whereas the

**Table 70-2** Classification of Soft Tissue Tumors That Occur in Children

Tissue	Benign	Malignant
<b>Ectoderm</b>		
Epidermis	Dermoid cyst, calcifying epithelioma (pilomatrixoma)	Epidermoid cancer
Sweat gland	Hidradenoma	Adenocarcinoma
Sebaceous gland	Sebaceous cyst	Epidermoid cancer
Melanocytes	Nevus	Malignant melanoma
Nerve tissue	Neurofibroma	Neurofibrosarcoma
<b>Mesoderm</b>		
Undifferentiated	Mesenchymoma, myxoma	Malignant mesenchymoma
Fibrous tissue	Fibroma, fibromatosis, keloid	Fibrosarcoma
Vascular tissue	Hemangioma, lymphangioma, glomus	Hemangioendothelioma, Angiosarcoma
Adipose tissue	Lipoma, lipoblastoma	Liposarcoma
Muscle	Rhabdomyoma	Rhabdomyosarcoma
Synovial tissue	Giant cell synovioma, ganglion cyst, synovial cyst	Malignant synovioma

projections are termed *acrochordons*. Treatment is by simple excision.

### Warts

Warts are uncommon before age 4 years but are a common pediatric complaint.<sup>207</sup> Various subtypes of human papillomavirus affect different body areas.<sup>206</sup> *Verrucae* spread through families, sports teams, and schoolmates and are most common on the hands and feet.<sup>207</sup> Topical treatment includes salicylic or trichloroacetic acid, liquid nitrogen, or fine-tip electrocautery. Excision is occasionally required.

*Condylomata acuminata* occur in the perineal skin and suggest, but do not prove, child sexual abuse. The virus may be transmitted by hand contact during diaper changes in infants or acquired at birth during vaginal delivery, but the lesions may take months to develop. One study suggested that sexual abuse is an unlikely source of transmission in children younger than 3 years if no other signs of abuse are present.<sup>208</sup> These lesions have a core of connective tissue covered in epithelium, occurring as solitary or cauliflower-like lesions. Spontaneous regression is known, but topical podophyllin may be required. Some cases may necessitate electrocautery under general anesthesia to enable a thorough rectoscopic and vaginoscopic assessment and treatment.

### Aberrant Skin Glands

Aberrant skin glands appear as rough, yellow-brownish skin resembling nevi or xanthoma. Histologic examination reveals adenoid hyperplasia, but a potential for later malignant change is reported. Therefore, excision of these lesions is recommended.<sup>207</sup>

### Calcifying Epithelioma of Malherbe

The calcifying epithelioma of Malherbe or pilomatrixoma is a solitary benign calcifying tumor of hair follicles. This is one of the most common acquired soft tissue lesions in children. Clinically, a circumscribed, firm, mobile, intracutaneous or subcutaneous nodule is palpable, with occasional yellowish or bluish coloration (Fig. 70-16). These lesions are most common before age 20 years, and 60% to 70% are found in the head and neck region.<sup>206</sup> Only 2% to 3% are multiple, and most are smaller than 1 cm, although lesions up to 4 cm have been reported.<sup>206,209</sup> They are more common than sebaceous cysts in younger patients. Local excision is indicated.<sup>209</sup>

### Sweat Gland Lesions

Sweat gland pathology results from disorders of the sebaceous, apocrine, or eccrine adnexal structures of the skin. One series reported that only 1.7% of pediatric skin biopsy specimens showed these lesions.<sup>206</sup> Hidradenomas originate from the ductal portion of the sweat gland and are seen as multiple small flesh-colored papules on the face, neck, and upper chest during

**Figure 70-16.** This operative photograph shows a pilomatrixoma (calcifying epithelioma of Malherbe). These lesions are circumscribed, are firm, and have a distinctive “knobby” appearance. Once removed, they are seen to have a yellowish content. Most of these lesions are found in the head and neck region.

puberty and adolescence. Two subtypes are of interest: the eruptive form results in many lesions in a short period, whereas the clear cell variant causes solitary and occasionally painful lesions.<sup>206</sup> Sweat gland carcinomas are uncommon and are rarely differentiated enough to subtype confidently.<sup>206</sup> They may be locally aggressive and metastasize to the local lymph nodes. Treatment primarily involves resection with individualized adjuvant therapy.

### Malignant Epithelial Tumors

Malignant epithelial tumors are rare in children.<sup>207</sup> General treatment principles include wide local excision and radiation therapy for prevention of recurrence.<sup>207</sup> Only 1% of all basal cell carcinomas occur in children. The basal cell nevus syndrome<sup>210</sup> is an autosomal dominant disease with basal cell lesions of the eyes, nose, and cheeks in association with anomalies of the mouth, skin, skeleton, central nervous system, eyes, and genitals. These patients may have concomitant xeroderma pigmentosum. Epidermoid or squamous cell carcinoma also is found in xeroderma pigmentosum patients.<sup>206</sup> Epidermoid cancers in pediatric transplant recipients also have been reported.<sup>206</sup>

### Tumors of Nerve Tissue

#### Neurofibromas

A neurofibroma is a benign neoplasm of abnormal proliferation of Schwann cells, usually of peripheral nerves. When multiple fibromas are present or associated with multiple café-au-lait spots, neurofibromatosis type 1 (NF1, von Recklinghausen’s disease), an autosomal dominant disorder, may be present. The *NF1* gene appears to produce a tumor suppressor product, and neurofibromatosis may be a disease to which the two-hit genetic hypothesis applies.<sup>211</sup> The diagnosis may be delayed, but children in affected probands are usually diagnosed earlier, even by prenatal

**Table 70-3** Clinical Patterns in Neurofibromatosis

Clinical Pattern	Description
Fibroma molluscum	Hundreds or thousands of pedunculated nodules; number makes resection impractical.
Plexiform neurofibroma	Occur usually in the face and scalp, causing bony deformity by pressure erosion; resections for cosmesis may be repeated because curative resection is rare.
Elephantiasis nervorum	With neurofibromas of the extremities, these cause greatly thickened skin simulating limb hypertrophy; resection is done to manage disfigurement.
Thoracic neurofibroma	May have intraspinal extension (dumbbell tumor); has a high incidence of malignancy
Visceral neurofibroma	May affect intestine, kidney, and bladder because of the presence of associated nerves; when large, neurofibrosarcoma incidence increases.
Skeletal syndromes	Include kyphoscoliosis, pseudarthrosis of tibia and ulna
Cranial syndromes	Meningiomas, gliomas, and optic gliomas have been reported.
Endocrine syndromes	Sexual precocity, medullary thyroid carcinoma, and pheochromocytoma have been reported.
Cardiovascular syndromes	Heart is rarely involved, but coarctation of the aorta and renal artery lesions have been reported.

ultrasonography.<sup>212,213</sup> Neurofibromas of the mucosa are associated with multiple endocrine neoplasia type 2B and can appear in childhood before medullary thyroid carcinoma or pheochromocytoma.<sup>214</sup> The *NF2* gene has been associated with acoustic neuromas.

Neurofibromatosis type 1 has several clinical forms, which are summarized in Table 70-3.<sup>215</sup> Because operative management can not cure a genetic disorder, a multidisciplinary team supports patients and parents through decision making, treatment, rehabilitation, and developmental challenges (Fig. 70-17). Malignant degeneration to neurofibrosarcoma and associated malignancies<sup>216</sup> may necessitate ultrasonography, CT, or MRI studies for new symptoms. Patients with

neurofibromatosis type 1 have a 7% to 12% lifetime risk of developing associated malignant peripheral nerve sheath tumors, which often arise within a plexiform neurofibroma.<sup>217</sup> These lesions are aggressive, metastasize widely, and portend a poor prognosis. Traditionally, clinical symptoms such as pain, rapid tumor growth, and new-onset neurologic deficit have been used to predict malignant change in previously stable neurofibroma.<sup>217,218</sup> Recent studies have suggested that 18-fluorodeoxyglucose positron-emission tomography (FDG-PET), in conjunction with CT or MRI, may help identify malignant lesions based on standardized uptake levels.<sup>219</sup>

These imaging modalities are useful in monitoring larger or deeper neurofibromas as well. Rapid growth is an ominous sign of malignant transformation. Excision or debulking may be combined with chemotherapy and radiation therapy.<sup>220</sup> Radiation therapy does not appear to be useful in slowing the progression of benign disease but has been documented to cause neurofibrosarcoma.<sup>221</sup> Treatment with chemotherapy and interferon-alfa has been of limited value.

### Xanthomas

A xanthoma is a tumor of lipid-laden histiocytes or foam cells forming yellowish skin nodules. It may be due to uncontrolled diabetes mellitus or biliary tract obstruction, which unbalances triglyceride and cholesterol metabolism, leading to accumulation in histiocytes. Xanthomas are typical features of Alagille syndrome (syndromic paucity of bile ducts) and familial hypercholesterolemia (Fig. 70-18). Correcting the underlying disorder reverses these lesions, but excisional biopsy may be indicated for bothersome lesions or for diagnostic purposes.

## Tumors of Mesoderm

### Undifferentiated Mesenchyme

#### MESENCHYMOMAS

Mesenchymoma is a mixed mesenchymal tumor of two or more cellular elements not commonly associated (not including fibrous tissue). It can occur after

**Figure 70-17.** MR image of a young boy with extensive neurofibromatosis type 1 who had undergone two previous cervical laminectomies to remove plexiform neurofibromas that were causing symptomatic cord compression. The left neck mass was enlarging, causing tracheal deviation and growing along the cervical nerve roots. This boy also had increasing left arm weakness and pain. A trial of chemotherapy with vincristine and dactinomycin did not stop progression of the disease.

**Figure 70-18.** Multiple xanthomas are seen in a child with Alagille syndrome.

radiation therapy or chemotherapy.<sup>222</sup> These lesions are usually benign in children and occur primarily in the head, neck, and extremities. Rib lesions in neonates and liver lesions also are described.<sup>223</sup> Malignant mesenchymoma is the corresponding sarcoma and is rare.

### MYXOMAS

A myxoma is a benign primitive connective tissue cell and stroma tumor resembling mesenchyme. It occurs mainly in the heart, producing symptoms by obstructing normal blood flow, and is removed by using cardiopulmonary bypass (Fig. 70-19).

## Fibrous Tissue Tumors

### Fibromas

A fibroma is a lesion composed of fibrous or fully developed connective tissue occurring as lytic bone lesions, breast lumps, finger swelling, and other forms.<sup>223</sup> Fibromatosis usually is first seen in infancy with multiple firm rubbery masses in the soft tissues, generally in the lower extremities and head and neck. When it is congenital and generalized, death may occur in the first weeks of life, due to pulmonary lesions.<sup>223</sup>

### Nodular Fasciitis

Nodular fasciitis is the most common fibrous tissue tumor or self-limiting reactive process.<sup>224</sup> These tumors may be subcutaneous, intramuscular, or fascial in location and are commonly found in the head and neck of children.<sup>224</sup> Half of cases are associated with discomfort, and one fourth of lesions occur in patients younger than 20 years. Excisional biopsy is necessary to differentiate these rapidly growing lesions from a malignancy.

### Fibrosarcomas

Fibrosarcoma is a neoplasm producing collagen that otherwise lacks cellular differentiation. Childhood fibrosarcoma has a bimodal age distribution (younger than 5 years and ages 10 to 15 years). Childhood

**Figure 70-19.** This 15-year-old presented with jugular venous distention and upper torso edema. **A and B,** A large (4 × 5 cm) mass (asterisk) was found in the right atrium on CT scan. **C,** The mass was excised in its entirety along with a full-thickness portion of the atrial septum (arrow). **D,** On histologic examination, the characteristics of an atrial myxoma are identified. This low-power photomicrograph shows a very hypocellular tumor with an abundant extracellular myxoid matrix.

fibrosarcoma is treated with complete excision. Adult-type fibrosarcoma is an aggressive lesion with a poor prognosis despite multimodal therapy. The two lesions may be difficult to differentiate.<sup>225</sup>

### Congenital Epulis

Congenital epulis is a benign granular cell tumor occurring almost exclusively in girls at or immediately after birth. It originates from the maxillary dental mucosa and averages 1 to 2 cm in diameter.<sup>226</sup> Its exact nature is not clear. Some classify it under tumors of peripheral nerves, whereas others consider it a fibrous tumor, hence the synonym granular cell fibroblastoma. Spontaneous regression is unusual, and simple excision is curative.<sup>226</sup>

### Keloid

A keloid is a sharply elevated, irregularly shaped, progressively enlarging scar caused by excessive collagen in the dermis during connective tissue repair. Unlike the hypertrophic scar (which does not progress), a keloid may recur after excision. Treatment with intradermal injection of corticosteroids, pressure garments (as used for burn patients), and cryosurgery may be attempted. Rarely, judicious excision with radiation therapy may be used.<sup>227</sup> Keloids developing after minor procedures are common. Their incidence is higher in blacks.

### Desmoid Tumors

Desmoid tumors are fibrous tumors that usually arise from musculoaponeurotic tissue of the skull or abdominal cavity, hence the modern name musculoaponeurotic fibromatosis.<sup>228</sup> They are not encapsulated and are locally invasive, although they do not metastasize. They are associated with Gardner syndrome.

When they arise from the retroperitoneum, complete resection may be impossible without risking damage to splanchnic vessels. High-dose radiation therapy or interstitial brachytherapy may be considered for residual tumor. Chemotherapy using methotrexate and vinblastine or the tyrosine kinase inhibitor imatinib mesylate has engendered favorable reports.<sup>229,230</sup> Corticosteroid therapy (tamoxifen, prednisone) and nonsteroidal therapy (indomethacin and sulindac) have been used in recurrent and inoperable tumors.<sup>231</sup> Shrinkage of a desmoid tumor has been reported by using interferon-alfa as well.<sup>232</sup>

### Vascular Glomus Tumors

A glomus tumor is an uncommon pediatric lesion consisting of a meshwork of fine arterioles connected to veins and intertwined with nerve tissue. Multiple tumors have a greater tendency to develop in children than in adults, possibly representing autosomal dominant inheritance.<sup>223</sup> The lesions on the skin are discrete blue-black spots and may be extremely

painful if present under nails. Excision is the preferred treatment.

### Adipose Tissue Tumors

A lipoma is a benign, soft, rubbery, encapsulated tumor of adipose tissue composed of mature fat cells occurring on the trunk, neck, and forearms. In one review of adipose tumors, lipomas represented 94%; lipoblastoma, 4.7%; and liposarcoma, 1.3%.<sup>233</sup> All are slow-growing tumors. Diagnosed often before age 3 years, lipoblastoma may be superficial and well encapsulated or it may be deep and infiltrative. Definitive treatment of adipose tumors is complete resection. Chemotherapy may play a role in treating residual liposarcoma. Local recurrence rates for lipoblastoma and liposarcoma are 10% to 20%.<sup>233</sup> Characterized by a myxoid stroma, embryonal lipoblasts, and mature fat cells, the myxoid variant of liposarcoma is similar histologically to lipoblastoma. Tumor karyotyping may be useful in differentiating these adipose tumors.<sup>233</sup>

Liposarcoma arises from the intramuscular fascia, where embryonal lipoblasts exhibit variable differentiation with occasional nuclear atypia. The myxoid variant is the most common and metastasizes late, if at all. The dedifferentiated subtype is highly malignant and may co-exist with spindle cell sarcoma.

### Tumors of Synovial Tissue

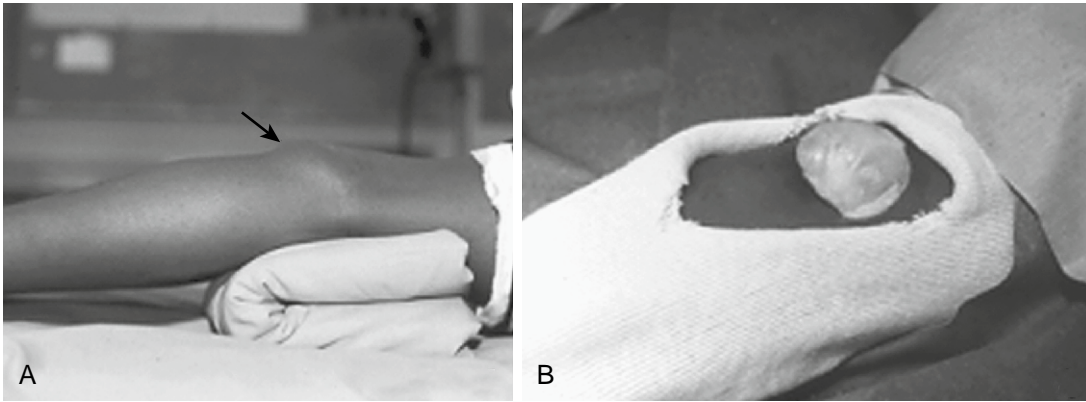

#### Synovial Cysts

Synovial cysts or ganglion cysts arise from joints or tendon sheaths, resulting in firm 0.5- to 2-cm, mucin-filled lesions with a fibrous capsule. They are most common on the hand, especially on the dorsum of the wrist, but also occur on the ankle, foot, and popliteal fossa (where they are called Baker's cysts [Fig. 70-20]). One fourth of the latter occur in children younger than 6 years.<sup>234</sup>

Pathology texts separate synovial cysts that have a true synovial lining (e.g., Baker's cysts) from ganglia, which are thought to be degenerative and are without a synovial lining.<sup>235,236</sup> Clinicians, however, usually use both terms interchangeably.<sup>237</sup> Symptoms of pain and weakness can occur, but most children present with an asymptomatic mass. Spontaneous resolution of all types of synovial cysts is common in children. Surgical treatment is reserved for patients with persistently symptomatic lesions.<sup>237</sup> Classic treatment includes traumatic disruption ("strike it with the family Bible") or corticosteroid injection. Both should be discouraged because of the high recurrence risk and associated pain. The use of nonsteroidal anti-inflammatory agents, coupled with rest or wrist splinting, is usually sufficient if the cyst causes transient discomfort.

#### Giant Cell Synoviomas

The giant cell synovioma is a benign tumor of the tendon sheath, generally occurring before age 10 years.<sup>223</sup> It occurs on the volar aspect of fingers in most cases.

**Figure 70-20.** **A**, This patient has been turned in a semi-prone position and a Baker cyst (*arrow*) is readily visualized with extension of the knee. **B**, On the right, the cyst is seen bulging through the skin incision. The cyst was excised due to its large size and interference with running. The child recovered uneventfully without recurrence.

A 10% to 15% recurrence rate can be expected after treatment by resection.<sup>223</sup> Malignant synovioma or synoviosarcoma represents 5% to 10% of soft tissue malignancies in patients younger than 20 years.<sup>238</sup> Most occur near the knee, but they also are found in the head and neck, anterior abdominal wall, and inguinal area. The mass may be palpable or reveal

itself as calcification on a radiograph. Cure by wide excision without chemotherapy can often be achieved, but the neurovascular anatomy related to the tumor may necessitate microsurgical reconstruction, if not amputation. The calcifying subtype has a better 5-year survival rate (83%) than the noncalcifying subtypes (25% to 50%).<sup>239</sup>

# LYMPHOMAS

Karen B. Lewing, MD • Alan S. Gamis, MD, MPH

Lymphomas are a result of chromosomal alterations resulting in the uncontrolled growth of cells of lymphoid origin. Among all ages, lymphomas constitute just 4% of all cancers diagnosed annually in the United States.<sup>1</sup> In children, however, this percentage increases to 11%.<sup>2</sup> Combined, Hodgkin's and non-Hodgkin's lymphoma are the second most common childhood solid tumors (behind brain tumors and ahead of neuroblastoma). These two malignancies compose approximately 15% of all childhood solid tumors annually.

Lymphomas have classically been divided into two distinct groups: Hodgkin's disease (HD) and non-Hodgkin's lymphoma (NHL). In 2001, HD was designated Hodgkin's lymphoma (HL) by the World Health Organization (WHO) lymphoma classification system.<sup>3</sup> Typically, patients with both HL and NHL are initially seen with enlarged lymph nodes and may have systemic symptoms of fever and fatigue and/or extralymphatic spread. However, these two types of lymphoma also have clear differences. HL typically is seen as an indolent process, whereas NHL is most often seen in children with a rapid onset of symptoms. Because of this propensity for rapid growth, children with NHL often have associated anatomic and metabolic co-morbidities to such a degree that their recognition and need for treatment constitutes a medical emergency. With HL, treatment is based primarily on staging and less on histologic subtype. In contrast, the current treatment of NHL depends on the histologic and immunophenotypic subtypes in addition to stage.

These two lymphomas are truly a study of contrasts. This is no more evident than in the evolution of their therapy. For years, HL has been one of the most curable cancers. Now, with markedly improved treatment protocols, NHL has a nearly equivalent cure rate.<sup>4</sup> Owing to the historic high survival with HL, its therapy has focused on reduction in intensity. Because of its previously poor prognosis, NHL therapy has focused on intensification of therapy. The use of higher doses of chemotherapy over a short period (as compared with prior methods) has resulted in the dramatic improvement in cure and response of NHL.

Although most histologic types of HL are treated similarly, it is important to classify fully the subtype of NHL because marked differences occur in the effective therapies administered for each type. In considering the surgeon's role in the therapy for childhood lymphomas, there are no real differences between the two types of lymphomas. However, in contrast to other solid tumors of childhood, in which initial resection of the tumor is important, the primary role of the surgeon in the initial management of lymphomas is to ensure the rapid attainment of adequate and properly preserved biopsy material to allow the pathologist the opportunity to make the diagnosis of the specific type and subtype of lymphoma. Except for certain situations, attempts to resect lymphomas at the time of presentation have no role in the modern management of lymphomas.

## HODGKIN'S LYMPHOMA

Thomas Hodgkin, in his classic thesis in 1832, described the gross necropsy examinations of seven patients.<sup>5</sup> He noted the association of generalized lymphadenopathy and splenomegaly in six patients without evidence of infection or inflammation. Histologic descriptions of the Reed-Sternberg (RS) cell, the pathognomonic multinucleated giant cell, did not occur until after the turn of the century.<sup>6,7</sup> Even though the etiology was unclear, therapeutic interventions began soon after the discovery of x-rays. More successful application of radiation therapy awaited the description of the disease's propensity for contiguous spread. With this knowledge, application of radiation to the involved and adjacent nodal areas (extended-field technique) resulted in improvements in survival in the late 1930s.<sup>8</sup> In the early 1960s, in acknowledgment of the limitations of the radiologic techniques of that era, the practice of systematic laparotomy, splenectomy, and celiac node and liver biopsy at the time of initial presentation was developed for the purpose of staging and for targeted therapy.<sup>9</sup> This has properly been described as the model for the careful staging of cancer

as a required prerequisite to the design of therapy, which is a hallmark of oncologic practice today.<sup>10,11</sup> During this same time, chemotherapy combinations entered into the physician's armamentarium. With their use, remission and cure rates markedly improved. The improvement has made HL one of the most curable cancers today, with a 5-year survival of 95% for patients diagnosed between 1996 and 2002.<sup>12</sup> With this high expectation for cure, attention over the past decade in pediatric oncology has focused on the reduction of long-term sequelae of treatment. To this end, chemotherapy has evolved from an adjunctive role to a primary one, with the hope of eliminating the need for irradiation (and its attendant sequelae) altogether. When irradiation is needed, if used in combination with chemotherapy, the focus has been to reduce the size of the fields (from extended to involved) and the doses used. The two classic chemotherapy combinations (MOPP: nitrogen mustard, vincristine [Oncovin], procarbazine, prednisone; and ABVD: doxorubicin [Adriamycin], bleomycin, vinblastine, dacarbazine) have evolved to reduce long-term sequelae. Hybrids of these combinations are being utilized to reduce the doses delivered to the patient, with equivalent results and less toxicity.

## Incidence and Epidemiology

Among all ages, 7500 individuals each year are diagnosed with HL in the United States, accounting for just 0.5% of all cancers and only 12% of all lymphomas.<sup>1</sup> However, in children, it is the sixth most common type of cancer, with approximately 500 children diagnosed annually.<sup>2</sup> This constitutes 5% of all childhood cases of cancer and 44% of all childhood cases of lymphoma. HL has an incidence of 5 cases/million children age birth to 14 years/year.<sup>13</sup> A bimodal distribution exists when considering all ages, but in children alone a gradual trend is seen of increasing incidence with increasing age (Fig. 71-1). HL is exceedingly rare in children younger

**Figure 71-1.** Incidence rates for lymphomas in children younger than 15 years. HD, Hodgkin's disease; NHL, non-Hodgkin's lymphoma. (From Gurney JG, Severson RK, Davis S, Robison LL: Incidence of cancer in children in the United States. *Cancer* 75:2186-2195, 1995.)

than age 2 years and peaks in the adolescent years.<sup>2</sup> Beyond age 11 years, it is the most common of the two types of lymphoma and accounts for about 15% of all cancer in young adults ages 15 to 24 years.<sup>13</sup> A slight male predominance (1.32:1) is noted, but in the youngest children the male-to-female ratio is much larger (12 to 19:1).<sup>2,14</sup>

HL occurs more often in whites than in blacks (1.3:1).<sup>15</sup> Familial clusters of HL have been noted. Whether this represents risk due to environmental exposure (most often thought to be infectious) or genetics is uncertain. Monozygotic twins of HL patients have been found to be at greater risk of developing HL than are dizygotic twins,<sup>16</sup> strongly implicating genetics as a principal risk factor. Conversely, again in young adults, an increased risk of HL is found with higher socioeconomic status.<sup>17</sup> Young adults with HL come from smaller families, have fewer infectious exposures as young children, and/or have later exposure to infections than do control populations.<sup>17,18</sup> This correlates closely with socioeconomic status and implicates a delayed infectious exposure as a principal risk factor.

Most likely, a combination of genetic risk and infectious exposure predisposes a young adult to HL. Immunodeficiency may be the link between these two risk factors, at least in a subgroup of HL patients. HL is more prevalent in human immunodeficiency virus (HIV)-infected patients.<sup>19-21</sup> Also, patients with HL have a higher incidence of cellular immunodeficiency at the time of diagnosis.<sup>22</sup> Etiologic theories encompass these two risk factors and focus primarily on the Epstein-Barr virus (EBV). Genomic material from EBV has been found in the RS cells in up to 79% of HL cases.<sup>23-25</sup> This has the highest association with the mixed cellularity subtype.<sup>26</sup> An association with EBV is not seen in patients with the nodular lymphocyte-predominant (LP) subtype.<sup>27</sup> A higher risk of HL has been noted in individuals with a history of infectious mononucleosis<sup>28-30</sup> and with previously high titers to EBV.<sup>31</sup> This risk was greater when infected at an older age, and the risk lessened with time from infection.<sup>29</sup> In one report, epidemiologic investigations identified a median incubation time of 4.1 years between infectious mononucleosis and the development of EBV-positive HL.<sup>30</sup> One hypothesis that incorporates these factors suggests the following sequence: (1) a genetic, iatrogenic, or viral immunosuppression; (2) subsequently or coincidentally, an EBV infection or oncogenetic rearrangement in a lymphoid precursor cell; (3) further genetic alterations, followed by (4) clonal expansion of lymphoid cells with morphologic features of RS cells, finally resulting in (5) the clinical syndrome known as HL, diagnosed by the presence of RS cells.<sup>32</sup>

## Classification and Histologic Subtyping

The diagnosis of classic HL requires the dual finding of the diagnostic Hodgkin's and RS cells (HRS cells) plus a reactive cellular background.<sup>33</sup> The RS cell is a large cell (15 to 45 mm) with an "owl's eye" appearance

**Figure 71-2.** This photograph depicts a Reed-Sternberg cell, which is pathognomonic for Hodgkin's disease. On the right side of the slide, the large nucleolus is outlined by the *dotted circle* and the entire cell is outlined by the *solid line*. Note the relatively pale nuclear chromatin. The nucleolus has the appearance of an "owl's eye" from which it receives its name. The *arrow* points to a mononuclear variant of the Reed-Sternberg cell, which has reticulated nuclear chromatin surrounding an almost rectangular macronucleus.

(Fig. 71-2). It has a multilobed nucleus (or is multinucleated), each with a prominent eosinophilic nucleolus surrounded by a clear zone (halo) and an intensely stained nuclear membrane. The "owl's eye" appearance is the result of a bilobed nucleus. The RS cell often makes up no more than 2% of the involved cells. Hodgkin's cells are the mononuclear variant of RS cells. The cellular background is a reactive, pleomorphic mixture of inflammatory cells including reactive lymphocytes, histiocytes, plasma cells, eosinophils, neutrophils, and fibroblasts, with varying degrees of fibrosis and sclerosis. The HRS cell is a clonal, neoplastic cell seen in classic HL and is thought to induce the reactive background through the abundant release of various cytokines.<sup>34</sup> The origin of HRS cells remained elusive until recently because of its paucity in sampled tissue. However, research now indicates that they are usually derived from germinal center B lymphocytes that are clonal and have lost their immunoglobulin gene transcription ability.<sup>35,36</sup> Post-germinal center B-cell origin has been described, as well as a rare case of HL derived from peripheral T cells.<sup>37-41</sup> In classic HL, HRS cells have a unique molecular defect with clonal immunoglobulin gene rearrangement and no immunoglobulin gene transcription or expression. HRS cells typically are CD15 and CD30 positive and negative for CD45 and B-lineage antigens.<sup>42</sup> In contrast, the nodular LP HL cells (popcorn cells) are usually positive for B-lineage antigens, CD15 and CD30 expressions are lacking, and the immunoglobulin genes are expressed.<sup>42</sup>

For histologic typing, the Rye classification was commonly used for 3 decades but has been supplanted by the WHO classification. The 2001 WHO classification

lists two main types of HL: classic HL and nodular LP. Classic HL is further divided into four subtypes by morphology. These subtypes include nodular sclerosis (NS, the most common), mixed cellularity (MC), lymphocyte predominant (LPHL), and lymphocyte depleted (LDHL).<sup>3</sup> The NS subtype is seen in 40% of younger patients and 70% of adolescents.<sup>43</sup> It is characterized by tumor nodules surrounded by broad sclerotic bands arising from a thickened fibrotic capsule.<sup>33</sup> This subtype has a strong predilection for involvement of the lower cervical, supraclavicular, and mediastinal lymph nodes. The MC subtype is found in 30% of cases and has an increased incidence in younger children.<sup>14</sup> HRS cells are typically increased in number. The lymph node architecture is often completely effaced by the HRS cells and their surrounding reactive cells. This subtype often is first seen with advanced, widely disseminated disease in extranodal sites. In addition to its relatively common incidence among all HL patients, it is the most common histologic type seen in HIV-infected patients.<sup>21</sup>

From 1978 to 1986, the National Cancer Institute (NCI)-sponsored SEER data revealed the following patient 5-year survival rates using the formerly used Rye classification histologic subtype: LP, 83.9%; NS, 82.2%; MC, 68.1%; and LD, 36.4%.<sup>44</sup> Reports have now shown that LPHL has a better prognosis with markedly reduced therapy needed to achieve cure.<sup>45,46</sup> This differentiation of therapeutic response between LPHL and the other classic HL histologic types appears to validate the distinction observed in the immunophenotyped RS cells.<sup>47</sup> Clinical trials are now underway to explore this difference further and to examine whether reduced therapy for nodular LPHL is possible. The worse outcome of the MC and LDHL types may reflect their typically higher stage at diagnosis.

## Clinical Presentation

Children are first seen with painless enlarged lymph nodes, typically in the cervical or supraclavicular nodal groups (Table 71-1). Nodes are often described as rubbery and fixed. They may be either single or matted with other nodes. Occasionally, because of rapid growth, tenderness may be present. Tumor lysis syndrome, a result of rapid and extensive tumor growth and a common complication in children with NHL, is rarely seen in children with HL.

HL tends to spread in a contiguous manner. Therefore, at presentation, one must examine carefully the nodal groups adjacent to the initially identified nodes. More than 90% of patients have involvement of either the cervical or mediastinal nodal groups, or both.<sup>48</sup> Interestingly, HL tends to spread from the cervical nodes of one side of the neck to the mediastinum before it spreads to the contralateral cervical nodes. When surgical laparotomy was included in the staging process (which is no longer routinely recommended), the spleen was noted to be involved in 27% of patients.<sup>48</sup> When evaluating the histologic subtypes and patterns of initial involvement, it is clear from Table 71-1 that the MC and LD subtypes of HL have

**Table 71-1** Hodgkin's Disease: Sites of Involvement at the Time of Initial Diagnosis

Nodal Sites	Histologic Subtype (%)			
	NS	MC/LD	LP	All
Mediastinum	73	46	8	59
Cervical	55-62	53-60	41-46	55-58
Axillary	11-15	14-16	13-14	13-14
Hilar	14-15	8-9	3-5	11-12
Upper neck	4	4	14	5
Epitrochlear	1	1	6	2
Spleen	24	35	17	27
Upper abdomen	13	18	5	14
Lower abdomen	8	17	8	11
Inguinal	1	3	10	2-3

NS, nodular sclerosis; MC/LD, mixed cellularity/lymphocyte depleted; LP, lymphocyte predominant.

more widespread involvement than do the NS or LP HL subtypes.

Mediastinal disease, in addition to a predilection for certain histologic subtypes, is most common in children older than 12 years, in girls, and in those with constitutional symptoms (also known as B symptoms).<sup>49</sup> Mediastinal disease may appear with significant respiratory compromise due to compression of the trachea, carina, or both, including the major bronchi.<sup>50</sup> These patients may have dyspnea on exertion or at rest, persistent cough, or stridor. They may have recently been treated for presumed asthma or bronchiolitis, without radiographic imaging. Patients with this presentation may have a history of orthopnea and are most comfortable in an upright forward-leaning position to relieve the pressure on the airway (from the anterior mediastinal mass). The physician must be vigilant for mediastinal disease because it may be silent until a patient is sedated for a radiologic or surgical procedure. These patients may prove impossible to aerate even with intubation because of distal tracheal or bronchial obstruction. It is imperative that all patients with suspected lymphoma (HL or NHL) have a chest radiograph or chest CT scan before any sedation or procedure. These patients may also have signs of superior vena caval obstruction, including edema and cyanosis of the face and venous distention. Extralymphatic involvement can include the liver (the most common extralymphatic organ involved), lungs, bone, bone marrow, and skin, among other sites. Whereas bone marrow involvement is present in only 4% to 14% of patients overall, among those patients with stage IV disease it is present 32% of the time.<sup>51</sup>

Most patients have no systemic symptoms at the time of initial diagnosis. About one fourth of patients will have one or more B symptoms, defined as weight loss of more than 10% in the previous 6 months, unexplained recurrent fevers greater than 38°C, or drenching night

sweats.<sup>48</sup> Pruritus, fatigue, and anorexia are other non-specific symptoms seen in HL patients. Laboratory findings in patients at diagnosis are nonspecific and typically are indicative of an inflammatory process. The erythrocyte sedimentation rate (ESR), serum copper, and ferritin levels are frequently elevated and may be monitored later for evidence of relapse. A high ferritin (>142 ng/mL) level or increased ESR (>50) has been associated with a worse prognosis.<sup>52,53</sup> The lactate dehydrogenase (LDH) value may be elevated as well. Although not common, leukopenia may be indicative of bone marrow involvement.<sup>51</sup>

## Diagnosis

The diagnostic evaluation should include physical examination and laboratory and radiologic studies (Table 71-2). The physical examination should be directed to the obviously involved nodal groups and also to the adjacent groups, keeping in mind the natural history of HL and its propensity for contiguous spread. The number of involved nodal groups in stage II patients (more than four) has been associated with a worse prognosis and should be carefully determined.<sup>54</sup> The size of the palpable nodal masses should be estimated and recorded. Bulky disease (nodes or nodal aggregates > 10 cm and/or mediastinal tumor width more than one third of intrathoracic width on a posteroanterior chest radiograph or CT) is associated with a worse outcome in low-stage patients and necessitates additional therapy to achieve equivalent outcomes.<sup>55-57</sup> Auscultation of the airway, palpation of the abdomen, and examination of distant nodal groups are critical as well.

Laboratory examination should include full blood cell counts and chemistries, including hepatic function tests, LDH, and ESR. Serum copper and ferritin levels also should be obtained. However, no clinical findings

**Table 71-2** Hodgkin's Disease: Diagnostic and Staging Evaluation at Presentation

Complete physical examination with documentation of involved nodal groups (including measurements of nodes), and involved extralymphatic organs
Complete blood cell count, chemistry panel including hepatic function tests, erythrocyte sedimentation rate, copper, ferritin, lactate dehydrogenase
Chest radiography to evaluate for possible mediastinal disease and airway compression
CT scans of areas identified on physical examination (also include chest, neck, and abdomen)
Positron emission tomography
Gallium scan
Bone scan
Excisional biopsy of node
Bone marrow biopsies and aspirates (bilateral)
Lymphangiogram (optional)
Staging laparotomy/laparoscopy (mandatory if considering radiation therapy alone) with splenectomy, nodal sampling, and wedge biopsies of hepatic lobes

are pathognomonic for HL. Ultimately, the diagnosis awaits the biopsy of involved sites, most commonly an excised lymph node. The surgeon's goal is to biopsy the most accessible nodal region to obtain adequate tissue for diagnosis. Open excision of the largest lymph node is preferred because fine-needle aspirations generally do not provide adequate tissue. Excisional biopsy is where the diagnosis is made, based on the pathognomonic finding of HRS cells within a reactive cellular background. For cytogenetic and molecular genetic evaluations, it is imperative that all tissues are placed in a sterile container for fresh samples. Formalin should never be used. For patients critically ill at diagnosis, such as those with severe airway obstruction, diagnosis by alternative methods needs to be considered. These may include nodal biopsy with local anesthesia alone, CT-guided percutaneous needle biopsy of the mass, aspiration of a pleural effusion, or a bone marrow biopsy and aspirate.

## Staging

Further evaluation of a patient with HL is required to determine the extent of disease at diagnosis and thus the stage of disease (Table 71-3). The common staging system for HL was adopted in 1971.<sup>58</sup> This system is based on the observation of contiguous nodal spread in HL. Patients are further divided into asymptomatic (A) and symptomatic (B) subcategories. This subclassification for symptomatic patients is based on the findings of a worse prognosis for B patients and the need for a systemic therapy approach in them (i.e., chemotherapy in addition to radiation). This likely reflects the finding that patients with B symptoms are more likely to have distant, widespread disease when pathologically staged.<sup>59</sup>

For HL, the decision for the method and the extent or intensity of therapy rests on the staging results. Traditionally, two types of staging were used in HL patients: clinical and pathologic. Until recently, all patients underwent both methods. Clinical staging includes physical, laboratory, and radiologic evaluations. Pathologic staging requires a staging laparotomy with splenectomy, nodal sampling, and wedge biopsies of both hepatic

lobes. The radiologic evaluations have been in evolution over the past decade. Lymphangiograms, once a critical component of staging in HL, have been supplanted by more modern and less invasive imaging modalities. CT examination is used most frequently.<sup>60</sup> For those who will be treated by irradiation alone, accurate assessment of abdominal disease is critical. Staging laparotomy with splenectomy, nodal sampling, and wedge biopsies of both hepatic lobes has been shown to increase the stage of disease in up to 35% of patients initially evaluated with CT<sup>61,62</sup> (i.e., the difference between clinical and pathologic staging). This would seem to indicate that abdominal exploration is important. However, again, with the use of systemic chemotherapy and the de-emphasis on irradiation, this discrepancy between clinical and pathologic staging no longer appears to have a significant impact on treatment or outcome.<sup>63,64</sup>

For the majority of children with HL, staging is based on clinical criteria and laparotomy (or laparoscopy) is not encouraged or recommended. Abdominal staging should continue to be used in patients destined to be treated with irradiation alone (although this is now rare in children) because abdominal disease would have a significant impact on planned therapy.<sup>65</sup> Staging laparotomy (or laparoscopy) with splenectomy is not without its risks. These are the typical postoperative complications of abdominal surgery. Moreover, with splenectomy, there is a lifelong risk of overwhelming sepsis with encapsulated organisms and these patients require lifelong antibiotic prophylaxis.<sup>66</sup> An increased risk of secondary leukemia also exists in those HL patients treated with chemotherapy who have undergone splenectomy (5.9%) compared with those who have not (0.7%) as part of their staging procedure.<sup>67-69</sup>

Nuclear medicine scans are another modality that are increasing in HL patients. Although early studies of gallium scanning found its value suspect,<sup>70,71</sup> it has its greatest impact in identifying unrecognized sites of disease at presentation and in follow-up. This is especially true for patients with mediastinal disease. Patients with NS subtypes will often have persistently enlarged cervical and mediastinal nodes due to scar tissue. Although these are enlarged on CT, negative

**Table 71-3** Ann Arbor Staging Classification for Hodgkin's Disease

Stage	Definition
I	Involvement of a single lymph node region (I) or of a single extralymphatic organ or site (I <sub>E</sub> )
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site and its regional lymph node(s) with involvement of one or more lymph node regions on the same side of the diaphragm (II <sub>E</sub> )
III	Involvement of lymph node regions on both sides of the diaphragm (III), which may be accompanied by involvement of the spleen (III <sub>S</sub> ) or by localized involvement of an extralymphatic organ or site (III <sub>E</sub> ) or both (III <sub>SE</sub> )
IV	Disseminated (multifocal) involvement of one or more extralymphatic organs or tissues with or without associated lymph node involvement or isolated extralymphatic organ involvement with distant (nonregional) nodal involvement

Adapted from Carbone PP, Kaplan HS, Husshoff K, et al. Report of the committee on Hodgkin's disease staging classification. *Cancer Res* 31: 1860-1861, 1971.

gallium scans (in patients in whom these sites were gallium avid at presentation) indicate a non-neoplastic cause (i.e., residual scar tissue).<sup>72,73</sup> It has been suggested that this is most accurately predictive in initially low-stage patients (I or II) and less so in patients with advanced disease (III or IV).<sup>74</sup>

In children, it is important also to recognize the phenomena of thymic rebound after therapy. This may result in both an enlarging mediastinal mass on CT and a positive gallium scan. An experienced radiologist will recognize this phenomenon by its timing (within the first 6 months after therapy has been completed) and by the normal (although enlarged) homogeneous appearance of the thymic tissue. However, false-negative interpretations can occur. Thus, close follow-up of these patients is critical. In the past, shortages of gallium have made this examination more problematic. However, fluorodeoxyglucose-labeled positron emission tomography (FDG-PET) has been found to be more sensitive and specific than either gallium or CT.<sup>75-78</sup> Similar to gallium scanning, it leads to a higher staging in a significant percentage of patients. FDG-PET during and after therapy has been highly predictive of patient outcome<sup>79,80</sup> and helps to differentiate residual scar tissue from residual lymphoma,<sup>81</sup> although false-positive findings with inflammatory conditions have been reported.<sup>80</sup> More experience with this new modality is required before it can be used alone. Finally, the bone marrow examination continues to be important, regardless of planned methods of therapy, because its involvement would upgrade the patient's disease to stage IV status and necessitate more intensive chemotherapy.

## Treatment

### *Principles of Therapy*

Several strategies have been effective in the treatment of HL. These have included radiation therapy alone, combinations of irradiation and chemotherapy, and, most recently, chemotherapy without radiation. For children in particular, four principles guide modern HL therapy. For those with early or low-stage HL (I to III), reduction of therapy duration and intensity to reduce long-term sequelae (while maintaining the current high cure rates) is a central principle in today's regimen designs. In concert with this, the reduction and eventual elimination of irradiation as a method of therapy in children with early or low-stage HL is important. The third and most recent principle is response-based therapy. This reduces therapy for those who do not require additional doses by adjusting or eliminating anticipated cycles of chemotherapy based on the tumor's response to the initial courses of therapy. Fourth, for those with advanced-stage HL (stage IV), intensification of therapy and identification of new and more effective regimens to increase relapse-free survival are needed.

Finally, advances in pediatric oncology have been substantial, primarily owing to patients being managed

on protocols through the cooperative groups (COG and SIOP). Children, including adolescents, diagnosed with HL should be referred to, and their treatment coordinated through, one of the many centers associated with these groups. These children, through participation in the clinical trials, receive the most advanced and effective therapy available today (Table 71-4).

### *Principles of Radiation Therapy in the Treatment of Hodgkin's Lymphoma*

Despite the goal of eliminating radiation from the therapeutic regimens for children with early-stage HL, it must be recognized that HL is a very radiosensitive neoplasm. A long record of efficacy exists in using radiation either alone or in combination with chemotherapy regimens for this neoplasm. Radiation therapy has traditionally been given to the sites of disease and contiguous, clinically uninvolved, areas. This is known as extended-field irradiation. Various fields of therapy have evolved and include the preauricular (Waldeyer's ring) field, the supradiaphragmatic mantle field (submandibular, submental, cervical, supraclavicular, infraclavicular, axillary, mediastinal, and pulmonary hilar nodal groups), the subdiaphragmatic field (splenic pedicle, spleen, para-aortic nodal groups), and two pelvic fields, inverted-"Y" (common iliac, external iliac, inguinal-femoral nodal groups) or spade (inverted-"Y" excluding those nodes below the common iliac group).

More recently, involved-field irradiation has become more widely used. This is a more attractive option when combined with chemotherapy. In children, involved-field irradiation has been shown to provide excellent local control (97%).<sup>82</sup> A study from Germany identified that not only were the remission rate and disease-free survival no different between involved-field and extended-field irradiation but the side effects (leukopenia, thrombocytopenia, nausea, gastrointestinal toxicity, and pharyngeal toxicity) were significantly reduced when using only involved-field irradiation.<sup>83</sup>

The use of radiation therapy alone remains an option for therapy in adults with low-stage (I to III) HL because it allows them the opportunity to avoid the toxicity associated with chemotherapy.<sup>84-87</sup> Even if relapse occurs in those treated with radiation only, the ability to salvage a long-term cure does not appear to be compromised by delaying the use of chemotherapy until the first relapse.

However, the severe and lifelong side effects of irradiation (cosmetic defects, growth retardation, endocrinologic sequelae, and secondary malignancy) on a growing and developing child are a compelling reason to look for alternative methods. Appreciation for these long-term effects has led to a gradual reduction in the dose and in the size of the field treated. More recently, the focus has been to eliminate irradiation completely in the treatment of children with HL. An adult study suggested that this may be possible for those individuals who achieve a complete

MOPP, Nitrogen mustard, vincristine, prednisone, procarbazine; ABVD, doxorubicin (Adriamycin), bleomycin, vinblastine, DTIC; OPPA, vincristine, prednisone, procarbazine, doxorubicin (Adriamycin) – C, cyclophosphamide; BEACOPP, bleomycin, etoposide, doxorubicin (Adriamycin), cyclophosphamide, vincristine, procarbazine, prednisone; Stanford V, vinblastine, doxorubicin (Adriamycin)–vincristine, bleomycin, nitrogen mustard, etoposide, prednisone; EF, extended-field irradiation; IF, involved-field irradiation; TNI, total nodal irradiation; cGy, centigray (1 cGy = 1 rad); CR, complete remission; DFS, disease-free survival; OS, overall survival.

response (CR) with four cycles of chemotherapy.<sup>88</sup> The CCG 5942 clinical trial compared no radiation therapy to low-dose (LD) involved-field irradiation in an attempt to eliminate radiation therapy in those patients who achieved a CR after four courses of chemotherapy. Patients who received LD involved-field irradiation had an improved event-free survival (EFS), but overall survival (OS) was not different between the two groups. Currently, combined-modality therapy remains the standard of care for children and adolescents with HL.<sup>89</sup> Trials of patients with stage IA and IIA classic HL and nonbulky disease (low-risk HL) are underway to evaluate whether radiation can be eliminated after three cycles of a more intensively timed chemotherapy regimen.

The small subgroup of children in whom irradiation alone may still be considered for front-line therapy are the fully grown adolescent boys with localized disease (I to IIA). Circumvention of chemotherapy in this particular group avoids the impaired fertility that is a particular concern in boys and is related to the alkylating agents. Also, the adolescent's growth is complete. Therefore, irradiation will not result in permanent cosmetic deformities (i.e., arrest of bone growth). On the other hand, even for this group of boys, new regimens that no longer contain alkylating agents have shown excellent efficacy when used in combination with LD radiation therapy.<sup>90</sup> Because of worries about secondary breast cancer, radiation therapy alone for

adolescent girls should be given only after strong consideration for the increased risk of breast cancer known to result from irradiation of the breast tissue at this critical age.<sup>91-95</sup>

### Principles of Chemotherapy

Chemotherapy is the therapeutic backbone for children with both early and advanced-stage HL. A large number of chemotherapy combinations have been used for HL. For years, two regimens have been the most widely and effectively used combinations for patients with early-stage HL. MOPP or ABVD is administered over a 12-month period and has resulted in excellent outcomes.<sup>96,97</sup> However, these combinations have proven significant long-term sequelae when administered in full doses for a year. The recognition that successful treatment with chemotherapy for children with HL would have significant impact on their quality of life and ultimate survival has led to newer combinations of chemotherapy. In general, these regimens have been variations of MOPP and ABVD. These hybrids have either replaced those agents having the worst sequelae (e.g., cyclophosphamide for nitrogen mustard) or have involved the originals being given at significantly lower doses, or both.

Newer regimens in low-stage patients are now being examined with lower-dose alkylating agents, which are the causes of the majority of the long-term sequelae seen

in these patients.<sup>90</sup> In addition, the number of cycles or overall duration has been significantly decreased as well.<sup>57,98</sup> Typically, a complete therapeutic protocol currently is given over 3 to 6 months. Radiation therapy sometimes remains a part of these regimens, although it is given at lower doses and encompasses smaller fields. In some studies, the chemotherapy regimens that have been given without irradiation have produced equivalent results to regimens with irradiation in patients with low-stage disease.<sup>99-101</sup> A trial to confirm these early results showed no difference in OS between low-risk patients who received radiation and those who did not.<sup>89</sup> But those patients who were given LD involved-field radiation therapy had a superior EFS. For those with high-risk HL, therapeutic regimens that are intensifying both dose and timing are showing improved outcomes over the traditional regimens, with disease-free survival (DFS) now in excess of 80%.<sup>102-104</sup>

### **Stage, Histology, and Response-Based Therapy**

Until recently, therapy for HL was primarily dictated by the stage at which the child was first seen. Now histology and response to therapy are added to the equation.<sup>45,105</sup> Those with LPHL and low-stage disease may be considered for further reductions in chemotherapy. If the disease is completely resected via an excisional biopsy, no further treatment may be needed. A current clinical trial is attempting to confirm the results of smaller studies showing favorable outcomes with surgical resection alone in stage I patients with LPHL, a single involved lymph node, and a complete resection. Early response to therapy has been shown to identify those with superior cure rates (94% vs. 78% EFS).<sup>105</sup> Many regimens now incorporate this concept into their design, with fewer cycles of chemotherapy or elimination of irradiation for those with early complete responses.

Symptomatic disease at the time of diagnosis calls for therapy similar to that for higher-stage patients. Current recommendations are for patients with stage I to III disease to receive three to eight cycles of chemotherapy, with the number of cycles dependent on the presence of bulky disease (mediastinal or nodal), number of involved nodal sites (in stage II), and achievement of remission after two to four cycles. Those with adverse risk factors receive six to eight cycles of therapy. The decision to use irradiation after chemotherapy remains under study. When irradiation is used, it should be given in low doses (<2500 cGy) and to involved areas only. Male patients with bulky mediastinal disease should receive radiation in addition to systemic chemotherapy, regardless of response to therapy. Attempts are being made to eliminate irradiation in female patients with bulky disease and a rapid response to therapy. Stage IV patients should receive more intensive regimens of systemic chemotherapy and involved-field radiation.

Currently, blood or marrow stem cell transplantation is reserved for those patients whose disease is refractory

to systemic chemotherapy or who have experienced relapse. Recent trials have shown that regardless of the duration of initial remission, those who are treated with high-dose chemotherapy and stem cell rescue have less treatment failure than do those treated with conventional chemotherapy.<sup>106</sup>

## **Results**

Most patients treated with combinations of chemotherapy and radiation enter into CR (>90%).<sup>107,108</sup> Many patients, especially those with the NS subtype, may have persistent adenopathy or mediastinal enlargement for months or years after therapy. Although most prove to be cured, close monitoring of these patients is necessary. For those who do not enter remission with today's front-line chemotherapy/irradiation combinations, the prognosis is poor. Therapeutic intensification with subsequent stem cell transplant should be strongly considered.<sup>106,109</sup>

For stage I and II patients, combined-modality (chemotherapy and radiation) therapy typically results in greater than 90% 5-year DFS rates; for stage III patients, greater than 80% 5-year DFS rates; and for stage IV patients, the outcome was until recently greater than 60% (see Table 71-4). This last group has seen significant advances, with successful outcomes now exceeding 80% in several recent trials.<sup>102,103</sup>

## **Acute Complications**

Acute complications of therapy in children with HL are due to either the tumor itself or the therapy. Because of airway compression, anterior mediastinal lymphomas can be a medical emergency. All patients suspected of having a lymphoma should have an immediate chest radiograph or CT scan to determine whether a mediastinal mass is present. Therapy with chemotherapy (preferable in children) or irradiation is effective in the immediate relief of these symptoms. The complications due to splenectomy are due to overwhelming sepsis from encapsulated organisms. This risk is increased because of the myelosuppression and immunocompromising effects of chemotherapy. Fever in the neutropenic patient necessitates hospitalization and intravenous antibiotic therapy. Bone marrow suppression may require transfusions of either red cells or platelets. Specific chemotherapy agents may have immediate complications. These include nausea and vomiting, restrictive pulmonary disease (bleomycin, irradiation), extravasation burns (nitrogen mustard, vincristine, vinblastine, doxorubicin [Adriamycin]), and chemical phlebitis (nitrogen mustard, vinblastine, DTIC). To alleviate these last risks, right atrial catheters are often placed. This also reduces the discomfort of repeated venipuncture required throughout the duration of treatment.

## **Long-Term Sequelae**

The concern over long-term sequelae guides much of modern therapy for HL, both in adults and particularly

in children. These sequelae result from both radiation therapy and chemotherapy.<sup>110,111</sup>

The long-term sequelae of irradiation in growing children are the overriding reason for the efforts to reduce or eliminate it from therapeutic regimens. Bone irradiation may result in shortening of the clavicles in those receiving mantle radiation or a shortened height in those receiving radiation to the spine.<sup>112</sup> Radiation to the neck often results in permanent hypothyroidism<sup>113</sup> and increases the risk of thyroid cancer.<sup>114,115</sup> If radiation is to be given to the pelvis of a female patient, consideration should be given to surgically moving the ovaries away from the field of irradiation.<sup>116</sup>

Second malignancies are a major concern after therapy for HL.<sup>117-119</sup> The most frequent cause of death in long-term survivors of HL is a second malignancy.<sup>120</sup> The relative risk of a second malignancy in HL patients has been estimated to be 5- to 11-fold that of the general population.<sup>118,121</sup> This represents a 15- to 25-year actuarial risk of 7% to 23%.<sup>118,121-123</sup> Second malignancies are more prevalent in those with HL treated before age 21 years than in the older age groups for all tumors except lung cancer.<sup>118</sup> These second cancers include leukemia and solid tumors. The risk of leukemia seems primarily related to the type of chemotherapy used,<sup>121,124</sup> with a cumulative incidence of 3.3%, with a plateau after about 10 years. However, one recent study found a decrease in secondary leukemia among those treated with the newer hybrid regimens.<sup>123</sup> This likely is a result of the reduction in nitrogen mustard and procarbazine (in MOPP) doses, the principal culprits in the development of secondary leukemia.<sup>125,126</sup> Patients treated with ABVD do not have an increased risk of leukemia. The reduction in the incidence of leukemia may be a result of the decreasing use of splenectomy in pathologic staging, because this operation has repeatedly been shown to increase the risk of leukemia in HL patients treated with chemotherapy.<sup>125,127</sup>

Solid tumors, including those of lung, stomach, melanoma, bone, and soft tissue, have accounted for most of the second malignancies, with a cumulative incidence of 13% to 22% at 15 to 25 years. No plateau has been appreciated.<sup>118,121,122</sup> This risk in HL survivors has not decreased when cohorts treated in the 1960s are compared with those in the 1980s.<sup>118</sup> This increased risk of solid tumors is related primarily to irradiation,<sup>128,129</sup> with some added risk when subsequent chemotherapy is used in relapse patients.<sup>130</sup> It has been recognized that radiation exposure to the breast tissue in adult women has resulted in a fourfold increase in rates of subsequent breast cancer,<sup>91-93,131</sup> whereas the risk of subsequent breast cancer is increased by 39-fold if the breasts are irradiated during adolescence.<sup>94</sup> For an adolescent, this increases the probability of developing breast cancer between the ages of 20 and 30 years from 0.04% to 1.6%.<sup>95</sup> and may be as high as 35% by age 40 years.<sup>118</sup> For all types of secondary cancer, adolescents seem to be at greater risk than younger children.<sup>115,132</sup> Recent evidence suggests that the risk of breast cancer is slightly reduced by the premature menopause induced by

the chemotherapy these patients receive.<sup>133,134</sup> Most patients who received chemotherapy and radiation therapy had menopause before age 41 years, whereas only 9% treated with radiation alone had premature menopause. Menopause before age 36 years had a significant impact on the reduced risk of breast cancer among those receiving radiation. Patients must be closely observed for second malignancies for decades after their therapy has been completed. No plateau in risk has yet been seen.<sup>111,135</sup>

Other long-term sequelae include cardiac complications secondary to mantle irradiation or the use of doxorubicin (Adriamycin in ABVD regimens), or both, that affect up to 13% of patients.<sup>136,137</sup> These complications are typically congestive heart failure due to myocardiopathy and secondary arrhythmias. Occasionally, restrictive pericarditis may occur as a result of radiation. Overall, the relative risk of death due to cardiovascular disease in HL survivors is elevated and especially so in those treated before age 21 years.<sup>111</sup> Pulmonary toxicity due to bleomycin or irradiation, (or both) affected up to 9% of children who received 12 courses of ABVD with 2100-cGy radiation.<sup>138</sup> This high incidence appears to be decreasing with the use of hybrid regimens and low-dose involved-field irradiation.<sup>139</sup>

Infertility and early menopause in women are primarily a result of ovarian dysfunction as a result of exposure of the ovaries to radiation.<sup>140,141</sup> When the ovaries are surgically moved out of the field of irradiation, these problems are less likely to occur.<sup>116,142</sup> Male patients have a 30% to 40% rate of gonadal dysfunction at the time of diagnosis before any therapy.<sup>143</sup> After more than three to six courses of MOPP therapy, all men are usually sterile.<sup>144</sup> This side effect does not follow ABVD therapy.<sup>145</sup> Spermatogenesis is only transiently reduced by pelvic radiation. Although spermatogenesis is significantly affected by the alkylating agents in MOPP therapy, testosterone production seems unimpaired. It is anticipated that with reduction in single and cumulative doses of chemotherapy, with older agents being replaced with less toxic ones, and with the reduction in radiation field size and dose, these long-term sequelae will be further reduced.

## NON-HODGKIN'S LYMPHOMA

In contrast to the similarities between adult and pediatric HL, the types of NHL that occur in adults and children, their presentation, their treatment, and their outcome are dramatically different. Most adults with NHL have low- or intermediate-grade lymphomas. In distinct contrast, children with these types of lymphomas are exceedingly rare. Instead, virtually all children with NHL have one of four high-grade, diffuse types: Burkitt's lymphoma (formerly small, non-cleaved cell lymphoma [SNCCCL]), precursor T-cell lymphoblastic lymphoma (T-LL), diffuse large B-cell lymphoma (DLBCL), or anaplastic large cell lymphoma (ALCL). Most patients will be seen initially with advanced or disseminated disease (stages III and IV).

These lymphomas typically appear as a rapidly expanding mass with a short symptomatic history. This propensity for rapid growth makes the diagnostic evaluation in a child with suspected NHL a medical urgency, if not emergency. Of all the childhood tumors, NHL has the greatest chance of acute complications at the time of presentation. Anatomic impingement of adjacent structures (mediastinal tumors on the trachea and bronchi, nasopharyngeal tumors on the orbits, bowel obstruction with or without intussusception) and metabolic derangements due to tumor lysis (before and after therapy is initiated) are not infrequent results of its very rapid growth. Better management of the initial anatomic and metabolic complications, improved methods of determining the subtypes of NHL (perhaps the most important reason for improved survival), and better chemotherapy combinations (more intensive, yet shorter) have brought the most dramatic improvements in DFS and OS for children with NHL over the past several decades.<sup>146</sup> Five-year relative survival was 86% for patients diagnosed with NHL from 1996 to 2002.<sup>12</sup> In addition to more intense therapy of shorter duration, the other major change in therapy for children with NHL is the virtual elimination of radiation from treatment regimens. This should reduce the long-term sequelae that would have otherwise resulted. For the surgeon seeing the child with suspected lymphoma, rapid evaluation and proper handling of biopsy material will have dramatic beneficial effects on the outcome for the child.

## Incidence and Epidemiology

NHL accounts for 4% of all cancers in adult and pediatric patients, with nearly 53,600 new cases diagnosed annually in the United States.<sup>1</sup> In children, NHL patients accounted for 4.5% of childhood cancers,<sup>12</sup> 8.7% of all solid tumors, and 57% of all lymphomas.<sup>2</sup> The annual incidence is 9.9 cases/million children younger than 15 years/year.<sup>15</sup> Before age 11 years, it is the most common of the two types of lymphoma. A high male-to-female ratio of 3.0 is found, making it the most disproportionately occurring tumor between the two genders during childhood. This large difference is present in all ages of childhood. A 1.4 greater risk occurs in whites than in blacks.<sup>15</sup> This, too, is seen in all ages, with the exception of children younger than 1 year. The age distribution demonstrates two small peaks in incidence from 6 to 7 years and between 12 and 14 years (see Fig. 71-1). The 6- and 7-year olds overwhelmingly have Burkitt's lymphoma, and the teenagers typically have T-LL.

NHL of B-cell origin, either Burkitt's lymphoma or DLBCL, occurs more often in patients with prior EBV exposure, in individuals with a history of immune suppression, and in equatorial Africa.<sup>147-149</sup> Considerable work now convincingly reveals that, in patients with an iatrogenic (e.g., post-transplant, immunosuppressive therapy) or acquired immunodeficiency, congenital-EBV infection has an etiologic role in either the development or the predisposition to B-cell NHL.<sup>150,151</sup> Correlations have been made between viral load levels

and the risk of post-transplant lymphoproliferative disorders (PTLDs).<sup>152-154</sup> Patients at greatest risk for PTLDs are those in whom their primary infection with EBV occurs within the first 3 to 4 months after transplantation. For T-LL or ALCL, no such etiologic correlations have been found.

## Classification

Over the years, several classification schemes have been used.<sup>155</sup> Among these are the Rappaport, the Kiel, the Lukes-Collins, the WHO, the International Working Formulation, and the Revised European-American Classification of Lymphoid Neoplasms (REAL).<sup>156</sup> REAL was developed as an effort to eliminate the confusion surrounding the diagnosis of the lymphoma subtype caused by the prior variety of classification schemas. The REAL is a consensus classification system based on morphologic, immunologic, and cytogenetic characteristics, in addition to clinical presentation, course, and putative cell of origin.<sup>156</sup>

REAL is the basis for the WHO classification in current use, a comprehensive classification system published in 2001. Childhood NHL primarily consists of just four subtypes in the WHO system: (1) Burkitt's lymphoma/leukemia and Burkitt-like (mature B-cell neoplasms accounting for 39% of NHL patients<sup>4</sup>); (2) T-cell lymphoblastic lymphoma (28%<sup>4</sup>), (3) diffuse large B-cell lymphoma, and (4) mature T-cell neoplasms (ALCL). DLBCL and ALCL were previously lumped together as large cell lymphomas and comprised about one third of the NHL of childhood. With the separation of these two entities, the cases previously identified as large cell lymphoma are now divided almost equally between DLBCL and ALCL.<sup>157</sup> The first two classifications are part of the "small, round, blue cell tumors," which presents the pathologist with the challenge of proper identification. To differentiate these from the other three classic small round blue cell tumors (neuroblastoma, rhabdomyosarcoma, and Ewing's sarcoma) requires the presence of the immunocytochemical marker leukocyte common antigen CD45 (LCA), which is absent on the other tumor cell types.

Burkitt's lymphoma has classically been divided into Burkitt's and non-Burkitt's (Burkitt-like in the REAL classification) subtypes. These are of a mature B-cell origin, with flow cytometric immunophenotyping revealing the presence of surface immunoglobulin IgM, CD10, CD19, CD20, CD22, CD79a, and human leukocyte antigen (HLA)-DR antigens. The histologic appearance of these two types differs in the degree of pleomorphism, with Burkitt's being more uniform appearing than non-Burkitt's. Although a distinction has been made for years between Burkitt's and non-Burkitt's subtypes of diffuse SNCL lymphomas, no clinical differences are found between these two subtypes.<sup>158</sup> Histologically, the cells of Burkitt's lymphoma are medium sized with round nuclei containing two to five nucleoli, abundant basophilic cytoplasm, and cytoplasmic lipid vacuoles. Owing to its extreme rates of proliferation

and spontaneous cell death, a number of macrophages are seen within this monomorphic field, consuming the dying cells and giving rise to the classic “starry sky” appearance of Burkitt’s lymphoma.<sup>156</sup>

Lymphoblastic lymphomas (LL) are distinguished by round or convoluted nuclei, finely dispersed chromatin, inconspicuous nucleoli, and scant cytoplasm. In the vast majority of these tumors, flow cytometry reveals the presence of the T-cell markers CD3 and CD7, with variable positivity for CD2 and CD5. These cells are typically Tdt positive, whereas Burkitt’s lymphomas are Tdt negative. This subtype is classified as a precursor T-cell LL in the WHO classification. A small number of LL cases are B-cell precursor and express pre-B-cell antigen profiles.<sup>157</sup>

Large cell lymphomas are a heterogeneous group of neoplasms. Histologically, approximately half are immunoblastic, 40% are large noncleaved cell, and fewer than 5% are large cleaved cell.<sup>159</sup> Flow cytometry shows relatively equal frequencies of B- or T-cell origin (36% and 33%, respectively) with 30% indeterminate.<sup>160,161</sup> A unique subset, identified by the immunophenotype CD30<sup>+</sup> (the antigen identified by the Ki-1 monoclonal antibody),<sup>162</sup> is recognized morphologically by its anaplastic characteristics, including very large cells with abundant cytoplasm, atypical lobulated nuclei, and prominent nucleoli. These cells exhibit a cohesive pattern with lymph node sinusoidal invasion. In the WHO classification, this is referred to as anaplastic large cell lymphoma. In the past, this subtype has also been referred to as malignant histiocytosis. The majority (60%) of these children have a T-cell immunophenotype.<sup>160,163</sup> Recent studies reveal that, although it was originally thought to be uncommon in children, it accounts for 40% to 50% of the large cell lymphoma cases.<sup>160,161,164,165</sup>

## Cell Biology

Cancer is a result of (1) the inappropriate or unregulated expression of a gene (or both) at either the wrong time in a cell’s cycle or in the wrong cell; (2) abnormal combinations of genes producing proteins not normally present in cells; or (3) the loss of gene expression and their products required for cellular control. The first two categories encompass the proto-oncogenes and oncogenes, and the last comprises the tumor suppressor genes. Lymphomas arise from precursors of lymphocytes at various stages of maturation, primarily because of errors in transcriptional factor control and production as a result of proto-oncogenes and oncogenes. Early B and T cells normally splice together different segments of their immunoglobulin and T-cell–receptor (TCR) genes to generate the diverse proteins capable of binding foreign antigens.<sup>166</sup> In lymphoid cancers, this system goes awry because of the inadvertent splicing juxtaposition of TCR genes (proto-oncogenes) to one of these regions. This leads to the abnormal and unregulated expression of this gene (now an oncogene) and the production of its oncoprotein. This oncoprotein eventually leads to the cell’s malignant transformation by a variety of mechanisms

and, hence, its uncontrolled growth.<sup>166-169</sup> This neoplastic process typically occurs as a result of nonrandom chromosomal translocations or inversions, although deletions and insertions of DNA sequences likely also contribute to the malignant transformation.

Burkitt’s lymphoma was the tumor in which this chromosomal translocation process was originally described.<sup>170</sup> The translocation involving chromosomes 8 and 14 was first identified in Burkitt cells in 1976.<sup>171</sup> As a result of this translocation, t(8;14), the *MYCC* oncogene, located on chromosome 8q24, is juxtaposed to the immunoglobulin receptor subunit gene on chromosome 14q32 (immunoglobulin heavy-chain gene). This translocation is found in both African (endemic) and American (sporadic) Burkitt’s lymphoma, although the exact breakpoints on chromosome 8 differ.<sup>172</sup> In a smaller percentage of Burkitt’s lymphoma patients, *MYCC* is juxtaposed to chromosome 2p11 ( $\kappa$  immunoglobulin light-chain gene), t(2;8), or 22q11 ( $\lambda$  light-chain gene), t(8;22).<sup>173</sup> It is thought that an increased pool of B cells, either through prolonged stimulation (as in the case of malaria) and/or through inhibition of cell death (as in the case of EBV) increases the chance occurrence of these translocations.<sup>174,175</sup> The oncoprotein MYC normally controls progression through G<sub>1</sub> into the S phase of the cell cycle. However, as a result of these translocations, its expression is dysregulated, leading to uncontrolled lymphoproliferation.<sup>176</sup>

## Clinical Presentation

### By Initial Site of Disease

Overall, unlike those with HL and adult NHL, children with NHL are often initially seen with extranodal disease and typically have disease that spreads by routes other than contiguous nodal pathways. In children, the abdomen is the originating site of disease in 31%; the mediastinum in 27%; and the head and neck in 29%.<sup>4</sup> Other sites include peripheral nodes, bone, and skin. Most abdominal disease primary lesions are due to Burkitt’s lymphomas, whereas most mediastinal/intrathoracic primary lesions are due to T-LL (Table 71-5). Disease that occurs primarily in the peripheral nodes and bones is often due to large cell lymphomas, and skin involvement is primarily associated with the Ki-1<sup>+</sup> large cell lymphoma subtype (ALCL).<sup>161,177,178</sup> Correlating with this distribution and the known age peaks of the two types of small cell lymphomas, abdominal primary lesions occur more often in children younger than 10 years, whereas mediastinal primary lesions are more likely to occur in adolescents. Children with abdominal primary lesions may present with nausea, vomiting, abdominal pain, and changes in bowel habits. On physical examination, they may be found to have an abdominal mass in any of the quadrants. Also, they may present with an acute abdomen due to either intussusception (typically due to infiltration of Peyer’s patches) (Fig. 71-3) or small bowel obstruction, perforation of an involved bowel wall, or an ileocecal mass mimicking acute appendicitis.<sup>179</sup>

Table 71-5	Non-Hodgkin's Lymphoma: Prevalence of Histologic Subtypes in Primary Sites					
	Abdominal	Thoracic	Head/Neck	Peripheral Nodes	Bone	Other*
SNCCL/B cell	74%	4%	48%	17%	6%	29%
LBL/T cell	3%	74%	24%	33%	31%	14%
LCL	23%	22%	28%	50%	56%	57%
Total	100%	100%	100%	100%	100%	100%

\*Includes bone.

SNCCL, small noncleaved cell lymphoma; LBL, lymphoblastic lymphoma; LCL, large cell lymphoma.

Adapted from Murphy SB, Fairclough DL, Hutchison RE, Berard CW: Non-Hodgkin's lymphomas of childhood: An analysis of the histology, staging, and response to treatment of 338 cases in a single institution. *J Clin Oncol* 7:186-193, 1989; and Wollner N, Lane JM, Marcove RC, et al: Primary skeletal non-Hodgkin's lymphomas in the pediatric age group. *Med Pediatr Oncol* 20:506-513, 1992.

A child older than age 5 years with an intussusception must strongly be considered to have NHL until proven otherwise. Moreover, NHL should always be part of one's differential diagnosis when faced with a 5- to 10-year-old child with an abdominal mass. Radiographic evaluation with either CT or ultrasonography typically reveals a homogeneous mass with or without evidence of central necrosis, arising either from the retroperitoneum or from the bowel wall. Accompanying adenopathy and metastatic dissemination to the liver and spleen is often seen. The bowel loops may simply be shifted away from the mass or may show evidence of intussusception or obstruction (or both).

Children with mediastinal primary lesions may have minimal symptoms, such as a mild cough or audible wheeze, or can have impending airway

obstruction. These latter patients may also have significant engorgement of the vasculature in the head, face, and upper thorax because of superior vena cava compression. Thrombosis may be present in these vessels as well. Often these patients will assume a forward-leaning position and cannot tolerate being placed in the supine position because of the anterior mediastinal mass. The patient's history may reveal orthopnea as well as shortness of breath and dyspnea on exertion. The recent onset of asthma symptoms is not uncommon. Shortness of breath also may be due to pleural effusions. A chest radiograph or chest CT scan is an essential component of the patient's initial evaluation before sedation or any procedure (Fig. 71-4). Chest radiography and chest CT will reveal the widened mediastinum

**Figure 71-3.** This 9-year-old presented with abdominal pain. **A**, The abdominal radiograph shows evidence of a possible small bowel obstruction. Because of the marked leukocytosis and other laboratory parameters, an intussusception due to non-Hodgkin's lymphoma was suspected. **B**, This was confirmed with a retrograde contrast study showing the intussusception (note the filling defect in the contrast medium, arrow) in the right colon. This was not able to be reduced radiographically and required operative reduction and intestinal resection.

**Figure 71-4.** This 8-year-old presented with dyspnea. The CT scan shows a very large anterolateral mediastinal mass (*asterisk*). There is also collapse of the adjacent right lung and a rather large pleural effusion (*arrow*). The diagnosis of T cell lymphoma was made on thoracentesis.

with often dramatic narrowing of the trachea and bronchi. Pericardial effusions are often present and may be seen on CT, magnetic resonance imaging (MRI), or echocardiography.<sup>180</sup>

Patients with head and neck lymphomas may have a history of rapidly progressive adenopathy, recent onset of snoring at night, mouth breathing, bad breath, epistaxis, proptosis or periorbital edema, diplopia, extraocular muscle paralysis due to entrapment, cranial nerve paralysis, and sudden blindness or a combination of these symptoms. Physical examination of the nares, oral cavity, and extraocular movements is critical and may reveal signs not appreciated as abnormal by the child. The presence of asymmetric and painless tonsillar hypertrophy should also alert the clinician to the possibility of NHL.<sup>181</sup>

Evaluation with CT often reveals a homogeneous mass that may show destruction of the adjacent bony structures. Bone NHL primary disease is usually seen as lytic lesions found on radiographs obtained for various reasons, including localized tenderness.<sup>182-184</sup> Skin lesions are typically ulcerative and fail to heal but also may be completely subcutaneous.<sup>177</sup> Patients with central nervous system (CNS) involvement may be asymptomatic, have seizures, or have signs and symptoms related to tumor infiltration in the brain.

Laboratory findings at the time of diagnosis are dependent on the amount of tumor present (regardless of the histologic subtype). Generally, patients will have an elevated ESR or C-reactive protein (CRP) level. Those with large tumor burdens typically will have high LDH levels as an indicator of tumor lysis risk,<sup>185,186</sup> disease regression, and disease progression. The degree of LDH elevation has been used as an adverse prognostic factor.<sup>4,187,188</sup> For those with a high tumor burden at presentation, laboratory signs of tumor lysis will also include elevated uric acid, phosphorus, and potassium

levels and a low calcium level. Some patients may already be in renal failure at the time of presentation and have an elevated creatinine.<sup>185,186</sup> Hematologic values are nonspecific, and the presence of cytopenias should raise the suspicion of marrow involvement. Cerebrospinal fluid (CSF) pleocytosis may or may not be present in those with CNS involvement.

More than 60% of patients have advanced or disseminated (stages III and IV) disease at diagnosis.<sup>4,189</sup> Bone marrow metastasis is defined as greater than 5% but less than 25% involvement. Patients with more than 25% disease in the bone marrow are classified as having leukemia. Fourteen percent of patients initially have some bone marrow involvement, and 3% have CNS involvement.<sup>4</sup>

### By Histologic Subtype

Burkitt's lymphoma was first described by the surgeon Denis Burkitt in Uganda, where he identified the common finding of enormous involvement of the nodes around the jaw.<sup>190</sup> Later, it was determined that, although this was a common presentation of those patients with endemic Burkitt's (African) lymphoma, those with sporadic Burkitt's (American) lymphoma more typically had presentation of disease either in the abdomen or the nasopharynx.<sup>191</sup> Patients with endemic Burkitt's lymphoma have accompanying abdominal disease in roughly half the cases, and patients with sporadic Burkitt's lymphoma have jaw involvement 15% to 20% of the time.<sup>192</sup> Patients with sporadic Burkitt's lymphoma have a higher incidence of bone marrow involvement (21% vs. 7%) but lower CNS dissemination (11% vs. 17%). Approximately two thirds of Burkitt's lymphoma patients will have disseminated or advanced disease (defined as stages III and IV) at diagnosis.<sup>193</sup>

T-LL patients most often are adolescents with supradiaphragmatic disease, affecting either the intrathoracic region or the head and neck. Disseminated disease is present in nearly 90% of T-LL patients at diagnosis.<sup>193</sup> In T-LL patients, involvement of the bone marrow has been found in approximately one fourth of children, with CNS disease at presentation in fewer than 10%.<sup>193</sup>

ALCL patients may present with disease in all sites but have a higher prevalence than the other two subtypes for skin, bone, and peripheral nodes.<sup>177,184,194</sup> ALCL may present as two distinct clinical forms: primary cutaneous ALCL and primary systemic ALCL (as fevers and weight loss and in advanced stage).<sup>157</sup> Disseminated disease in ALCL patients is present at diagnosis in up to 65% of patients.<sup>193</sup> Involvement of the bone marrow or CNS in ALCL patients is rare (Table 71-6). DLBCL may present as a mediastinal primary lesion or as nodal or extranodal disease, most commonly in the abdomen or head and neck.<sup>157</sup>

### In Immunodeficient Patients

For patients with congenital or acquired immunodeficiency, NHL presentation will vary from polyclonal plasmacytic hyperplasia, most often localized in nasopharyngeal nodes or tonsils, to a clonal polymorphic

**Table 71-6** Prevalence of Primary Sites among the Three Primary Types of Childhood Non-Hodgkin's Lymphoma

	SNCCCL	LBL	LCL
Abdomen	56%	3%	25%
Intrathoracic	2%	65%	21%
Head/neck	34%	23%	29%
Peripheral nodes	2%	7%	11%
Other	5%	3%	14%
Total	100%	100%	100%

NHL, Non-Hodgkin's lymphoma; SNCCCL, small noncleaved cell lymphoma; LBL, lymphoblastic lymphoma; LCL, large cell lymphoma.

Adapted from Murphy SB, Fairclough DL, Hutchison RE, Berard CW: Non-Hodgkin's lymphomas of childhood: Analysis of the histology, staging, and response to treatment of 338 cases at a single institution. *J Clin Oncol* 7:186-193, 1989.

lymphoma slowly arising in the lymph nodes or extranodal sites, to widely disseminated, rapidly progressive immunoblastic lymphoma.<sup>195,196</sup> Symptoms may be nonspecific, with fever and malaise. Hepatosplenomegaly and lymphadenopathy may be presenting signs. Gastrointestinal symptoms of longer than 14 days duration with anorexia, weight loss, and diarrhea should raise suspicion of this condition.<sup>154</sup> NHL has become more common with the use of very potent anti-rejection drugs after solid organ or bone marrow transplantation. Involvement of the transplanted organ is not unusual.<sup>154,197</sup>

## Diagnosis

Children initially suspected of having NHL should be evaluated immediately because of the high risk of either metabolic or anatomic complications before therapy begins. The rapid growth of these tumors may create a life-threatening complication overnight in a child who seemed relatively healthy the previous day (Table 71-7).

No clinical findings are pathognomonic for NHL. Ultimately, the diagnosis awaits the biopsy of involved sites, most commonly an excised lymph node or percutaneous needle biopsy. Fine-needle aspirations do not provide enough tissue for the necessary subtyping, which is performed with flow cytometry, molecular genetics, and cytogenetics. It is critical for the excised tissue to be delivered quickly to the pathologist for processing. For cytogenetic and molecular genetic evaluations, it is imperative that all tissue is placed in a sterile container for fresh samples. Formalin should never be used.

For patients critically ill at diagnosis, such as those with severe airway obstruction, diagnosis by alternative methods may be required. These may include nodal biopsy with local anesthetic alone, CT- or US-guided percutaneous needle biopsy of the mass, aspiration of a pleural effusion, or bone marrow biopsy and aspirate. In the majority of cases of NHL, the role of the surgeon is to obtain adequate tissue for diagnosis. Debulking and attempts at local control are unnecessary

(with one exception) because NHL is a systemic disease that requires chemotherapy. The one instance in NHL patients in which initial total resection may be considered are those patients with an abdominal mass in whom bowel resection is already required because of perforation or obstruction. In this case, total resection of the tumor should be considered. In this setting, resection reduces the stage of the patient's disease, improves survival, and reduces the amount of therapy required.<sup>198</sup> For all other patients, resection of the mass provides no improvement in staging or long-term cure and delays the time to initiation of chemotherapy. It should be remembered that most patients have disseminated disease at presentation. Also, it is important to note that with chemotherapy alone, more than 90% will achieve a complete remission.

Once NHL is suspected, a concerted and well-conceived plan of evaluation is important to achieve a diagnosis as quickly as possible. This should include laboratory examination to evaluate tumor burden and presence or risk of tumor lysis syndrome. The radiographic evaluation in these patients is extremely important.<sup>60</sup> No procedures or sedation should be attempted until a mediastinal mass has been excluded. To identify the extent of disease, CTs of the neck, chest, abdomen, and pelvis are required. An examination of the head, either CT or MRI, should be obtained in those patients with CNS symptoms, with CSF pleocytosis, or in whom the primary lesions are parameningeal based. Bone scans should typically be obtained. <sup>18</sup>FDG-PET or gallium scans are currently recommended. Gallium scans are an effective method for assessing the extent of disease at initial diagnosis, to evaluate residual disease at the end of therapy, and for ongoing monitoring for relapse after therapy.<sup>199</sup> A positive gallium scan at the end of therapy is a strong predictor of relapse. <sup>18</sup>FDG-PET scans are gradually replacing gallium scans in the diagnostic evaluation and monitoring of NHL

**Table 71-7** Non-Hodgkin's Lymphoma: Diagnostic and Staging Evaluation at Presentation

- Complete physical examination with documentation of involved nodal groups (including measurements of nodes) and involved extralymphatic organs
- Complete blood cell count, chemistry panel (including hepatic and renal function tests), erythrocyte sedimentation rate, lactate dehydrogenase
- Chest radiography to evaluate for mediastinal disease and airway compression
- CT scans of areas identified on physical examination (also include chest, neck, and abdomen)
- Bone scan
- Gallium scan
- Excisional biopsy of node or mass with samples sent for routine pathology, molecular genetics, cytogenetics, and flow cytometry
- Bone marrow biopsies and aspirates (bilateral)
- Lumbar puncture with CSF analysis of cytocentrifuged sample

CT, computed tomography; CSF, cerebrospinal fluid.

patients. Advantages of PET over gallium include same-day imaging, improved resolution, and a higher target-to-background ratio.<sup>200</sup> Diagnostic PET scans are reliable (greater than 90% positive) in patients with DLBCL. Three studies of patients with HL and NHL found PET to be superior to gallium for diagnosing disease sites.<sup>80</sup>

Pathologic evaluation of the biopsy material should include general histochemical techniques to confirm the lymphoma and its subtype. Critical additions to the basic evaluation are flow cytometric analysis of cell-surface markers to determine the immunophenotype of the lymphoma, cytogenetic evaluation for diagnostic translocations, fluorescent in situ hybridization (FISH), and DNA analysis using either Southern blotting or the polymerase chain reaction for detection of the pathognomonic oncogenes (gene rearrangements), even in the absence of identifiable cytogenetic translocations.<sup>201</sup> Examination of markers in tumor cells for EBV is important in the evaluation of PTLDs. These are all essential components at the time of initial diagnosis and should be performed at an institution capable of performing all of them. Therapy differences between the subtypes of lymphoma are such that assignment to the wrong subtype due to a lack of adequate diagnostic material will adversely affect the chance of cure. These evaluations may be performed with biopsy material from any involved site, including the primary mass, enlarged lymph nodes, effusions, and bone marrow. A new technique, known as gene expression profiling, which uses DNA microarrays, has been shown to categorize patients further into specific histologic and genetic subsets of lymphoma, with much greater predictability of the clinical outcome.<sup>202</sup> This new technique will likely revolutionize diagnostic and prognostic characterization for NHL.

Completing the diagnostic protocol is the determination of whether or not there is CNS or bone marrow dissemination. Lumbar puncture for cytocentrifuged CSF analysis should be performed in all patients. However, in those with localized abdominal Burkitt's lymphoma, and those with large cell lymphoma, the benefit gained from this is arguable because of the low incidence of CNS disease in these subpopulations. Bone marrow evaluation should include bilateral iliac crest biopsies and aspirates.

## Staging

Once the diagnosis of NHL has been made, staging permits determination of the extent of disease at presentation. This provides direction in monitoring disease response to therapy. In contrast to HL, relapse does not necessarily occur at the site of initial or previous disease in NHL. Thus, this initial staging should not limit the extent of monitoring for relapse after therapy is completed.

Staging is important in the determination of therapeutic planning. The most widely used staging schema today is the St. Jude's or Murphy system (Table 71-8).<sup>203</sup> This is an adaptation of the Ann Arbor scheme and is applicable to all types of childhood NHL. It divides

**Table 71-8** St. Jude's (Murphy) Staging System for Childhood Non-Hodgkin's Lymphoma

Stage	Definition
I	Single tumor (extranodal) or single anatomic area (nodal), excluding mediastinum or abdomen
II	Single tumor (extranodal) with regional node involvement On same side of diaphragm: a) Two or more nodal areas b) Two single (extranodal) tumors with or without regional node involvement Primary gastrointestinal tract tumor (usually ileocecal) with or without associated mesenteric node involvement, grossly completely resected
III	On both sides of diaphragm: a) Two single tumors (extranodal) b) Two or more nodal areas All primary intrathoracic tumors (mediastinal, pleural, thymic) All extensive primary intra-abdominal disease; unresectable All primary paraspinal or epidural tumors regardless of other sites
IV	Any of the above with initial CNS or bone marrow involvement (<25%)

CNS, central nervous system.

patients into localized (stage I or II) and disseminated or advanced (stage III or IV) disease. Involvement of the CNS or bone marrow immediately places the patient in the stage IV category. Patients with more than 25% bone marrow involvement are, by definition, diagnosed with leukemia rather than with lymphoma. These would include B-cell or Burkitt's leukemia (L3 leukemia morphologic classification) and T-cell leukemia. The former patients are treated on B-cell NHL protocols with much better results than previously obtained on acute lymphoblastic leukemia (ALL) regimens. Many of the B-cell NHL protocol results reported in the literature include these patients in their stage IV populations. The T-cell leukemia patients remain on ALL protocols, but many similarities exist between these protocols and those used in T-LL therapy.

## Prognostic Risk Factors

When all patients are treated similarly, the stage of the lymphoma at diagnosis is a strong predictor of outcome.<sup>4</sup> Prediction of a patient's eventual outcome stratifies patients at high risk for relapse to more intensive or novel therapies and patients at low risk to shorter, more moderate therapies. Many prognostic factors have been evaluated over the years. All prognostic factors are dependent on the therapy subsequently given.<sup>4</sup> It has been definitively shown that histology-based therapy is of critical importance in the successful outcome of patients (Table 71-9).<sup>189</sup>

CNS involvement in both SNCCCL and LBL patients has predictably worse outcomes.<sup>189</sup> In patients with Burkitt's lymphoma, the adverse effect of CNS disease

on outcome has, in some studies, been more attributable to tumor burden at diagnosis than to the presence of CNS disease alone (i.e., those with greater tumor burden are more likely to have CNS disease).<sup>204</sup> Patients with Burkitt's lymphoma older than 15 years of age have a worse prognosis than patients younger than 15 years old. An LDH greater than 500 IU/L also predicts a worse outcome for patients with Burkitt's lymphoma.<sup>205</sup>

DLBCL and ALCL patients (historically large cell lymphoma patients) have unique prognostic characteristics that are likely to change as this entity is better described and therapy is more appropriately administered by

subtype. Skin involvement at presentation in patients with large cell lymphoma has been shown to be a poor prognostic indicator.<sup>198</sup> In one study of patients with advanced large cell lymphoma, the presence of CD30<sup>+</sup> cells indicated a better OS.<sup>206</sup> However, in another study, no effect on prognosis was noted.<sup>160</sup> B-cell immunophenotype has been shown to improve prognosis.<sup>160</sup> Patients with intrathoracic primary lesions have a better prognosis than do those with primary lesions elsewhere.<sup>206</sup> Children with NHL arising in the bone, regardless of the histologic subtypes, have an excellent prognosis with histology-directed chemotherapy alone.<sup>207</sup>

## Treatment

Therapy for childhood NHL has evolved over the past several decades, and is based on the knowledge that this tumor is extremely chemosensitive. For Burkitt's lymphoma and large cell lymphoma, the duration of therapy has become shorter, as it became apparent that most, if not all, patients were experiencing relapse within the first 6 to 8 months of therapy.<sup>193,208</sup> Despite reduction in therapy to 6 months or less, no increase in relapse has been seen. Relapses for the most part have occurred within the first 6 to 8 months after diagnosis and virtually all have occurred within the first 2 years.<sup>187-189, 208,209</sup> Therapy for Burkitt's lymphoma has shown a clear improvement as methotrexate and cytarabine doses have been increased. These two agents, in addition to cyclophosphamide, vincristine, doxorubicin (Adriamycin), and prednisone (and etoposide for the stage IV patients), now play a critical role in the successful outcome of these children.<sup>193,198,209,210</sup> The addition of rituximab (an anti-CD20 monoclonal antibody) and rasburicase (a recombinant urate oxidase for treatment of hyperuricemia) is currently being studied.

For T-LL, the duration of therapy has been decreased to 2 years. The most effective regimens for LBL have been ones similar to the intensive T-cell ALL protocols in current use. For ALCL patients, the use of T-cell regimens without much CNS-directed therapy has been efficacious.

For Burkitt's and large cell lymphomas, it has become apparent that no benefit in DFS or OS is gained with the use of radiation for treatment, either to involved areas or to the CNS for prophylaxis.<sup>164,177,211</sup> Rather, prophylaxis to prevent CNS relapse is effectively accomplished with intrathecal chemotherapy.<sup>204</sup> Although some type of CNS prophylaxis is thought to be needed for all patients with NHL to prevent CNS relapse, in one small group of patients, it is not. Patients with localized, resected gastrointestinal primary tumors with Burkitt's or large cell lymphomas do not have CNS relapse, even in the absence of CNS prophylaxis.<sup>208</sup>

For patients with LBL, irradiation to areas of bulky disease has been eliminated. In the past, irradiation was used for CNS prophylaxis in patients without CNS disease at diagnosis, but recent studies substituting intrathecal chemoprophylaxis have not shown increased CNS relapses. For those patients with LBL with CNS disease at diagnosis, irradiation remains an important part of their therapy.

Several additional points deserve mention. The use of corticosteroids before a diagnostic procedure should absolutely be avoided. This can induce rapid necrosis in the lymphoma, making subtype determination difficult if not impossible, and potentially jeopardizing the patient's outcome. However, once adequate tissue has been obtained, chemotherapy including corticosteroids is an excellent method for rapid reduction of a life-threatening mass. Because of the extreme sensitivity of NHL, one can anticipate rapid reduction of tumor size once therapy is initiated. Radiation therapy is not necessary. It is not unusual to have symptoms completely resolve within 24 hours and

have patients be in complete radiographic remission within 7 days. Many protocols now call for a period of reduced-dose chemotherapy for the first week to obtain a more controlled tumor reduction because of the severe tumor lysis that may accompany more rapid, therapy-induced necrosis.

NHL in immunodeficient individuals is most often a B-cell lymphoma, either small or large cell. Therapy for these patients has typically been directed toward these histologic types. For patients with ongoing iatrogenic immune suppression, a reduction of the immunosuppressive agent with or without acyclovir may be adequate to induce a remission in up to 75% of cases.<sup>154,212</sup> However, this may not be possible after transplant because of the risk of rejection. Interferon-alfa has been used with mixed success in these patients and may exacerbate rejection. A small proportion of patients with localized disease may be cured with operative resection of the involved nodal tissue. When the tumor is resistant to these approaches, chemotherapy regimens can be used, although mortality has been higher than that found in immunocompetent patients. In the past few years, new methods using monoclonal antibody therapy, primarily rituximab, have been used with promising results alone, but these antibodies are most efficacious when combined with chemotherapy.<sup>213</sup>

## Results

When reviewing the outcomes of children treated for NHL, it is quickly apparent that considerable improvement in DFS and OS has occurred over the past several decades (see Table 71-9).<sup>4</sup> Today, typically 90% to 100% of patients will achieve complete remission.<sup>164,208,214</sup> Five-year relative survival rates for children ages birth to 19, diagnosed between 1996 and 2004, were 83.3%.<sup>13</sup> Patients with localized disease have an overall excellent prognosis, regardless of histologic subtype, with DFS typically exceeding 90% to 95%. Burkitt's lymphoma patients with advanced disease have experienced DFS exceeding 80% in the recent trials. Patients with LBL with disseminated disease are not faring as well, but DFS for these patients is exceeding 65% to 70% in most trials. Overall, when they occur, treatment failures typically happen within the first 2 years after diagnosis. Patients with Burkitt's lymphoma who experience relapse primarily do so within the first 6 to 8 months. **LBL patients will have an occasional late failure after 2 years**, although even in this group of patients the vast majority of failures will occur early.<sup>214</sup> Patients with large cell lymphoma have more late relapses. Thus, radiographic follow-up is an important modality in the ongoing post-therapeutic evaluation of NHL patients for several years. With the advent of modern radiographic techniques, second-look operations have not been beneficial to patient outcome.<sup>198,215</sup>

## Acute Complications

Depending on the tumor burden at diagnosis, patients may initially have a constellation of significant metabolic derangements known as tumor lysis

syndrome.<sup>185,186</sup> This includes hyperuricemia, hyperphosphatemia, hyperkalemia, and hypocalcemia. Recognition of this syndrome is critical to prevent life-threatening complications, including acute renal failure. Without treatment, the incidence of acute renal failure may be as high as 30%.<sup>216</sup> Tumor lysis syndrome is the result of the rapid turnover of cells within the tumor. The fraction of tumor cells in S phase at any given time can approach 27% in some patients.<sup>217</sup> These tumors have a high degree of spontaneous lysis at the time of diagnosis because they rapidly outgrow their blood supply. Any manipulation, including transfusion or operation, may induce a sudden worsening of this syndrome.

Therapy is primarily based on the risk of developing hyperuricemia. For those at high risk, determined by the presence of an elevated LDH, creatinine, or uric acid value, intervention is important. For most patients with little or no elevation in these values, adequate hydration (>3000 mL/m<sup>2</sup>/day) and monitoring of blood pH (maintain between 7.0 and 7.5) is adequate, along with the initiation of allopurinol to reduce the production of uric acid through inhibition of xanthine oxidase.<sup>218</sup> Rasburicase, which cleaves uric acid into allantoin, a soluble by-product, has been approved for use by the U.S. Food and Drug Administration (FDA). This agent, administered daily for 1 to 5 days, dramatically reduces measurable uric acid levels to immeasurable levels, thus allowing the clinician to focus on prevention or treatment of hyperphosphatemia, which requires maintaining acidic urine.<sup>219,220</sup> Despite these measures, it may be necessary to place patients on dialysis either to treat oliguria/anuria or to prevent it in the presence of rapidly increasing uric acid, phosphorus (typically >10 mg/dL), or potassium (>7.5 mEq/L) levels.<sup>193,221</sup> In an effort to avoid this complication, some regimens have used an initial low-dose therapy (usually 1 week) to more slowly reduce the tumor burden.

Because of the much more myelosuppressive regimens required in NHL therapy, infection is a much larger risk for NHL patients as compared with HL

patients.<sup>189</sup> In one recent study, 63% of the deaths were due to infection. Most patients require transfusion support during treatment because of the myelosuppression. The chemotherapy itself may cause acute complications, including severe chemical burns due to extravasation of certain vesicant agents (vincristine, anthracyclines). Because most children require the placement of right atrial catheters to facilitate their therapy, thrombosis of this area and the surrounding vasculature has become more frequent.<sup>222</sup> Mucositis is seen in a significant number of patients during therapy for Burkitt's lymphoma as well.

### *Long-Term Sequelae*

As long-term survival has improved, the concern over lifelong sequelae has increased in these patients. With current therapy, these complications include cardiac toxicity,<sup>137</sup> infertility as a result of the alkylating agents used,<sup>223</sup> and secondary leukemias due to epipodophyllotoxins (etoposide, tenoposide) and alkylating agents used in the NHL regimens.<sup>224</sup> The risk for developing cardiac toxicity is related to several factors, including irradiation dose, cumulative anthracycline dose, and age at exposure. Patients are at an increased risk for anthracycline-related cardiomyopathy if they are female, have received doses greater than 200 to 300 mg/m<sup>2</sup>, and were younger when given anthracyclines.<sup>225</sup>

The risk for infertility is related to the cumulative dose of the alkylating agents. Fertility is likely to be maintained in males receiving less than 4 g/m<sup>2</sup> of cyclophosphamide and no other alkylating chemotherapy or radiation.<sup>225</sup> In female survivors, the risk of infertility increases with age at the time of treatment. Prepubertal patients tolerate higher cumulative doses of alkylating agents than adult women. Survivors of childhood lymphoma must be monitored closely for early identification and proper intervention to maintain a good quality of life in these long-term survivors.

# RHABDOMYOSARCOMA

Shinil K. Shah, DO • Peter A. Walker, MD • Richard J. Andrassy, MD

**R**habdomyosarcoma (RMS) is a soft tissue tumor originating from immature mesenchymal cells that form any tissue except bone. It is the most common type of soft tissue sarcoma in children and adolescents, accounting for approximately 50% of all soft tissue sarcomas. As a result of prospective, multicenter clinical trials conducted by the Intergroup Rhabdomyosarcoma Study Group (IRSG) (established in 1972) as well as other collaborative networks, the overall survival of patients with RMS has increased to as high as 70% with current multimodal therapies.<sup>1</sup>

Approximately 350 new cases of RMS are diagnosed annually in the United States, corresponding to a yearly incidence of 4.6 cases per million children aged 20 years or younger.<sup>2</sup> RMS is the third most common childhood extracranial solid tumor, after neuroblastoma and Wilms' tumor.<sup>3</sup> A bimodal age distribution is found, with approximately 65% of cases occurring in children younger than 6 years and the remaining cases occurring in children aged 10 to 18 years.<sup>4</sup> More than 80% of cases are diagnosed before the age of 14.<sup>5</sup>

Children with RMS appear to have an increased incidence of other congenital anomalies, with the central nervous and genitourinary systems being the most commonly affected.<sup>6</sup> In the most recent Intergroup Rhabdomyosarcoma Study (IRS-IV), 883 patients were enrolled and analyzed between 1991 and 1997.<sup>1</sup> The distribution of primary tumor sites was as follows: head and neck, 7%; parameningeal, 25% (nasopharynx, paranasal sinus, middle ear mastoid, pterygoid-infratemporal sites); orbit, 9%; genitourinary, 31%; extremities, 13%; retroperitoneum, 7%; trunk, 5%; and all other sites, 3%.

Histopathologically, RMS is classified with the category of small, round, blue cell tumors of childhood, a category including neuroblastoma, Ewing's sarcoma, small cell osteogenic sarcoma, non-Hodgkin's lymphoma, and leukemia. Six major pathologic subtypes of RMS are outlined by the International Classification of RMS (presented in order of decreasing 5-year survival): (1) embryonal (botryoid); (2) embryonal (spindle cell); (3) embryonal, not otherwise specified (NOS); (4) alveolar, NOS or solid variant; (5) anaplasia, diffuse; and (6) undifferentiated sarcoma. Botryoid RMS

is associated with a superior 5-year survival rate of 95% and most commonly occurs in the bladder or vagina in infants and young children and in the nasopharynx in older children.<sup>7</sup> The most common location for spindle cell RMS is paratesticular, head and neck, extremities, or orbit.<sup>8</sup> Nearly 60% of all pediatric RMS, embryonal and embryonal variant RMS account for the majority of cases in younger patients.<sup>9,10</sup> Alveolar, anaplastic, and undifferentiated variants of RMS account for approximately 35% of all new cases and generally have the poorest prognosis. Although the embryonal subtypes are the most common type of RMS, the alveolar subtype is seen more often in patients presenting later in life, that is, during the second peak in incidence.<sup>10</sup> A "solid alveolar" variant lacks the characteristic alveolar septations but behaves similarly to the conventional alveolar subtype.<sup>11</sup>

The impact of specific histologic subtype on outcome has varied somewhat in different studies. Confounding variables in examining the importance of histologic type include different subtypes that preferentially occur in specific sites, are present as different primary tumor sizes, and have different invasiveness capabilities. For example, with extremity RMS in IRS-IV, clinical group and stage, but not histologic subtype, were important prognostic variables.<sup>12</sup> Other studies support that histologic subtype is an important independent prognostic factor, with embryonal RMS having a significantly favorable outcome.<sup>11,13</sup> In IRS-IV, 3-year failure-free survival (FFS) was 83% for embryonal, 66% for alveolar, 55% for undifferentiated, and 66% for unclassified sarcoma ( $P < .001$ ).<sup>1</sup>

## STAGING

Two classification schemes are currently used to categorize patients with RMS. The clinical grouping system was devised by the IRS in 1972 and is a surgicopathologic system that relies on the initial surgical assessment (Table 72-1).<sup>10</sup> This classification scheme demands an initial surgical approach, which may vary between institutions and surgeons. Stratification

Table 72-1		Clinical Grouping Classifications for Rhabdomyosarcoma	
Clinical Group	Tumor	Extent of Disease	
		Resectability/ Margins	Lymph Node Status
1	Localized	Complete resection Negative margins	Negative
1a	Localized	Complete resection Negative margins	Confined to tissue of origin Negative
2a	Localized	Complete gross resection Microscopically + margins	Negative
2b	Localized	Complete gross resection Microscopically + margins	Positive regional nodes
2c	Localized	Complete gross resection Positive margins	Positive regional nodes
3a	Localized/ locally extensive	Residual disease after biopsy only	
3b	Localized/ locally extensive	Residual disease after debulking of > 50% tumor	
4	Distant metastasis		

From Qualman SJ, Coffin CM, Newton WA, et al: Intergroup Rhabdomyosarcoma Study: Update for pathologists. *Pediatr Dev Pathol* 1:550-561, 1998.

of survival is based on the ability for complete resection. However, clinical grouping has consistently been shown to be an independent prognostic indicator predicting outcome. Overall survival curves, according to clinical group of patients enrolled in all IRS studies, are shown in Figure 72-1.<sup>9</sup>

More recently, the IRS, which is now part of the Sarcoma Committee of the Children's Oncology Group (COG), has implemented a pretreatment staging system based on the tumor/node/metastasis (TNM) system (Table 72-2).<sup>14</sup> The system is modified for RMS to incorporate known important prognostic variables, including primary tumor site, lymph node involvement, distant metastatic disease, and size. Primary tumor site is known to be an important prognostic factor with RMS. Favorable sites include the orbit, eyelid, other nonparameningeal head/neck sites, and nonbladder, nonprostate genitourinary structures (paratesticular, vaginovulvar, uterine). Unfavorable sites include extremities (including buttock), trunk, retroperitoneum, perineum, urinary bladder and prostate, and cranial parameningeal sites. IRS-IV was the first study to use this staging system to classify

patients prospectively. Failure-free survival (FFS) rates for patients with local or regional tumors, according to stage, are shown in Figure 72-2. In this cohort of patients, pretreatment staging appeared to be a more accurate predictor of outcome than was the clinical grouping classification system.

## MOLECULAR BIOLOGY

Further characterization of RMS tumors utilizing specific molecular fingerprints is important in establishing a definitive diagnosis in difficult cases. Additionally, specific molecular markers offer promise as prognostic indicators. One of the challenges in the treatment of RMS is to stratify patients into risk categories, ensuring that low-risk patients are not exposed to overly toxic treatment regimens and high-risk patients are not undertreated. Identification of the specific molecular pathways involved in RMS also offers potential therapeutic targets.

Globally, mutations in certain tumor suppressor genes, including *TP53*, predispose individuals to RMS. It is important to note that patients with Li-Fraumeni syndrome and neurofibromatosis type 1 are more likely to develop RMS. Also, up to 10% of patients with RMS may have one of these syndromes.<sup>15,16</sup>

Embryonal RMS is characterized by loss of heterozygosity (LOH) with loss of maternal genetic information and duplication of paternal genetic information at the 11p15 locus.<sup>17</sup> This genetic locus is the site of the insulin-like growth factor-2 (*IGF-2*) gene, which codes for a growth factor thought to play a role in the pathogenesis of RMS through one of several possible mechanisms. The LOH results in overexpression of *IGF-2*.<sup>9,15</sup> Another potential etiologic molecular finding is the loss of 9q22, which corresponds to a tumor suppressor gene in embryonal RMS patients.<sup>18</sup>

**Figure 72-1.** Overall survival according to clinical group assignment (Intergroup Rhabdomyosarcoma Study [IRS] I to IV). Survival of patients treated on IRS-I, IRS-II, IRS-III/IV-P (IV pilot), and IRS-IV by clinical group at diagnosis is shown. A significant difference is seen in outcome by the extent of initial surgical resection, with the best outcome among the patients with completely resected tumors (group 1), followed by those with microscopic residual (group 2) and gross residual (group 3) disease. Patients with metastatic disease (group 4) at diagnosis fare poorly. (J.R. Anderson, personal communication, 2000; from Pizzo PA, Poplack DG [eds]: *Principles and Practice of Pediatric Oncology*, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Table 72-2 TNM RMS Pretreatment Staging Classification					
TNM Stage	Sites	Tumor*	Size†	Node‡	Metastasis§
Stage 1	Orbit Head and neck (excluding parameningeal) Genitourinary: nonbladder/ prostate	T1 or T2	a or b	N0 or N1 or Nx	M0
Stage 2	Bladder/prostate Extremity Head and neck parameningeal Other (includes trunk, retroperitoneum, etc.)	T1 or T2	a	N0 or Nx	M0
Stage 3	Bladder/prostate Extremity Head and neck parameningeal Other (includes trunk, retroperitoneum, etc.)	T1 or T2	a b	N1 N0 or N1 or Nx	M0 M0
Stage 4	All	T1 or T2	a or b	N0 or N1	M1

\*Tumor: T1, confined to anatomic site of origin. T2, extension and/or fixation to surrounding tissue.

†a, <5 cm in diameter; b, ≥ 5 cm in diameter.

‡Regional nodes: N0, regional nodes not clinically involved; N1, regional nodes clinically involved by neoplasm; Nx, clinical status of regional nodes unknown (especially sites that preclude lymph node evaluation).

§Metastasis: M0, no distant metastases present; M1, distant metastases.

In approximately 70% of alveolar RMS, a common translocation between chromosomes 2 and 13, t(2;13)(q35;q14), is present.<sup>19</sup> This translocation usually involves the *PAX3* gene (which regulates transcription driving neuromuscular development) and the *FOXO1* gene, which is involved in the differentiation process of myoblasts).<sup>20</sup> Less commonly, the translocation involves the *PAX7* gene located at 1p36 to the same location on chromosome 13.<sup>21</sup> The exact molecular pathway leading to the development of alveolar RMS potentially caused or exacerbated by these translocations remains to be elucidated. *PAX3/FOXO1* expression can increase *IGF-2* expression and an IGF-binding protein, providing a common pathway for both embryonal and alveolar RMS. These known molecular disturbances are just now being adopted and studied clinically. Several studies have demonstrated a worse prognosis with the presence of a *PAX3/FOXO1* fusion

gene in alveolar subtypes of RMS.<sup>15,22</sup> Additionally, the t(2;13) translocation has been shown to characterize alveolar RMS with a poor prognosis, whereas the t(1;13) translocation is associated with improved outcome.<sup>23</sup> These preliminary findings and other molecular features will be examined more fully in IRS-V.

## CLINICAL PRESENTATION

The clinical presentation of RMS is highly variable and depends largely on tumor site, patient age, and the presence and/or absence of metastatic disease. The majority of symptoms are secondary to the local mass effect. RMSs involving the head and neck region including orbits, parameningeal tissues (middle ear, nasal cavity, paranasal sinuses, nasopharynx, and infratemporal fossa), and nonparameningeal tissues (scalp, face, oral cavity, oropharynx, hypopharynx and neck) are most commonly embryonal subtype and rarely involve regional lymph nodes. Local symptoms may include proptosis, ophthalmoplegia, nasal/sinus obstruction with or without discharge, cranial nerve palsies, meningeal symptoms, or a painless, enlarging localized mass. Paratesticular RMS may mimic a hernia, hydrocele, or varicocele and present as a painless swelling in the scrotum or inguinal canal. There is a high rate of lymph node spread to the retroperitoneum. Tumors involving the bladder and/or urinary tract or prostate may cause obstruction, hematuria, constipation, and/or urinary frequency. Vaginal tumors are more common in very young patients and may present as vaginal bleeding, discharge, or a mass. Tumors involving the uterus more commonly present in older girls with extensive tumor at diagnosis.

**Figure 72-2.** Failure-free survival for nonmetastatic disease patients according to staging classification in Intergroup Rhabdomyosarcoma Study-IV.

- **Electrocardiography or echocardiography (selective)**

RMSs involving the extremity usually present as a mass, tend to be more aggressive with the majority being the alveolar subtype, and have a high incidence of spread to regional lymph nodes (approximately 50%). Approximately 15% of patients present with metastatic disease. Presentation in the neonate is extremely rare, with most being embryonal/botryoid/undifferentiated subtypes (0.4%).<sup>12,24-29</sup>

## DIAGNOSIS

The diagnosis of RMS is usually made by biopsy. Depending on location, this may involve endoscopy or needle biopsy (genitourinary tumors) or excisional/incisional biopsies (trunk/extremity). Incisions made for biopsy should be placed in such a way that complete excision would be possible if subsequent wide local excision is necessary. Sentinel lymph node mapping is advised in tumors involving the trunk and/or extremities. Prior to definitive surgery, a full evaluation including imaging, laboratory work, and bone marrow evaluation should be performed (Table 72-3).<sup>5</sup>

## SURGICAL TREATMENT

### Primary Resection

It is evident from the impact of clinical grouping on eventual survival rates (see Fig. 72-1) that complete tumor resection, with no microscopic residual disease, offers the best chance for cure. However, in many sites (e.g., orbit, bladder, prostate, vagina, uterus) complete tumor resection is not feasible while still preserving function of vital organs or structures and avoiding mutilating surgical procedures. One of the major achievements in the surgical treatment of RMS over the past 30 years is the progressive increase in organ salvage rates (e.g., bladder, vagina, uterus, prostate) and a decrease in disfiguring surgery while not adversely affecting overall patient survival. The decision as to how aggressive to make the

original surgical approach depends on primary tumor site, size, presence or absence of lymph node involvement, and distant metastases. These decisions must be made in the context of a multidisciplinary team, including the surgeon, oncologist, pediatric radiologist, and radiotherapist to allow optimal care for the patient. The recommended initial surgical approach is to perform a nonradical tumor resection if the primary site and tumor size is amenable and the treatment team believes that a complete resection with negative margins is feasible. Otherwise, a biopsy sufficient to provide the definitive diagnosis as well as tissue for ongoing biology studies, if applicable, is recommended.

### Primary Re-excision

Primary re-excision (PRE) of a tumor is defined as a second attempt at complete resection before the initiation of any other form of therapy. PRE is recommended when an initial resection results in positive margins if this can be accomplished without sacrificing vital structures or organs, causing significant functional impairments, or resulting in a poor cosmetic outcome. A strategy of PRE has been shown to improve survival in patients with extremity tumors (who tend to have a worse prognosis secondary to histology)<sup>30</sup> and in perineal RMS,<sup>14</sup> by converting a significant proportion of patients from group IIa to group I. When the initial resection was performed for presumed benign disease, or when the margin status is not known, PRE also is recommended. The benefit of PRE was recently examined by the Italian Cooperative Study Group. They concluded that PRE was the treatment of choice for children with RMS and nonrhabdomyosarcoma soft tissue sarcoma (NRSTS) age 3 years or younger who cannot receive radiation therapy, and also for paratesticular sites.<sup>31</sup> PRE and postoperative irradiation showed equivalent results in achieving local control in extremity and trunk sites. PRE was not effective in tumors larger than 5 cm. As with the primary tumor resection, PRE is performed to allow a clinical group I classification (no residual), but only if this does not require a mutilating radical surgical procedure. If not feasible, reliance on adjuvant irradiation and chemotherapy is advisable.

### Lymph Node Evaluation

It has become increasingly recognized that RMS frequently spreads to regional lymph nodes early, that these involved nodes can go undetected by sophisticated imaging techniques, and that lymph node involvement significantly worsens the prognosis. Because of these findings, pediatric surgeons frequently must evaluate the status of the regional lymph nodes with RMS. Any clinically or radiographically suspicious lymph node requires pathologic confirmation. It is important to note that lymph node excision serves a diagnostic purpose only. There is no therapeutic value.<sup>5</sup> With extremity RMS patients in IRS-IV, 37% of all patients and 50% of those in whom surgical lymph node evaluation was performed had positive regional lymph node involvement.<sup>12</sup> This study also found that

17% of patients with clinically negative regional nodes had positive biopsy on histologic examination. Patients with positive regional lymph nodes had a 3-year FFS of 40% versus approximately 70% in patients without nodal involvement. It is important to determine regional lymph node status accurately so that if it is positive, more aggressive treatment approaches (e.g., irradiation) can be used. Thus, these patients are recognized to be at higher risk. With perianal RMS, 46% of patients have been found to have regional lymph node involvement.<sup>14</sup> In this group of patients, N1 patients had a 5-year overall survival rate of 33% versus 71% in N0 patients. Regional lymph node metastases also were frequently documented with paratesticular RMS.<sup>32</sup> With paratesticular and perineal/perianal RMS, an increase in regional lymph node involvement is found with age older than 10 years, indicating that there should be a heightened index of suspicion in older children and adolescents with RMS.

Specific recommendations regarding regional lymph node evaluation will be reviewed according to the specific site. However, in general, a strategy of routine surgical evaluation of regional lymph node status is recommended for RMS patients with primary tumors of the extremity, perineum, and for older patients (>10 years) with paratesticular sites, even if there is no clinically apparent disease. If disease is found in the regional nodes, distal lymph nodes should be sampled to determine metastatic disease.<sup>16</sup> Additionally, during the course of tumor resection at other sites (e.g., genitourinary, retroperitoneum), lymph node sampling should be performed, if feasible.

Although not yet standard of care, lymphatic mapping with sentinel lymph node biopsy may allow adequate staging while limiting operative morbidity.<sup>32,33</sup> Most experience with this technique has been gained with extremity and truncal tumors, and with adult breast cancer and melanoma.<sup>16</sup> Typically, lymphoscintigraphic mapping (using technetium-labeled sulfur colloid injected at the primary tumor site with subsequent images showing the lymphatic drainage route) is performed before the planned operation (either 24 hours before or immediately before the surgical procedure). Intraoperatively, vital blue dye is injected at the primary tumor site and a radioisotope detector is used to identify the lymph node with the highest "counts." Utilizing a small incision and limited dissection, a blue sentinel lymph node(s) with evidence of radioactive tracer is excised. These techniques limit the extent of the operation and, potentially, the morbidity as compared with formal lymph node dissection as previously performed. Because the goal is to determine nodal disease for future treatment (i.e., radiation therapy), this approach may play a larger role in the future.

## Second-Look Operation

The majority of patients with RMS are initially seen with tumors that do not allow complete resection to achieve either clinical group I or II status secondary to size, invasion, or location. In IRS-IV, among all patients

without metastatic disease (n = 883), 62% were classified as group III (i.e., gross residual disease after biopsy only or attempted resection).<sup>1</sup> After intensive multi-agent chemotherapy with or without irradiation, these patients usually benefit from a second-look operation. The goals of the second-look operation are to remove residual tumor and to determine pathologic response, because clinical and radiographic assessment is often inaccurate.<sup>34</sup> The primary benefit of a second-look operation is to resect residual tumor before additional adjuvant treatment, which has been shown to improve patient survival and/or to classify patients as complete responders.<sup>16,35</sup> Alternatively, a negative biopsy (i.e., no tumor) on second-look operation does not exclude or diminish the possibility of recurrence.<sup>35,36</sup> Moreover, there appears to be no advantage from a second-look operation in patients with a complete clinical response determined radiographically.

## Surgical Treatment for Recurrent Disease

Despite the successes of primary therapy for RMS, survival after relapse remains very poor. Approximately 30% of RMS patients will experience relapse, and between 50% and 95% of these will die of progressive disease.<sup>37</sup> Factors associated with a better prognosis in recurrent disease include embryonal/botryoid histology and stage or group I disease.<sup>5</sup> In a large review of relapsed RMS patients from IRS-III, IRS-IV pilot, and IRS-IV studies (n = 605), 95% of all failures occurred within 3 years from treatment initiation.<sup>37</sup> Patterns of relapse were as follows: local, 35%; regional, 16%; distant, 41%; and unknown, 8%. Overall, the median survival time from first recurrence or progression was 0.8 year, and the estimated 5-year survival after recurrence was 17%. Factors in this study associated with overall higher survival after relapse included botryoid histology and initial clinical group I assignment. For embryonal RMS, local recurrence predicted improved survival compared with those with regional or distant recurrences. Unfortunately, this review did not report data regarding the effect of surgical therapy at the time of relapse on outcome. RMS patients with local relapse compose a very challenging patient population, and the results of repeated attempts at surgical resection are not fully known. Many RMS patients with locally recurrent disease are those with primary tumors of the extremities, pelvis, retroperitoneum, and other sites at which repeated surgical procedures are difficult. Such patients often require aggressive and often mutilating procedures (e.g., amputation, pelvic exenteration).

The IRSG recommends that patients with locally recurrent disease be treated according to risk stratification. For more favorably rated relapse patients, intensive multiagent chemotherapy is given, followed by radiation therapy, surgical treatment or both, when feasible.<sup>37</sup> For less favorably rated patients, initial dose-intensified chemotherapy and maintenance therapy with agents such as etoposide or experimental therapies may be offered. In a smaller study of RMS and NRSTS patients with first relapse (n = 44), repeated

surgical resection appeared to benefit survival with embryonal RMS but not with alveolar RMS or other soft tissue sarcoma histologic subtypes.<sup>38</sup> A retrospective review of patients treated at MD Anderson Cancer Center for recurrent RMS over an 11-year period ( $n = 32$ ) demonstrated a 37% disease-free survival (mean follow-up period of 4.9 years). Morbidity was 35%, and the percentage of operations considered aggressive was 52%. Several factors present in survivors included embryonal/botryoid histology and RMS of vaginal/paratesticular origin. Factors associated with those who died included alveolar histology and extremity and bladder/prostate disease. No carefully reviewed data are available at this time from which to make definitive surgical recommendations for patients with recurrent/relapsed RMS. Results from the Cooperative Weichteilsarkom Studiengruppe identified certain factors that may predict relapse. Three hundred thirty-seven of 1164 patients initially determined to be in remission at the end of initial therapy for RMS were analyzed to identify particular factors that predict relapse.<sup>39</sup> Factors identified included increased age, histology (alveolar), tumor size ( $>5$  cm) and site, stage after surgery, and lack of radiation therapy.<sup>40</sup>

### Surgical Treatment for Metastatic Rhabdomyosarcoma

Approximately 15% of RMS patients are first seen with metastatic disease, most commonly involving lung (39%), bone marrow (32%), lymph nodes (30%), bones (27%), or other sites. The 3-year overall survival for 129 metastatic RMS patients enrolled in IRS-IV was 39% with an FFS of 25%. In this cohort of patients, 24% had metastases isolated to the lung. The surgical management of these patients is typically restricted to biopsy to confirm the diagnosis, followed by intensive multimodality therapy in an attempt to salvage these patients. In the most recent review of metastatic RMS patients from IRS-IV, survival did not differ between patients who underwent operation and histologic confirmation of lung metastases and those diagnosed radiologically only. The value of aggressive resection of RMS pulmonary metastases has not been extensively studied, primarily because of the rarity of these patients. For other soft tissue sarcomas in children and adults, aggressive resection of isolated pulmonary metastases is thought to be beneficial for prolonged survival.<sup>41,42</sup>

## SITE-SPECIFIC SURGICAL GUIDELINES

### Head/Neck Tumors

Nonparameningeal orbital and other head and neck RMS tumors are considered favorable sites and are classified as stage 1, regardless of size or nodal status. Surgical therapy for orbital and other deep-seated head and neck RMS tumors is largely restricted to biopsy followed by adjuvant chemotherapy and radiation therapy (Fig. 72-3) (except for small lid lesions, in which

**Figure 72-3.** This neonate was born with this large tongue mass. Biopsy showed it to be a rhabdomyosarcoma. Tracheostomy was done to protect his airway, and gastrostomy was performed for enteral alimentation. The patient has required numerous debulking procedures in addition to chemotherapy.

wide local excision may be feasible). Parameningeal tumors have slightly poorer prognosis due to the presence of abundant lymphatics and the tendency for delayed diagnosis because these lesions tend to be somewhat hidden in presentation (as opposed to orbital RMS). Previously, extensive mutilating operations were performed. However, with more effective systemic therapy, these operations are rarely indicated and essentially never used for primary therapy. Metastatic disease to regional nodes is present in less than 3% of cases.<sup>25</sup> Unless there is clinical evidence of lymph node involvement, routine nodal sampling is not warranted. As discussed earlier, recurrent disease portends a much poorer prognosis. Thus, an aggressive surgical approach may be justified. Additionally, surgical intervention may be warranted when there is evidence of persistent disease after adjuvant therapy. These tumors are optimally managed by oncologic otolaryngologists and neurosurgeons, when needed. More superficial lesions, such as parotid tumors, may benefit from primary surgical resection especially when wide surgical excision is feasible (Fig. 72-4).

### Tumors of the Extremities

Extremity RMS constitutes 15% to 20% of all pediatric RMS.<sup>16,42</sup> These tumors are considered to be in an unfavorable site and are classified as stage 2 if smaller than 5 cm and N0, or as stage 3 if greater than or equal to 5 cm or N1 status. In IRS-IV, the median age of these patients was 6 years. Most (71%) had alveolar histology, and more than 60% were classified as clinical group III or IV.<sup>12</sup>

Surgical evaluation of extremity RMS includes magnetic resonance imaging (MRI) and careful physical examination to determine tumor size and involvement of surrounding structures. For primary tumors smaller than 5 cm, depending on anatomic location, complete resection is the goal. The exact required surgical margin remains a matter of debate. The standard 2-cm margins are not always practical in children.

Moreover, there is no clear evidence that a larger margin decreases the chance of recurrence. After distortion of the tissues associated with resection and histopathologic processing, this actual “pathologic margin” is usually smaller. This should be taken into consideration during the operation.<sup>44</sup> Unfortunately, only a minority of extremity RMS patients (31 [22%] of 139 patients in IRS-IV) could be treated with complete primary surgical resection with negative margins.<sup>12</sup>

For patients with larger tumors, or those in unfavorable anatomic sites (e.g., popliteal or antecubital fossae or the groin), an initial incisional biopsy is recommended. The biopsy incision should be oriented longitudinally (i.e., along the long axis of the limb) so that it does not interfere with a later attempt at resection. An incisional biopsy has an increased likelihood of providing the definitive diagnosis and also provides tissue for ongoing biology studies, as compared with fine-needle or cone biopsies. After intensive multi-agent chemotherapy and possibly radiation therapy, a second-look operation can be planned to resect residual disease.

A high rate of regional lymph node involvement is found with extremity RMS. Therefore, evaluation of the regional lymph drainage basin (axillary nodes in upper extremity disease, and femoral triangle nodes in lower extremity disease) is mandatory, even if there is not evidence of clinically apparent nodal disease.<sup>16</sup> In IRS-IV, approximately 40% of all extremity RMS patients had positive regional lymph nodes.<sup>12</sup> Of 139 patients overall, only 76 actually underwent surgical lymph node evaluation, and 50% of these were positive. An additional 13 patients had regional node disease diagnosed by imaging alone. Among patients with negative imaging

**Figure 72-4.** A 13-year-old presented with a large right parotid mass. CT scan shows the large mass (asterisk) in the right parotid gland. The patient underwent total parotidectomy and tolerated the operation well. However, metastatic disease subsequently developed.

and physical examination, but who underwent surgical evaluation of nodal status, 17% were actually positive. This implies that some patients with negative imaging who did not undergo surgical lymph node evaluation probably had undetected positive lymph nodes. Lymph node disease status is a critical component of the preoperative staging classification scheme (see Table 72-2) and has a direct impact on the treatment plan. Undetected positive nodal disease will lead to inaccurate staging and perhaps less than optimal treatment.

Survival with multimodality therapy now approaches 75%, with a significantly lower rate for patients with nodal disease.<sup>16</sup> As reviewed previously, for extremity RMS with microscopically positive or indeterminate margins, or after an initial resection was performed for presumed benign disease, PRE is recommended and has been shown to improve survival.<sup>30</sup>

## Genitourinary Tumors

Within the genitourinary system, RMS can arise from the vagina, vulva, uterus, paratesticular region, prostate, or bladder. Rarely, the kidney or ureter may be involved. In the IRS-IV study, genitourinary RMS accounted for 12% of all patients and more than 30% of nonmetastatic tumor patients, with bladder/prostate genitourinary primary tumors occurring most commonly.<sup>42</sup>

### Bladder/Prostate Tumors

For these deep-seated tumors, the surgical approach is usually limited to initial biopsy. Other surgical approaches, including internal ureteral stents and/or percutaneous nephrostomy tubes, may be necessary in the presence of urinary obstruction. Suprapubic catheters are generally not advised secondary to risk of seeding the tract with tumor.<sup>44</sup> Historically, aggressive initial surgical resection was performed with good local control rates but with significant morbidity and low bladder salvage rates. Currently, bladder salvage is a primary goal with these patients. In selected cases in which the primary tumor involves only the dome of the bladder, complete initial resection may be feasible. However, for most bladder and prostate tumors, the primary therapy is chemotherapy and radiation therapy, followed by a more limited and conservative resection.<sup>45</sup> The rate of exenterative cystectomy with current approaches is approximately 30% (Figs. 72-5 and 72-6).<sup>46-48</sup> Even in those patients in which bladder salvage is possible, a significant percentage of patients may have bladder dysfunction.<sup>16</sup> It is difficult to determine the exact number of patients affected with post-resection urinary dysfunction because most studies do not use urodynamics to assess this complication.<sup>44</sup>

For these tumors, careful consideration should be given to the type of initial biopsy. Often, laparotomy with open biopsy can be avoided, and alternative techniques such as transurethral cystoscopic needle biopsy, image-guided core needle biopsy, laparoscopic exploration with needle biopsy, or others can help to reduce morbidity.<sup>49</sup>

**Figure 72-5.** This CT scan shows a large mass emanating from the pelvis. Biopsy confirmed this mass to be a rhabdomyosarcoma. The bladder has been marked with an *asterisk*.

The estimated 5-year FFS with genitourinary non-bladder/prostate tumors is approximately 80%, indicating a favorable outcome with the conservative surgical approach.<sup>1</sup> If, however, these tumors fail to respond well to primary chemotherapy, as determined by surveillance imaging, a role exists for aggressive tumor resection, including anterior or total pelvic exenteration if needed to achieve local control.

### Vagina, Vulva, or Uterus

These tumors are usually embryonal or botryoid histologic subtype (Fig. 72-7) and are considered to be in a favorable site (stage I), with an overall 5-year survival rate of more than 80%.<sup>50</sup> Current recommendations are to perform an initial biopsy, often transvaginally, and to rely on effective primary chemotherapy. The need for complete surgical excision is rare. There is no

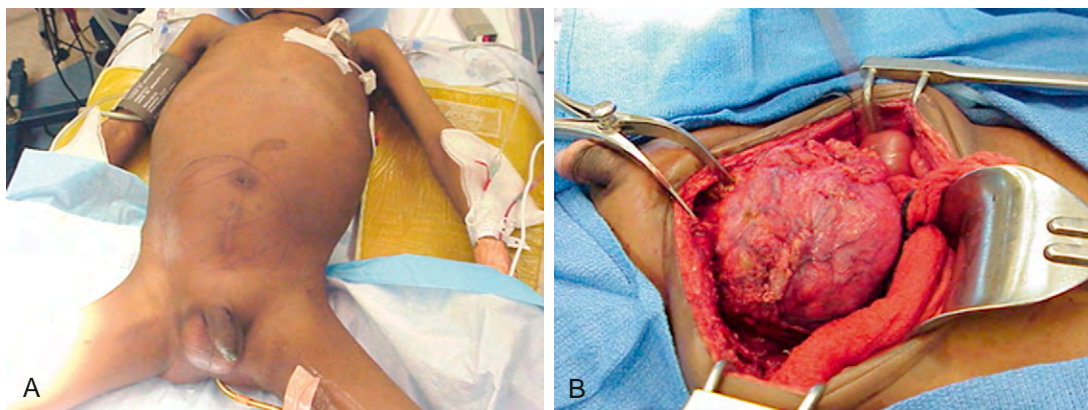

role for initial aggressive resection such as vaginectomy or hysterectomy.<sup>51</sup> These patients are then best followed with routine abdominal and pelvic MRI (rather than computed tomography [CT]) to document tumor response.<sup>52,53</sup> A second-look operation with cystoscopy and re-biopsy is common. Lymph node involvement is uncommon. As with other pelvic RMS, relapsed or persistent disease in the vagina, vulva, and uterus is associated with a very poor outcome. In such cases, aggressive attempts at local control including radiation therapy (external-beam therapy or brachytherapy), partial or total vaginectomy, hysterectomy, or pelvic exenteration are all viable options. Unless there is direct involvement of the ovary by advanced/recurrent disease, there is no role for oophorectomy.

### Paratesticular Tumors

Paratesticular RMS were found in 14% of all IRS-IV study patients.<sup>42</sup> Only 5% of these patients were clinical group IV after the initial surgical intervention. This is considered a favorable site, with all paratesticular patients classified preoperatively as having stage I disease regardless of tumor size, invasiveness, or lymph node status. The overall FFS rate for paratesticular RMS is more than 80%, with patients younger than 10 years having approximately 90% FFS.<sup>1</sup>

The recommended initial surgical approach for paratesticular tumors is radical orchiectomy with proximal ligation of the spermatic cord at the internal inguinal ring via an inguinal incision. A transscrotal incision for biopsy or resection is contraindicated. When done, a subsequent hemiscrotectomy may be required to resect the contaminated tumor bed. Meticulous surgical technique is extremely important. Tumor spillage upstages patients to clinical group IIa regardless of the completeness of resection.<sup>54</sup> When paratesticular tumors are fixed to the scrotal skin or invade the overlying scrotal skin, hemiscrotectomy is indicated. With this surgical approach, 90% to 95% of patients are able to have complete resection (groups I or II).<sup>32</sup>

Paratesticular RMS has a high incidence (~30%) of regional spread to the retroperitoneal lymph nodes

**Figure 72-6.** This patient's CT scan is seen in Figure 72-5. **A**, The patient presented with lower abdominal distention and a large mass that was palpable. **B**, The mass (visualized in the operative photograph) was not responsive to chemotherapy, and an attempt at complete resection was made. Most, but not all, of the mass could be excised. The patient eventually died of metastatic disease.

**Figure 72-7.** This neonate was born with this protruding mass from her vagina. Biopsy of the mass showed rhabdomyosarcoma. She underwent chemotherapy and has recovered uneventfully. Rhabdomyosarcoma of the vagina has been termed *sarcoma botryoides*.

(RPLNs). Therefore, careful evaluation of these nodes is an important part of the surgical staging workup for these patients. All patients should have thin-cut (3.8 to 5.0 mm) abdominal and pelvic CT scans to assess the retroperitoneum. Because the outcome with paratesticular RMS has been shown to be partially age dependent, as has the frequency of RPLN positivity, the treatment guidelines also vary by age.

Current recommendations for RPLN evaluation are as follows: For patients younger than 10 years, clinical group I, and with no lymph node enlargement on CT scan, no RPLN dissection or sampling is recommended. These patients are then followed with repeated CT scans every 3 months. For patients with suggestive or positive CT scans, ipsilateral retroperitoneal dissection is recommended and further therapy depends on the pathologic LN status. For all patients 10 years or older, ipsilateral RPLN dissection is recommended up to the level of the renal hilum. In this procedure, a systematic approach is used to remove lymph nodes from each station from the internal inguinal ring, along the iliac vessels and aorta, up to the renal hilum. This risk-based application of surgical RPLN evaluation is meant to ensure that underestimation of the extent of disease is minimized but also that only the higher-risk patients are exposed to these invasive surgical procedures. It is apparent in multiple studies and in multiple RMS tumor sites that CT misses 15% to 20% of patients who actually have involved lymph nodes, which are subsequently identified with surgical removal and histologic examination.<sup>12,14,55</sup> RPLN dissection is associated with significant morbidity, including loss of ejaculatory function and lower extremity lymphedema.<sup>56</sup>

RPLNs are somewhat controversial in the management of paratesticular RMS. The International Society of Pediatric Oncology (SIOP) de-emphasizes RPLN surgical evaluation, and discourages RPLN dissection, yet reports similar favorable survival rates.<sup>57</sup> SIOP

investigators concluded that avoidance of RPLN dissection might underestimate the extent of disease in a few patients but that this does not compromise survival. Moreover, these investigators believe that avoiding this surgical intervention with known complications helps to reduce the overall morbidity burden to the patient. Additionally, SIOP investigators and others have also reported that hemiscrotectomy may not be required when a prior scrotal approach has been used, although all cooperative groups strongly recommend an initial inguinal approach.<sup>57,58</sup>

## Other Sites

RMSs occurring in other sites are rare. However, when they do occur, they can present unique challenges to both pediatric surgeons and oncologists. Tumors arising in the trunk (paraspinal, thoracic or chest wall, including pleura, lung, or heart as a primary site), abdominal wall, intra-abdominal (including biliary), and/or pelvic/retroperitoneal areas (including perineum/perianal) were found in approximately 12% of all IRS-IV patients.<sup>42</sup> For truncal tumors, primary surgical resection is the preferred initial approach for tumors smaller than 5 cm in patients in whom a negative operative margin can be realistically anticipated. For larger primary tumors, initial incisional biopsy is preferred. There is a higher incidence of alveolar subtype RMS in truncal RMS, which has a worse prognosis than other sites. Additionally, especially with larger tumors, postoperative reconstructive procedures may be necessary.<sup>16</sup> Paraspinal masses need to be differentiated from extrasosseous Ewing's sarcoma. Because of the rarity of these tumors, no data are available from which to make definitive surgical guidelines regarding regional lymph node evaluation. For many truncal lesions, the primary lymphatic drainage basin can be equivocal and preoperative lymphoscintigraphy may be helpful.

Retroperitoneal and nongenitourinary pelvic tumors are among the most difficult to manage because of the relatively "hidden" location and subsequent late presentation. More than 90% of these patients are first seen as clinical group III (gross residual disease with biopsy or attempted resection) or IV (metastatic disease) with large, invasive tumors.<sup>43</sup> The preferred surgical approach for these patients is generally initial biopsy, aggressive multiple-agent chemotherapy, radiation therapy, and second-look operation, if indicated. The role for debulking large retroperitoneal or nongenitourinary pelvic tumors is not entirely clear. Adding to this controversy is the finding that the subset of retroperitoneal/nongenitourinary pelvic RMS patients, with embryonal tumors who had debulking surgical procedures in IRS-IV or IV-pilot (1984 to 1991), had an improved 4-year FFS versus similar patients who underwent biopsy only (72% vs. 48%;  $P = .03$ ).<sup>59</sup> Additionally, in IRS-IV patients (1991 to 1997) with localized retroperitoneal/pelvic RMS, debulking of 50% of the tumor prior to initiation of chemotherapy was found to reflect positively on outcome (5-year survival rate of 75% and FFS rate of 70%).<sup>60</sup> These findings should be viewed as preliminary data rather

than a recommendation for routine debulking of large retroperitoneal or pelvic tumors.

Biliary RMS generally has a good prognosis without the need for aggressive surgical resection. Most patients have the botryoid variant of embryonal RMS that responds well to chemotherapy. Biopsy followed by neoadjuvant chemotherapy frequently results in resolution of symptoms, including jaundice. Surgical intervention is fraught with complications, including the inability to resect all disease in most cases and infections associated with external biliary drains.<sup>61</sup>

Perineal and perianal RMSs also are rare sites that have an overall poor outcome at least in part because of late presentation.<sup>62</sup> From 1972 to 1997, 71 patients had perineal and perianal tumors, with a 5-year FFS rate of 45%.<sup>14</sup> Important surgical issues for these patients are (1) more than one third of

patients are seen initially with presumed benign disease (usually infections); (2) approximately 50% have regional nodal disease, which adversely affects survival; and (3) primary re-excision frequently lowers the clinical group assignment, which improves outcome.<sup>14</sup>

## CURRENT/FUTURE RESEARCH

The ongoing IRS-V study is divided into separate protocols for patients categorized into various risk strata or categories (Table 72-4). Low-risk patients (D9602 protocol) are estimated to have 3-year FFS rates of 88%, based on previous studies.<sup>63</sup> This subgroup is limited to patients with localized embryonal, botryoid, or spindle cell tumors. In general, these patients receive either VAC (vincristine,

dactinomycin [actinomycin D], cyclophosphamide) or VA (vincristine, actinomycin D) chemotherapy and radiation therapy to residual tumor with resection.

Intermediate-risk patients (D9803 protocol) have a predicted FFS rate of 55% to 76% and include those with localized alveolar or undifferentiated sarcoma, stages 1 to 3; embryonal RMS stages 2 and 3 with gross residual disease; or stage 4 embryonal RMS patients younger than 10 years. In IRS-V, these patients are randomized to VAC and radiation therapy or VAC alternating with vincristine, topotecan, and cyclophosphamide and radiation therapy.

High-risk patients (D9802 protocol) have a 3-year FFS of less than 30% and include stage 4 alveolar or undifferentiated tumors and embryonal RMS patients older than 10 years. In general, these patients receive

up-front chemotherapy with irinotecan followed by VAC and radiation therapy. For patients responding to irinotecan, treatment continues with four additional cycles of irinotecan and vincristine, in addition to VAC.

An important component of ongoing IRS studies is the investigation of the biology of these tumors. This aspect of the care of RMS patients must be emphasized. Its success hinges on full participation by pediatric surgeons and oncologists. All newly diagnosed or relapsed RMS patients should be considered for enrollment in ongoing biology study protocols. The surgeon should facilitate the submission of fresh tumor specimens as well as peripheral blood and bone marrow when indicated, so that continued improvements in the care of these children can be realized.

# NEVUS AND MELANOMA

Arlet G. Kurkchubasche, MD • Thomas F. Tracy Jr., MD

There is an increasing awareness of the importance of pigmented lesions in infants and children. Referrals for evaluation and management of pigmented skin lesions represent a significant component of the outpatient pediatric surgical experience. Also, with the increased incidence of melanoma and limited options for treatment of melanoma, early diagnosis and surgical management must adhere to the guidelines established by the American Joint Committee on Cancer (AJCC).<sup>1</sup>

## EMBRYOLOGY AND ANATOMY OF MELANOCYTIC LESIONS

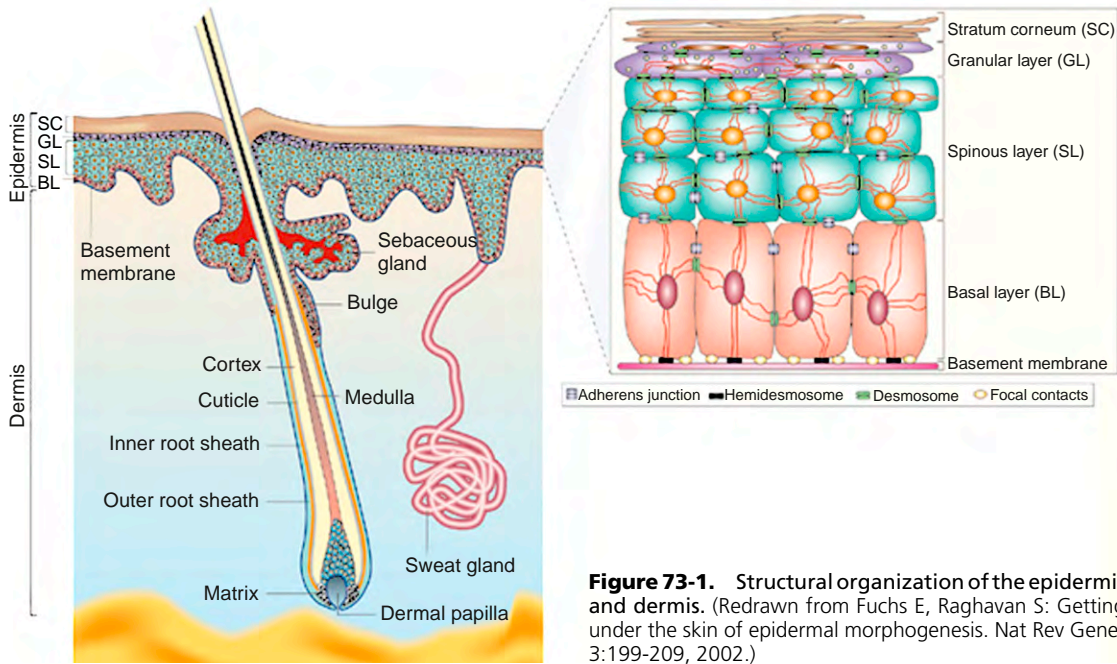

The terminology used for the description of pigmented cutaneous lesions is often confusing. Therefore, a basic understanding of the epithelial anatomy and physiology is essential to the clinical identification and correct classification of these lesions. Figures 73-1 and 73-2 depict the basic anatomy of the epidermis and dermis.

The melanocyte is a dendritic cell and neural crest derivative (Fig. 73-3). During development, the melanocyte precursors (melanoblasts) migrate to the dermis, hair follicles, leptomeninges, uveal tract, and retina. After the eighth week of development, they migrate from the dermis to the epidermis. Failure of migration results in congenital nevi and a variety of dermal melanoses, which can be considered hamartomatous lesions because they represent normal tissues in an abnormal location. Melanocytes normally reside in the basal layer of the epidermis as a single cell associated with a group of keratinocytes. Melanin is transferred in storage granules referred to as melanosomes through the dendritic arm and is internalized by the keratinocytes, which then migrate through the layers of the skin. Nevus cells are derived from melanocytes or their precursors and distinguish themselves by (1) the absence of dendrites, (2) the clustering of cells, (3) their variable location within the dermis and epidermis, and (4) their variable content of melanin. In contrast to the congenital nevi that result from failure of migration of melanocytes from the dermis to the epidermis, acquired nevi are proliferative lesions and

represent benign neoplasms of the skin located within the epidermis or dermis (or both).

The term *macule* refers to a circumscribed, pigmented lesion, less than 5 mm in diameter without elevation or depression from the surrounding skin, whereas a *patch* refers to a larger area of involvement without palpable characteristics. *Papules* represent solid elevated lesions less than 5 mm in diameter, and *plaques* are raised lesions larger than 5 mm. *Nodules* arise from the dermis or subcutaneous tissues. Dermal *melanoses* are pigmented lesions resulting from the deposit of melanin in melanophages, from free melanin in the dermis, or in dermal melanocytes. *Melanocytosis* refers to an increased number of melanocytes.

The epidermis consists of multiple layers, commencing with the basal layer that is the site of mitotic activity leading to the proliferation of keratinocytes. This basal layer consists of columnar cells anchored to the basement membrane via hemidesmosomes and anchored in the dermis via penetrating fibrils (see Fig. 73-1). Interspersed between the basal cells are melanocytes, which morphologically are dendritic cells and the source of melanin (see Fig. 73-2). These cells are not secured via desmosomes or tonofilaments. There are functional units (epidermal melanin units) composed of a melanocyte and the keratinocytes that are responsible for the transfer of melanin, which ultimately results in the pigmentation of the skin. The differentiation in racial pigmentation is not based on numbers of melanocytes but instead on the variable production of melanosomes and their content and rate of degradation. Melanosomes are cytoplasmic organelles that result from the fusion of vesicles containing tyrosinase and vesicles containing structural melanosomal proteins, both of which are generated by the endoplasmic reticulum of the melanocyte. Patients with albinism lack tyrosinase, which is essential for making melanin. These melanosomes are transferred from the perinuclear area along microtubules to the dendritic tips, where these are phagocytosed by the keratinocyte. As the squamous cells differentiate, the melanosomes are degraded by lysosomal enzymes. The prickle cell layer is the next histologic layer and site of Langerhans cells, which are bone marrow–derived dendritic cells, akin to macrophages, and have antigen-presenting capacity.

**Figure 73-1.** Structural organization of the epidermis and dermis. (Redrawn from Fuchs E, Raghavan S: Getting under the skin of epidermal morphogenesis. *Nat Rev Genet* 3:199-209, 2002.)

With further differentiation, the keratinocytes become flattened and form the granular cell layer distinguished by the presence of keratohyaline granules. These granules become the source of the fibrous protein keratin and lamellar granules (Odland bodies), which contain lipids and enzymes and are secreted into the intercellular spaces forming the cement between the epidermal cells and keratinocytes. The outermost

layer is the stratum corneum or horny layer composed of devitalized keratinocytes (see Fig. 73-1).

### CLASSIFICATION OF NEVI

Nevi can be grossly categorized as pigmented and nonpigmented skin lesions. The basis of their designation rests on whether melanocytes are involved in the disorder, and the classification actually distinguishes between epidermal and melanocytic nevi.

*Epidermal nevi* refer to nonmelanocytic lesions that result from proliferation of components of the epidermis and encompass a number of variants based on the involvement of adnexal structures such as sebaceous glands, hair follicles, and apocrine glands. When large or extensive, they may be associated with important ocular, neurologic, and musculoskeletal conditions. These skin lesions must be recognized as clinically benign. However, with the hormone-induced changes during puberty, there is an association of nevus sebaceous with benign tumors as well as basal cell carcinoma.

*Melanocytic nevi* (also known as nonepidermal nevi or dermal nevi) can be classified according to whether they involve disorders of melanocyte migration or proliferation. These lesions are most commonly categorized based on age at presentation as either congenital or acquired (Fig. 73-4). Congenital melanocytic nevi (CMN) result from failure of embryologic migration of the melanocyte precursors and form hamartomatous lesions that are evident at birth, which may evolve over time. Acquired melanocytic nevi are the result of benign proliferative disorders of nevi (melanocytic derivatives) and, therefore, constitute neoplasms.

**Figure 73-2.** The melanocyte rests within the basal layer of the epidermis and is associated with a group of keratinocytes to which it delivers the melanosomes. (Redrawn from Gray J: *The World of Skin Care*. Available at [http://www.pg.com/science/skincare/Skin\\_tws\\_16.htm](http://www.pg.com/science/skincare/Skin_tws_16.htm).)

**Figure 73-3.** The neural crest derivation of these dendritic cells explains the association of melanocytic disorders with CNS, bony, and ophthalmic disorders. (Redrawn from [www.nature.com/nrg/journal/v3/n6/images/nrg819-i1.jpg](http://www.nature.com/nrg/journal/v3/n6/images/nrg819-i1.jpg).)

They have a tendency to increase in number during childhood, adolescence, and early adulthood but then spontaneously regress with age. To identify those lesions presenting a risk for malignant degeneration, these two groups are further stratified according to the size of the lesion. The two subsets, which require greatest clinical vigilance, are (1) the giant congenital melanocytic nevi and (2) the atypical acquired nevi.

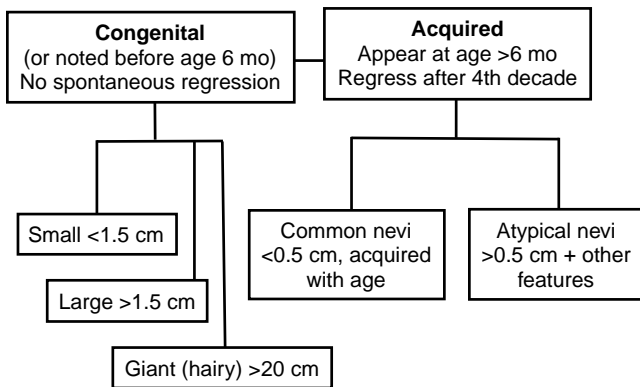

An alternate classification scheme for melanocytic nevi focuses on the relationship between the physical and histologic features of the lesion. This results in a stratification based on where the nevus resides in relation to the epidermal-dermal junction (Table 73-1). This system avoids the diagnostic reliance on an often inexact recollection of when a nevus first appeared in infancy or childhood. In this scheme, both congenital and acquired nevi can be described as being (1) junctional (situated at the junction of the

epidermis/dermis), (2) compound (involving both regions), or (3) dermal (confined to the dermis). These are generic histologic terms and do not imply biologic behavior. Although this schema allows for classification of all congenital and acquired nevi, some nevi are sufficiently clinically distinct to retain specific descriptive or eponymous names. These warrant individual discussion because it is their features that may prompt referral for biopsy to exclude malignancy. Examples of these lesions include the blue nevus, Spitz nevus, and halo nevus.

## NONMELANOCYTIC NEVI

### Epidermal Nevi

Epidermal nevi are skin lesions not associated with the proliferation of melanocytes. Instead, these represent congenital hamartomas of ectodermal origin that are classified based on their hyperplastic element (Table 73-2). Keratinocytic lesions involve the epidermal layer only, whereas the organoid lesions involve the sebaceous, apocrine, eccrine, and follicular structures. They are clinically distinct and appear as raised, pigmented, velvety to wart-like proliferations of the dermis along dermatomal distributions. Lesions are usually apparent in infancy, but some may appear in later childhood. The incidence in newborns is estimated to be 0.3%. The most common sites involved are the scalp, face, trunk, and proximal extremities. Often a hairless patch is noted on the scalp, or a raised linear yellow-tan to orange plaque is evident on the face or trunk during infancy. With age and the hormonal changes during puberty, these lesions change in appearance and become verrucous or develop more coarse hair growth.

**Figure 73-4.** Pigmented lesions are classified based on their age at appearance and further stratified by size and other physical features to yield two subsets that require close monitoring of the patient for the development of melanoma.

	Junctional	Compound	Dermal
<b>Histologic Location</b>	Junction of epidermis and dermis	Involving both dermis and junctional region	Involving dermis only
<b>Configuration</b>	Flat, round-oval, symmetric	Raised, become more elevated with age	Protuberant, dome shaped, pedunculated
<b>Surface</b>	Smooth, hairless	Smooth to verrucous, may have hair	Smooth to verrucous
<b>Pigmentation</b>	Uniform dark brown to black	Flesh colored or brown, may have uniform distribution of darker spots, may develop halo	Flesh colored, tan to pink, may have halo or telangiectases

AJCC, American Joint Committee on Cancer

\*Only in the presence of ulceration or reticular dermal invasion.

A number of syndromes are associated with these epidermal nevi, particularly when they are large or extensive. The epidermal nevus syndromes typically involve abnormalities of the central nervous system, ocular system, and skeletal system. While the classification of these lesions and syndromes remains based on clinical findings, advances in molecular biology suggest that these disorders are based on genomic mosaicism and that future biologic classification will become possible.<sup>2</sup> The common variants of epidermal nevi (see [Table 73-2](#)) include:

- Nevus sebaceous ([Fig. 73-5](#)), which represent 50% of the epidermal nevi
- Keratinocytic nevi
- Nevus comedonicus ([Fig. 73-6](#))
- Inflammatory linear verrucous nevus
- Linear Cowden nevus
- Becker's nevus (pigmented hairy epidermal nevus)

These lesions are associated with a risk for transformation. Whereas syringocystadenoma papilliferum is the most likely benign neoplasm identified, basal cell carcinoma, squamous cell carcinoma, and keratoacanthoma are known to be primarily associated with nevus sebaceous after puberty. Recommendations for excision are based on this natural history.

## MELANOCYTIC NEVI

### Congenital Melanocytic Nevi

CMN are variable-size pigmented lesions that present during the first few months of life. These lesions grow proportionally with the infant and are generally categorized as small (<1.5 cm), medium (1.5-20 cm), and large (>20 cm). Those especially large lesions (>40 cm

Primary Name	Other Names	Cutaneous Features	Histologic Features	Other Features or Associations
Linear sebaceous nevus (LSN)	Nevus sebaceous, organoid nevus, Jadassohn nevus, phakomatosis	Yellowish orange plaque, affects scalp and face, hairless, 2-3 cm diameter	Epidermal, follicular, sebaceous and apocrine abnormalities	Epidermal nevus syndrome with seizures, CNS and ocular anomalies
Linear nevus comedonicus (NC)	Comedone nevus, nevus follicularis	Firm dark papules that look like comedones in linear pattern	Keratin-plugged hair follicles	Cataracts, variable CNS and bony defects (e.g., scoliosis, fused vertebrae, spina bifida occulta, absent fifth finger)
Linear epidermal nevus (LEN)	Nonorganoid epidermal nevus	Verrucous, nonerythematous, nonpruritic hyperkeratosis	Keratinocytic changes only	Significant involvement of other organ systems, neurodevelopmental delay, seizures, movement disorders
Inflammatory linear verrucous epidermal nevus (ILVEN)	Psoriasiform hyperplasia	Linear persistent pruritic plaque, usually on limb, tends to coalesce as linear formation	Inflammatory infiltrate, hyperkeratosis	Pruritic, female predominance 4:1, uncommon musculoskeletal associations
Linear Cowden nevus	Nonorganoid epidermal nevus	Thick linear lesion	Papillomatous	Cowden disease (germline <i>PTEN</i> mutation)

**Figure 73-5.** This young child has the classic appearance of a nevus sebaceous, which is a solitary yellow-orange hairless, oval to round, and usually less than 2 to 3 cm in diameter.

**Figure 73-6.** In the right axilla of this 5-year-old is a nevus comedonicus (arrow). This lesion is a well-circumscribed plaque that is composed of keratin-plugged hair follicles. It was present at birth and has been slowly enlarging.

in final diameter) are also referred to as garment nevus, giant hairy nevus, or bathing trunk nevus because they tend to cover large truncal areas in confluence (Fig. 73-7). Although the pigmentation and surface are initially uniform and flat, the lesions evolve into thick, dark, and often hair-covered lesions.

Histologically, the melanocytic cells in CMN are located deeper than those in acquired nevi (Fig. 73-8). The melanocytic cells can be contained (1) in the lower two thirds of the dermis, (2) between collagen bundles, or (3) in the lower two thirds of the reticular dermis or subcutis and associated with appendages, nerves, and vessels. The absence of superficial involvement may

explain why transformation is often not noticed until late in its development. The incidence of transformation is greatest in the large or giant congenital nevi and low in small to medium-sized lesions.

Excision of small and medium-sized CMN can be delayed or avoided in favor of lifelong medical observation, because transformation is presumed not to occur in the prepubertal years. Biopsy may be of value in stratifying the risk of malignant degeneration. If histologic examination shows the more superficial variant, continued observation is warranted because any transformation is likely to be associated with epidermal changes that will be apparent on close follow-up or meticulous self-examination. If the histologic variant demonstrates deep melanocytes, then prophylactic excision is warranted. The estimated lifetime risk of melanoma in small to medium-sized CMN is estimated at 1% and most often occurs after puberty.

The management of large or giant CMN is more controversial. The melanoma risk for these lesions is increased and estimated to be 5% to 10% over a lifetime, with 50% of this risk during the first 5 years of life.<sup>3,4</sup> The highest risk lesions in this group are associated with the nevus that is situated over the posterior trunk (see Fig. 73-7), greater than 40 cm in maximal dimension, and associated with satellite nevi. Melanoma in these patients can arise from the deep dermal layer or even originate from sites distant from the skin, such as the central nervous system or retroperitoneum.<sup>4</sup> These patients are at risk for development of other soft tissue malignancies such as rhabdomyosarcoma or neurofibrosarcoma (peripheral nerve sheath tumor).<sup>5</sup> They are also at risk for neurocutaneous melanosis and central nervous system malformations such as Dandy-Walker malformation, defects of the vertebra, and skull and intraspinal lipomas. In these patients, screening magnetic resonance imaging (MRI) of the brain and spinal cord is recommended during the first 6 months of life. Two thirds of patients with neurocutaneous melanosis have giant CMN, and the others have multiple non-giant lesions. The prognosis for patients with symptomatic neurocutaneous melanosis is extremely poor even in the absence of malignancy.<sup>6</sup>

**Figure 73-7.** Giant congenital melanocytic nevus (garment nevus) of the back and buttock in a neonate.

**Figure 73-8.** Congenital melanocytic nevus is characterized by nevus cells extending from the dermal-epidermal junction (open arrow) along skin appendage structures into the deep dermis (solid arrow).

Because operative resection of these extensive lesions is often not feasible and never completely eliminates the risk for development of melanoma, these patients must have close expert surveillance. Areas of epidermal change within the nevus should be sampled. However, caution must be exercised in interpreting the histologic results, because evidence suggests that proliferative nodules may resemble melanoma but behave in a benign manner.<sup>7</sup> Features useful in differentiating cellular nodules from melanoma include (1) lack of high-grade uniform cellular atypia, (2) lack of necrosis within the nodule, (3) rarity of mitoses, (4) evidence of maturation, (5) lack of pagetoid spread, and (6) no destructive expansile growth.<sup>8</sup>

*Speckled lentiginous nevi* are probably variants of CMN because they frequently present in early infancy. These nevi are evaluated and treated with the same level of concern as would be warranted for congenital nevi of similar size. A variable number of black, brown, or red-brown macules and papules are seen within a usually oval patch of tan-to-brown hyperpigmentation, which is generally 3 to 6 cm in diameter.

## Common Acquired Nevi

Common acquired nevi are benign neoplasms of the skin, which appear after 6 months of age and persist through the fourth decade after which they may disappear. They are most frequently located on sun-exposed areas and are rare on the breast or buttock. Common to all these acquired nevi is that they are less than 6 to 8 mm in diameter, symmetric, with a homogeneous surface with even pigmentation and a regular outline with a sharply demarcated border. On close inspection, they may have some pigmentary stippling.

Histologically, these acquired nevi are subdivided into subtypes based on the location of the nests of nevus cells and this feature corresponds with certain clinical findings (see Table 73-1). *Junctional nevi* tend to be flat with brown to black pigmentation, and the

nevus cells are located at the dermal-epidermal junction. When the nevus cells extend from the junction into the dermis, the lesion is described as a *compound nevus*. Clinically this corresponds to a lesion that is slightly raised and pigmented brown to black.

When the nevus cells migrate completely into the dermis, the lesion is an *intradermal nevus*, which is raised and typically not pigmented. In general, the deeper the nests of nevus cells, the more raised and less pigmented the lesion (i.e., dark flat lesions vs. raised tan lesions). The temporal evolutionary path of nevi was originally described by Stegmaier and explains the clinical observations of progressive change within individual nevi or their resolution.<sup>9</sup> New nevi tended to be small and flat (junctional) and either develop a raised profile or disappear with time as a consequence of fibrosis. In one study, when the nevi on adolescents were followed over a 4-year period, it was demonstrated that there was a net increase of 50% in total number of nevi despite complete regression of 15% of the nevi.<sup>10</sup> This demonstrates the degree of active turnover in individual patients. Freckling and lighter-colored skin are associated with increased numbers of nevi. In darker-skinned individuals, nevi also develop, but with a different distribution usually found on the palms and soles, unlike in individuals with a more fair complexion.

Sun exposure during childhood, especially when it is intense, intermittent, and not necessarily associated with sunburn, is a promoter for nevus development and the major environmental factor associated with the risk of melanoma. Recent evidence suggests that sunscreen use has led to a false sense of security in that it provides incomplete protection to ultraviolet (UV) rays. Sunscreen use alone does not provide sufficient protection, and expanded public health education must focus on the avoidance of midday sun and use of physical barriers such as UV protectant clothing and hats.<sup>11-13</sup>

The role for excision of these commonly acquired lesions is limited when they are clearly defined by their age at presentation and the features described in Table 73-1. The natural evolution and changes on these common lesions should not be mistaken for malignant progression.

## Atypical Nevi

Atypical nevi, previously referred to as dysplastic nevi or Clark's nevi, are common lesions occurring in as much as 5% of the population. They may occur either in a familial pattern or sporadically. The onset of their first appearance is principally during adolescence on the sun-exposed areas of skin, and they continue to increase in number and size with age. Unlike the common acquired nevi, these lesions are usually larger than 5 mm (up to 15 mm) and have an irregular surface ranging from completely flat to flat with a raised center resembling a fried egg (Fig. 73-9). The pigmentation usually is dark and irregular, and the border of the lesion is often irregular as well. These lesions are most common in individuals with light skin and hair

**Figure 73-9.** Clark's nevus (dysplastic nevus) with "fried egg" appearance.

color. UV light has been implicated in the transformation of melanocytes in these nevi.

When a patient has multiple atypical nevi or moles, they may be diagnosed with the atypical mole syndrome. While it can be normal to have up to 10 to 20 moles, people with this syndrome may have in excess of 100 moles. Individuals with 50 to 100 moles and one or more first or second-degree relatives with melanoma are considered to have the familial atypical mole and melanoma (FAMM) syndrome that identifies them at significant increased risk for the development of melanoma, which may approach 100%. The melanoma lesion may arise *de novo* on any part of the body and not necessarily from a preexisting atypical lesion. Simple excision of an atypical nevus therefore does not obviate the patient from close dermatologic follow-up. In families with the atypical mole syndrome, nevi arising on the scalp can be an early predictor to the atypical mole syndrome, although the scalp nevus itself may involute with time. The moles in these individuals tend to be similar in appearance, the corollary being that a new nevus that varies in appearance or location should be regarded with suspicion. The ability of nonclinicians to identify the "ugly duckling" has been found to be reliable.<sup>14</sup>

Atypical nevi are not necessarily removed to confirm the histologic pattern of atypia but should be sampled when the differential diagnosis includes melanoma. The biopsy specimen should encompass a 1- to 2-mm rim of normal tissue and be sufficiently deep to allow for assessment of depth of invasion in the event that melanoma is identified. The original designation of dysplastic nevus has been replaced with the term *atypical nevus*, and the pathologic description should use the term *nevus with architectural disorder* and indicate the extent of cytologic atypia. The concordance between clinically atypical nevi and the histologic findings of dysplasia is poor. Newer adjuncts to clinical examination such as dermatoscopy (epiluminescence microscopy) may assist the clinician in the future in

determining which lesions require excisional biopsy. These lesions are at the heart of much of the unfortunate controversy and misinformation that surrounds patients and referring physicians with terms and descriptions of atypia and dysplasia. These descriptive features have prompted inappropriate re-excision of some lesions and sentinel lymph node biopsy for a completely benign process. Expert dermatopathologic review, as discussed in the following sections, is essential for achieving the highest standard of care.

### Specific Congenital or Acquired Melanocytic Lesions Requiring Distinction from Melanoma

Several melanocytic lesions and nevi are discussed separately owing to their unique features, which frequently prompt their evaluation for malignancy. These lesions can be congenital or acquired and can be described in terms of their junctional, compound, or dermal location. A recent review by Schaffer provides some practical advice regarding these specific lesions.<sup>11</sup>

*Halo nevi* (*Sutton's nevi*) are unique lesions that appear between 6 and 15 years of age and are typically located on the trunk or extremities. They appear as round or oval lesions with a central area of pigmentation that may be tan to brown and is surrounded by a rim of depigmentation (Fig. 73-10). Histologically, the central nevus is usually a compound or dermal nevus surrounded by a uniform infiltrate of T lymphocytes. Pigmentation may come and go, and the role for excision is limited to those that develop atypical characteristics within the pigmented lesion itself. There is no association with malignancy, and these nevi only cause clinical suspicion because regressing melanoma may be gray or white.

A *blue nevus* is a benign proliferation of dendritic dermal melanocytes. The etiology is attributed to a dermal arrest in embryonic migration of neural crest melanocytes that fail to reach the epidermis, creating a hamartoma (normal cells in an abnormal location).

**Figure 73-10.** The classic appearance of a halo nevus. These small pigmented lesions are surrounded by a rim of hypopigmentation. They are typically seen in adolescents and are most commonly located over the trunk, especially on the back. Treatment is usually not needed unless the pigmented portion of the halo nevus appears atypical. In that case, excision of the entire lesion, including the halo, is recommended.

This is a lesion with large amounts of pigment within the dermis, resulting in absorption of the longer wavelengths of light and scattering of blue light known as the Tyndall effect. Two variants of blue nevi are distinguished based on size: (1) the common blue nevus, which is usually less than 5 mm, and (2) the cellular blue nevus, which measures 1 to 3 cm.

The *common blue nevus* appears in adolescence and is most often located on the head and neck, the sacrum, and the dorsal aspect of the hands and feet. These lesions are usually nodular, given their dermal location, and can be mistaken for nodular melanoma, except that there will be no history of rapid ongoing growth. Dermatoscopy shows a uniform blue-gray pigment profile that helps distinguish blue nevus from melanoma.

The *cellular blue nevus* is usually 1 to 3 cm in diameter and presents on the scalp, buttock, sacrum, and face. It may be congenital or acquired. Histologically, it is located within the deep (reticular) dermis and is a well-demarcated nodule. Cellular lesions may have occasional mitoses, but significant atypia and necrosis are absent. A potential for malignant degeneration exists only in the cellular lesions and is clinically heralded by an increase in size and ulceration.

The presence of multiple blue nevi should prompt consideration for the Carney complex of myxomas, spotty pigmentation, and endocrine neoplasia. The persistence of extensive *dermal melanoses* such as those found in mongolian spots, especially when in a ventral distribution, should prompt evaluation for lysosomal storage diseases such as Hurler's syndrome and GM<sub>1</sub> gangliosidosis.

*Spitz nevi* are raised, often light or nonpigmented lesions (light tan-red or reddish brown) that appear dome shaped with either a smooth or a verrucous surface (Fig. 73-11). Typically, these lesions are compound nevi, although pure junctional and pure dermal variants exist as well. Dermatoscopic examination shows a starburst pattern (Fig. 73-12). These lesions tend to occur on the face or lower extremities and measure 0.3 to 1.5 cm in diameter. There is a slight female predominance, with 50% of these occurring in children younger than 10 years of age and 70% in those younger than 20 years of age. The increased red coloration is in part due to increased vascularity, with telangiectasia in the superficial dermis. The vascular

**Figure 73-11.** Two Spitz nevi on the face.

surface features explain why these lesions are more prone to bleeding with minimal trauma.

The pigmented variant of the Spitz nevus is known as a nevus of Reed and typically occurs on the leg of a young woman. The appearance of Spitz nevi may be quite sudden, prompting the concern for potential melanoma. Spitz nevi were previously classified as “benign juvenile melanoma,” a misnomer that was responsible for the misconception that pediatric melanoma was less aggressive than the adult melanoma counterpart. Most Spitz nevi are completely benign. However, atypical clinical features such as a diameter greater than 1 cm, asymmetry, or ulceration should prompt a complete excision. Most often, a young patient who has undergone a shave biopsy is referred for complete excision of the lesion so that it may be fully evaluated by a dermatopathologist.

The histologic features of Spitz nevi can be complex, but they generally are reassuring in that the lesion is uniform and symmetric. The junctional nests of melanocytes have few or no mitoses. The nevus includes spindle cells and large epithelioid cells in variable architectural arrangements; thus, prior designations have included the “spindle and epithelioid cell nevus.” Multinucleated cells may be present but should not

**Figure 73-12.** This patient has a Spitz nevus on her arm. Dermatoscopic examination shows a classic starburst pattern. (Photographs courtesy of Dr. Eric Ehssam. Reprinted with permission.)

exhibit much pleomorphism. Nucleoli are often prominent and rounded. Some of these features in another clinical context could be reminiscent of melanoma, which requires that these lesions be evaluated by dermatopathologists with significant experience in all of the elements of this variant. Those Spitz lesions with unusual histologic features should be excised completely.

In approximately 10% of all cases, histologic features within these lesions do not permit distinction of a Spitz nevus from melanoma. These atypical Spitz nevi then become diagnostic and treatment dilemmas. In these complicated instances, one might consider the safest course of action would be to treat the lesion as equivalent to a melanoma of the same depth. Although some have advocated sentinel lymph node biopsy (SLNB) as a diagnostic tool to identify metastasizing Spitz nevi and classify them as melanoma, this approach has been strongly criticized as being unnecessarily invasive for the limited information gained. In the limited numbers of patients who have undergone SLNB and were then treated with radical lymph node dissection (RLND) and chemotherapeutic agents, there has been no recurrence of disease. This is not consistent with the normal course of “metastatic melanoma” as discussed later. The current biologic and clinical evidence demonstrates that the presence of melanocytic lymphoid infiltrate does not predict clinical behavior and may not identify metastasis or even malignancy as it does for melanoma.<sup>15</sup>

The *nevus of Ito* and *nevus of Ota* are congenital dermal melanocytic disorders that develop because of incomplete migration of melanocytes resulting in hamartomatous lesions. Both of these lesions are most commonly found in Asian populations. In the case of the nevus of Ota, the lesion appears along the distribution of the ophthalmic and maxillary branches of the trigeminal nerve on the face and is evident as a blue-gray patch. These nevi may also involve the ocular and mucosal surfaces. The nevus of Ito involves pigmentation over the shoulder area and is often associated with a nevus of Ota. The pigmentation becomes more prominent with age and may be amenable to laser therapy.<sup>16</sup> Although melanoma has been reported to arise infrequently in the nevus of Ota, the association with glaucoma must be recognized and lead to ophthalmologic referral.<sup>17</sup>

### Nevi Occurring at Special Sites

Acral nevi are found on the palms and soles. They may have linear streaks, but if they have mottled pigmentation and are greater than 7 mm, they must be viewed with suspicion.<sup>18</sup> Longitudinal melanonychia are pigmented streaks emanating from the nail matrix and can be a normal variant that is most frequently seen in darker-skinned individuals. Dark bands and those lesions wider than 6 mm, associated with nail dystrophy or extending beyond the nail fold, should be sampled to exclude melanoma.<sup>19,20</sup> Labial melanotic macules are benign lesions on the lower lip of women that resemble freckles but do not darken with

sun exposure. However, lesions in the oral cavity must be taken seriously and evaluated.<sup>21</sup> In young women presenting with melanotic lesions over the vulvar area, caution must be applied to not overtreat these generally benign lesions.<sup>22</sup>

### PRACTICAL CONSIDERATIONS FOR EXCISION OR BIOPSY OF MELANOCYTIC LESIONS

The many major and minor differences in the clinical and pathologic features for the benign lesions presented thus far have led to understandable confusion about the role for excision of these lesions in infants and children. Pressure for excision from families and pediatricians is often significant and may be based on important but vague family histories of “skin cancer” despite the fact that the vast majority of those family experiences are not with melanoma. Once referred to a pediatric surgeon, many patients and families expect that a procedure will be performed rather than the start of what may be a period of observation and collaborative consultation with dermatologists and pediatricians. Before the referral, the patients are often not informed about the relative risks and benefits of excision for a young group of patients who may require anesthesia or conscious sedation. Scarring is unpredictable and should not be acceptable in the presence of a benign lesion that does not have cosmetic consequences and has no future transformation potential. The natural evolution of acquired lesions and the changes that occur with age, puberty, and exposure to UV radiation need to be taken into account. Moreover, clinical judgment and experience should guide decisions for resection. Simple considerations such as scalp pliability and the tolerance for suture or staple removal from large scalp lesions should be considered and possibly delay the resection of a large nevus sebaceous until after early puberty when this lesion first demonstrates any potential for transformation. On the other hand, one cannot overlook the dangers of transformation during the first 5 years in infants with giant congenital nevi. Staged resections and tension-relieving incisional techniques must be considered as well as the use of important techniques such as tissue expansion and rotational flaps that may be required for the best functional and cosmetic outcome. We have therefore established only general guidelines for our practice for excisional management of congenital and acquired lesions (Table 73-3).

CMN and speckled lentiginous nevi are treated by excision in a similar manner based on the size of lesion. Lesions greater than 20 cm may develop malignant transformation early and warrant consideration for excision at an early age. With a lifetime risk of melanoma at 1%, smaller and intermediate lesions must be monitored closely. Elective resection may be indicated after puberty based on a predicted later onset of potential transformation in those lesions greater than 5 cm. Complicated head

**Table 73-3** General Guidelines for Excision of Congenital and Acquired Lesions

Type of Lesion	Age at Presentation, Site	Configuration, Size, Surface	Pigmentation	Biopsy Indication
Common acquired Atypical nevus	After age 6 mo Usually adolescence; sun-exposed areas	Small (<5 mm) flat Irregular, 5-15 mm Uneven, maculopapular "fried egg"	Brown-black Uneven, dark	None Acute change*
Blue nevus	Any time; on scalp, dorsum of hands/feet	Nodular, <5 mm smooth	Dark gray to blue-black	None
Cellular blue nevus	Scalp, sacrum, buttock, face	5-15 mm	Dark gray to blue-black	Acute change*
Spitz nevus	Face, lower extremities	Dome shaped, 5-15 mm, smooth to warty	Light tan to pink, telangiectasia	Acute change*
Halo nevus	6-15 yr; back	Central nevus with halo of depigmentation, flat to slightly raised	Area of depigmentation	Acute change in center of lesion*
Becker's nevus	Adolescent male; shoulder	Variable shape, flat	Brown macule or patch of hair	Acute change*

\*Based on clinical behavior.

and neck lesions present significant challenges that require a number of surgical considerations and applications.

Perhaps the greatest potential for misdirected concern remains with acquired melanocytic nevi. For the common nevi that are less than 5 mm, there are no evidence-based indications for excision. Atypical nevi defined as larger lesions (5-15 mm) with an irregular surface and a dark, irregular pigmentation warrant excision when physical changes suggest melanoma and not for prevention of transformative changes. Patients with the atypical nevus syndrome or FAMM have the highest risk for malignant melanoma. They require continuous monitoring by the team of consulting physicians and surgeons and a low threshold for biopsy for lesions that appear different from their "usual" nevi (the "ugly duckling" sign).

Blue nevus lesions are common lesions without malignant potential. The cellular blue nevus variant that is greater than 1.0 cm requires a biopsy when ulceration and physical changes become evident. Similarly, the halo nevus has no indication for excision unless suspicious changes occur in the central nevus.

Spitz nevi are often the most worrisome lesions because they can often appear rapidly with dome-shaped firm lesions, simulating a nodular melanoma. These temporal and physical characteristics, along with their variable coloration, often prompt biopsy. Demonstration of epithelioid and spindle features, with or without atypia, after shave biopsy is a common reason for referral for complete excision with a 2-mm margin. With these lesions, expert pathologic review must be available to differentiate them from melanoma and to avoid SLNB, which has no role in these lesions in young patients.

Nonmelanocytic nevi are represented by epidermal nevus variants, which have no risk for transformation other than the nevus sebaceous at adolescence. We therefore recommend excision of sebaceous nevi before the teen years and when the patient is cooperative with the removal of sutures from the often large

and augmented scalp closures that result from complete excisions.

## PEDIATRIC MELANOMA

Melanoma remains a rare cancer in childhood, with children representing less than 2% of all patients with melanoma.<sup>23</sup> There has been a worldwide increase in the incidence of melanoma in adulthood with a doubling over a period of 25 years with age-standardized incidences now at 15/100,000/year and 22/100,000/year in men and women, respectively.<sup>24</sup> Melanoma in children has become more prevalent, but the rates of increase are not as dramatic and primarily affect the postpubertal age group. Current estimates are an annual incidence of 0.8/million in the first decade of life. The maximal rates reported are from Australia and New Zealand where melanoma affects 30/million in the 10- to 14-age group.<sup>25</sup> Regardless of geographic factors, these data are indicative of an increased lifetime risk of cutaneous melanoma of children born today (1/58) when compared to children born in 1980 (1/250).<sup>26</sup>

Fortunately, there has also been a leveling off in the mortality associated with melanoma. This has been attributed to improved early detection, with 90% of new diagnoses involving thin, less than 1-mm melanomas. Some of this improvement in early diagnosis can be linked to the use of expert dermoscopy<sup>27</sup> and computer-based dermoscopy in differentiating between small melanomas and atypical moles.<sup>28</sup> Evidence has shown that the melanoma risk is associated with fair complexion, the presence of freckles and moles, as well as intermittent intense sun exposure, even in the absence of severe sunburns. Careful clinical surveillance of patients with risk factors for the development of melanoma is important in all age groups. Among these risk factors, the atypical mole syndrome, FAMM, and large CMN remain the most important. The most important factor for the

development of melanoma is the presence of melanocytic nevi, with an eightfold increase in relative risk for those with more than 100 moles. If someone has five or more atypical nevi, they have a nearly 50-fold risk of developing melanoma.<sup>24</sup> If there is a family history of melanoma, the incidence approaches 100%. Recent studies based on genetic analysis of families with mutations in the melanoma predisposition gene *CDKN2A* suggest that the FAMM syndrome has a 70% lifetime penetrance of melanoma with sun exposure and mutations in the melanocortin-1 receptor further impacting its development.<sup>29,30</sup>

It is critical to understand that even in these patients, most (80%) lesions arise *de novo* and not from preexisting lesions. For example, in a series of 33 prepubertal patients with melanoma, seven cases arose from CMN (not giant nevi), two from an acquired nevus, and 24 (73%) *de novo*.<sup>23</sup> Although heritable factors and pigment traits contribute to the development of nevi, the only controllable factor for melanoma is the environmental cumulative effects of sun exposure, which is best limited with physical barriers such as clothing and hats and avoidance of midday sun. The use of sunscreen appears to be principally effective in preventing sunburn, of which blistering sunburns during childhood and adolescence have been implicated in the development of melanoma.<sup>12</sup>

### Specific Predisposing Conditions

The diagnosis of melanoma is made in children in several discrete clinical contexts. Congenital melanoma is the least common. It can be due to transplacental transmission or may arise from a primary cutaneous lesion. The appearance of any rapidly growing, ulcerating, or bleeding lesion in the newborn must be evaluated promptly. The incidence of this clinical scenario is so low that projections about outcome are difficult to make, but the prognosis is generally considered poor. However, there are reported instances of spontaneous regression. Moreover, the presence of micrometastases do not appear to impact survival.<sup>7,31</sup>

Melanoma associated with CMN has been well described (Fig. 73-13) and presents a unique set of clinical issues. The lifetime risk for development of melanoma in patients with CMN lesions is variably estimated between 5% and 40%.<sup>32</sup> More conservative estimates indicate a 5% to 10% lifetime risk, with half of this risk distributed within the first 5 years of life.<sup>3,33</sup> Two recent prospective studies of patients with giant CMN showed the incidence of melanoma during the first 5 years of life was between 3.3% and 4.5%.<sup>32, 33</sup> Those patients with a posterior axial giant CMN and numerous satellite lesions have the greatest risk<sup>10</sup> when compared with those with lesions restricted to the head and extremities. These tumors may originate from deep dermal sites and are often not readily apparent based on skin changes. Despite the sometimes ominous appearance of the satellite lesions, these have not been documented as the primary site for melanoma. Proliferative nodules within giant CMN often raise the

**Figure 73-13.** Congenital melanocytic nevus of the scalp with a melanoma arising from it (raised centrally pigmented lesion).

specter of malignancy, but numerous authors caution against hasty conclusions in this clinical scenario.<sup>7,34</sup> Neurocutaneous melanosis occurs in conjunction with the largest CMN and presents the opportunity for non-epithelial melanoma to occur. Although techniques for resection and reconstruction have improved such that disfiguring contour changes can be avoided with soft tissue transfers, these remain surgically challenging operations and there is no assurance of alleviation of this risk, despite full-thickness resection of the CMN. In contrast, the smallest (<1.5 cm) lesions are not clearly associated with any increased risk for melanoma. It is within the intermediate group that little data exist to help guide management. In the experience of Massachusetts General Hospital, CMN lesions up to 5 cm have not been associated with melanoma in patients younger than 20 years of age.<sup>32</sup> Illig and associates reported melanoma arising in CMN lesions less than 10 cm only after age 18 years.<sup>35</sup> Rhodes and Melski calculated a lifetime risk of 2.6% to 4.9% in persons with small CMN living to 60 years of age.<sup>36</sup>

While large and perhaps some intermediate CMN identify patients at risk for the development of melanoma, radical excisional therapy has been tempered by the recognition that cautious observation and selective biopsy present an alternative therapy, especially because the melanoma may arise from sites other than the CMN. When resectional therapy is considered, extensive preoperative planning allows for the optimal use of reconstructive techniques including the use of skin and tissue expanders and a variety of rotational flaps or free tissue transfers in addition to the standard use of skin grafts.

Other conditions predisposing to the development of melanoma include patients with the rare, inherited disorder xeroderma pigmentosum in whom the inability to repair UV-induced DNA damage results in a 2000-fold increased risk of skin cancer. Patients with heritable immunodeficiency syndromes are reported to have a threefold to sixfold increased risk. Pediatric patients on immunosuppression due to chemotherapy for childhood malignancies or solid organ

transplantation experience an increase in total nevus counts and induction of atypical nevi. Although neonatal phototherapy for hyperbilirubinemia has been demonstrated to induce an increased number of nevi, it is uncertain whether this will escalate risk for future melanoma.<sup>37</sup> Despite our efforts to identify patients for screening, it is worthwhile to remember that 60% to 80% of malignant melanoma in children younger than 20 years occurs in the absence of known cutaneous risk factors for melanoma.<sup>38</sup>

## Diagnosis

The difficulty in making the diagnosis of melanoma during childhood relates to a number of variables. The natural evolution of congenital and acquired nevi during childhood and adolescence often limits the use of criteria extrapolated from adult patients. There is limited value to the mnemonic ABCDE (Asymmetry, Border irregularity, Color variegation, lesion Diameter greater than 6 mm, and Evolution of a pigmented lesion; Fig. 73-14) because variegations and irregular shape are not infrequently associated with the atypical nevi. Specifically, the physical characteristics of giant CMN predispose to melanoma arising in the deep dermal layers and extending within the deep subcutaneous tissues, rather than becoming apparent as an epithelial change. Consequently, several authors have pointed out that childhood melanoma may present in a markedly different manner from the adult counterpart. In aggregate, these pediatric series indicate that recent growth, ulceration, or bleeding may be the most frequent presenting features. In contrast to the adult experience with diagnosis of thin (<1 mm) melanomas, pediatric melanomas are typically greater than 1.5 mm thick. This may be due to delays in diagnosis, a deeper origin within a CMN, and a higher incidence of nodular melanomas in children.<sup>26</sup> In a pediatric series of melanoma from St. Justine, Montreal, the most common presenting symptoms were recent growth, pain, ulceration, itching, bleeding, and

**Figure 73-14.** This malignant melanoma demonstrates some of the classic ABCD features for melanoma: Asymmetry, Border irregularity, Color variegation, and Diameter greater than 6 mm.

change in color.<sup>39</sup> Three of 13 patients had lesions that resembled pyogenic granuloma. Only one patient presented with evidence of metastatic disease. Most of the melanomas were nodular (11/13), and only two were superficial spreading. The mean tumor thickness was 3.2 mm in this series.

In another series, the clinical parameters that favor melanoma in children younger than age 12 years were found to be a rapid increase in size (55% of patients), bleeding (35%), or color change (23%) of a nodular lesion.<sup>38</sup> Less frequent signs or symptoms included a subcutaneous mass (6%), pruritus (15%), and enlargement of a regional lymph node (7%). In 7% of patients in whom a melanoma developed in association with a preexisting nevus, the patients had no clinical complaints.

A study of 33 prepubertal patients attempted to delineate the clinical features and outcomes of pediatric melanoma.<sup>23</sup> In this series, the sites of origin were most frequently the extremity (15 lesions), followed by trunk (10 lesions) and head or neck (8 lesions). Interestingly, about 14 of 28 patients had amelanotic lesions that were raised and resembled pyogenic granuloma. Superficial spreading (15 lesions) and the nodular subtypes (9 lesions) of melanoma were the most common lesions, and the median thickness was 2.5 mm.

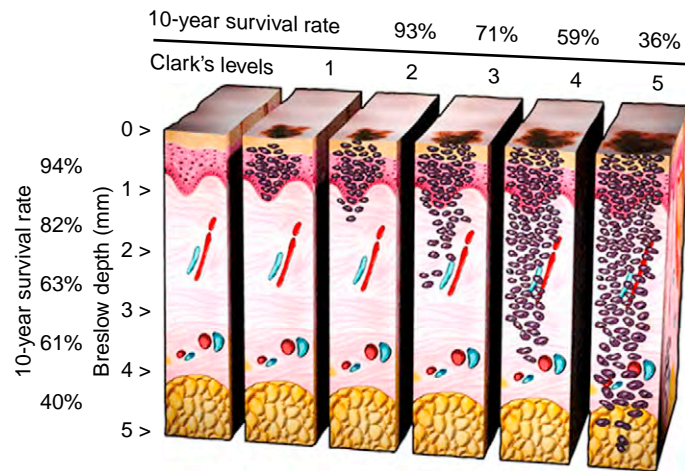

The consistently thicker lesions in childhood melanoma suggest either a delay in diagnosis or reflect biologic characteristics, such as the propensity for nodular melanoma and for lesions arising from the deep dermal layers. These lesions unfortunately may be misdiagnosed initially. Only their sudden appearance and rapid growth over a few months may prompt biopsy. Therefore, despite the infrequency of this diagnosis, the pediatric clinician must consider melanoma in the differential diagnosis of cutaneous lesions.

The role of clinical dermatoscopy, computer dermatoscopy (digital epiluminescence microscopy), and even ultrasound imaging of the skin has been described for monitoring high-risk adult patients. However, there are no current reports focusing on the pediatric population.<sup>27,40-42</sup>

## SURGICAL MANAGEMENT OF THE LESION SUSPECTED TO BE MELANOMA

Once a decision has been made to evaluate a lesion for possible malignancy, the aim is to accomplish this with the least negative impact on function and cosmesis. The clinical scenarios most often encountered are (1) a primary referral for excision of a suspicious lesion, (2) re-excision of a lesion that was previously incompletely excised and showed atypia, or (3) re-excision of a lesion with dysplastic and potentially malignant features.

In these instances, most young children benefit from excision under general anesthesia, which allows the surgeon to focus on achieving a full-thickness biopsy with an adequate margin. When the lesion is

**Figure 73-15.** This drawing shows the 10-year survival rate for Clark and Breslow classification schemes. As is evident, excisional biopsy of lesions suspicious for melanoma must be full thickness to allow assessment of the Breslow level, which helps determine future therapy. (Redrawn from <http://www.med-ars.it/various/livelli4.jpg>. © 2001 Images by Med-Art.)

being excised for the first time or re-excised for atypia, it is reasonable to target a 1-to 2-mm circumferential margin. There are no prospective data to provide an evidence-based approach in this setting. In the setting of dysplastic changes or frank malignancy, the parameters set forth by the AJCC for melanoma should guide extent of margin based on the Breslow stage and Clark's level (Fig. 73-15). Sometimes a shave biopsy of such a lesion does not provide sufficient data and one should therefore plan an adequate excision that may require 1- to 2-cm margins. It is in these settings that a discussion must be held with the family regarding the consequences of resection and the option for proceeding with SLNB under the same anesthetic.

An assessment for the potential for primary closure must occur at the preoperative visit. Lesions over joints, on the distal extremities, and on the face require consideration of more advanced techniques, such as tension-relieving plastic operations, skin grafts, and rotational flaps. Despite the anxiety about a potential tumor, parents must understand that healing and scarring are unpredictable. The best results for achieving adequate margins are obtained by marking out and measuring the margins along the periphery of the lesion while it is in situ. The orientation of the incision depends on the site of the lesion and its relationship to the lines of Langer. Also, consideration should be given to the potential need for re-excision.

The deeper tissues can be excised with electrocautery to limit blood loss. Any suspicious lesion should be marked for orientation in the event that re-excision becomes necessary. Specimens should be submitted for permanent analysis. Frozen section examination has no role in this setting. Techniques for skin closure require consideration of the physical characteristics of the wound as well as the tolerance of the child for suture removal. The use of long-acting local anesthetic agents such as bupivacaine should be encouraged for postoperative analgesia in combination with appropriate oral medications. In the event of more extensive

resections or resections across joints, the use of immobilizing splints should be considered.

In the presence of established malignancy, there is no doubt that a re-excision with margins is mandated. In the more common atypical nevus with dysplasia, the likelihood of malignant degeneration is low and therefore a conservative re-excision is advised. This topic is most heatedly debated in the context of a Spitz nevus with cellular atypia. Whereas most Spitz nevi can be histologically identified as benign lesions, many show atypical features that complicate their differentiation from melanoma. These histologically ambiguous melanocytic tumors have generated intense interest and controversy. A recent review provides an excellent perspective of these dermatopathologic controversies and has offered a well-designed proposal for the evaluation of pediatric patients with Spitz nevus-like melanocytic tumors when there is diagnostic controversy.<sup>43</sup> Expert review may lead to the recommendation for adjunct procedures, such as SLNB. The controversy regarding SNLB for all melanoma, owing to its failure to improve survival of melanoma patients across all stages, is even more dramatic in children. Whereas SLNB has been proposed as a means for differentiation between a benign and malignant lesion, it has limited effectiveness because the presence of melanocytic cells within a sentinel lymph node does not necessarily indicate the presence of metastasis. The features of the melanocytic cell and its location within the lymph node may indicate that these are benign nodal melanocytes that arrive at draining nodes by lymphatic migration or are formed in adjacent nodes during development. However, even the presence of "metastatic" cells in the sentinel lymph node does not appear to have the same biologic effect as it would in true melanoma because the frequency of recurrent disease is virtually absent in the scenario of Spitz nevi with cellular atypia.

The collective experience from organized cancer centers offering SNLB for Spitz nevi-like melanocytic tumors has shown that the rates of "positive nodes"

range from 29% to 50%. With this significant number of lymph node–positive patients, one might expect the original diagnosis to have been melanoma and the clinical course to follow that of conventional melanomas. Yet, there have been no reported deaths of lymph node–positive patients with primary Spitz tumors. Although these findings underscore the irrelevance of SLNB, they do present some interesting speculations about the altered tumor biology of these melanocytic tumors in young patients. Expert dermatopathologists have developed a number of protocols to distinguish these nodal melanocytes from metastatic melanoma, but they contend that the characteristics of the original lesion are best used to arrive at an accurate diagnosis. There is no doubt that experts in defined reference laboratories must review the original tumor. As occurs in many difficult areas of experience and judgment, sporadic cases of metastases after Spitz lesions erode confidence and have had medicolegal implications.

If controversy persists, then fluorescence in situ hybridization (FISH) or comparative genomic hybridization should be performed and may lead to results that favor the diagnosis of either nevus or melanoma.<sup>44</sup> Again, the pediatric surgical community must be aware of the lack of correlation with survival for melanomas based on SLNB. It has been our experience that within our center and among the reference laboratories, significant controversy can still remain in a few cases. These are highly individualized cases in which the long-term follow-up will be most important, recalling that nodal melanocytes may not resolve the question for the family. The best clinical course would avoid the trap to perform SLNB or to falsely offer it as a clinical advantage in these difficult cases. SLNB is a procedure that currently adds unnecessary expense, pain, and discomfort and has no proven benefit for these fortunately rare scenarios.

When the diagnosis of melanoma is confirmed, staging and treatment protocols are derived from the adult literature. The recommendations for the extent of re-excision are based on the thickness of the tumor and generally require a 0.5-cm margin for in situ lesions, a margin of 1 cm for lesions up to 2 mm, and 2-cm margins for lesions greater than 2 mm in thickness. SLNB is advised for lesions thicker than 1 mm or for those between 0.76 mm and 1 mm with ulceration or reticular dermal invasion (Table 73-4). The new staging system of the AJCC is primarily based on (1)

Breslow tumor thickness with 1, 2, and 4 mm indicating the current cutoffs for thin, intermediate, and thick lesions, respectively, and (2) histologic features such as ulceration, which is perhaps most important in the intermediate-thickness group. Clark levels are taken into account **only in thin melanomas**. Lymph node involvement is stratified by the number of nodes involved and whether microscopic or macroscopic metastases are present. Finally, three subgroups of distant metastases are distinguished: (1) skin and soft tissue, (2) lung, and (3) other visceral. Patients with visceral metastases have the worst prognosis. In this new classification, the serum marker lactate dehydrogenase is used to further stratify risk. If elevation of this marker is verified in the presence of either skin, soft tissue, or lung metastases, the prognosis is equivalent to that for those patients with visceral metastases.<sup>1</sup>

The standard imaging techniques used to identify potential metastatic disease sites include computed tomography (CT), magnetic resonance imaging, and positron emission tomography (PET). Combined PET/CT has been approved for this use because it has been demonstrated to be particularly helpful in identifying developing metastases.<sup>45</sup> The limitations of PET continue to relate to lesion size. It cannot compete with lymph node biopsy in patients with nonpalpable lymph nodes.<sup>46</sup>

In adult melanoma therapy, SLNB has become a mandatory procedure in the current AJCC staging system to detect lymph node micrometastases. When the SLNB is positive, the recommendation is to proceed with an RLND. A negative SLNB, however, does not guarantee lack of distant spread. This algorithm protects against early locoregional recurrences, but it has not been shown to have an impact on overall survival. These protocols have been applied to pediatric patients with melanoma and atypical melanocytic tumors. In a review at the University of Colorado Health Sciences Center, 20 patients younger than 21 years of age underwent SLNB for melanoma or atypical nevi.<sup>47</sup> No complications occurred as a result of the SLNB, and results showed that positivity correlated with tumor thickness. Five of 15 patients with melanoma had a positive SLNB, as did 3 of 5 with melanocytic proliferation. Seven of 8 patients underwent completion lymph node dissection (one patient with blue cell nevus did not). Complications such as lymphedema and wound infection occurred with the completion lymphadenectomy in 4 patients.<sup>47</sup> When this was further explored in a subsequent study, the investigators found a higher incidence of positive SLNB in a group of patients younger than 20 years with either melanoma or melanocytic lesions (40%) as compared with a group of adults (18%).<sup>48</sup> None of the pediatric patients with a positive SLNB experienced a recurrence, whereas 25% of the adults did. These series and others suggest that although SLNB is feasible, it may not be of sufficient value or benefit to the patient.<sup>49</sup> Adjunct molecular techniques such as polymerase chain reaction assays for melanocytic enzymes such as tyrosinase or MART1 have not yet shown correlation with clinical outcomes.

**Table 73-4** AJCC Guidelines for Surgical Management of Melanoma

Lesion Depth	Margin (cm)	Sentinel Node Dissection
In situ	0.5	
<1 mm	1.0	
0.76-1.0 mm*	1.0	+
1-2 mm	1.0-2.0	+
>2 mm	2.0	+

AJCC, American Joint Committee on Cancer

\*Only in the presence of ulceration or reticular dermal invasion.

Adjuvant therapies include chemotherapy, radiation therapy, and immunotherapy.<sup>50</sup> The use of cytotoxic agents has a limited role in current adjuvant therapy. Radiation therapy has limited applicability and is primarily reserved for palliation. Most active trials and current research focus on the use of immunomodulating agents, of which interleukin 2 (IL-2) and interferon alfa (IFN- $\alpha$ 2b) are approved agents. In limited series, these agents have shown the ability to induce partial and even total remission. The use of high-dose IFN- $\alpha$ 2b is limited to patients with tumors greater than 4 mm deep and/or lymph node metastases. There have been inconsistent reports as to the ability of pediatric patients to tolerate high-dose interferon regimens. While in one series no dose reduction was necessary,<sup>51</sup> it became necessary in 50% of patients in a second series.<sup>52</sup> Vaccines are also within the armamentarium for treating melanoma and consist of either polyvalent vaccines or defined melanoma antigens such as the ganglioside GM<sub>2</sub>, which is the most immunogenic ganglioside expressed on melanoma. Furthermore, recent reports on the use of heat shock proteins as vehicles for the vaccines have been encouraging.<sup>26,53</sup>

## OUTCOME AND PROGNOSIS

Statistics for pediatric-specific studies on melanoma are limited. The most recent report (2001) from the National Cancer Institute Surveillance, Epidemiology, and End Results database indicated that patients

younger than 20 years of age had an overall 5-year survival of 93.6%. The hazard ratio of death from melanoma increased for male gender, increased age, and more advanced disease, as well as for location other than trunk or extremity.<sup>54</sup> This compares well with an older review that showed overall 5-year survival rates at 34% for stage 4 disease and as high as 90% for stage 1 and 2 disease.<sup>55</sup> The most important prognostic parameters remain the thickness of the tumor and the clinical stage of disease.

Postoperative follow-up is best performed under strict guidelines, as suggested by Garbe and Eigentler.<sup>24</sup> Risk-adapted, scheduled follow-up examinations in the German protocols have been validated for three monthly intervals during the first 5 years and every 6 months for the next 5 years. Most (83%) recurrences were identified on screening rather than by the patient (17%). One half were detected sufficiently early that complete surgical excision was possible. They further stratified risk by indicating that patients with thin melanoma lesions could undergo surveillance by physical examination rather than a technology-based system every 6 months. Those with lesions greater than 1 mm thick should undergo lymph node ultrasonography and determination of the S-100 tumor marker protein.<sup>24</sup>

Melanoma remains a challenge for diagnosis and treatment. With a concerted effort to study new modalities in the context of clinical trials, information should be derived that will allow for rational treatment of this rare and potentially lethal disorder.

# VASCULAR ANOMALIES

C. Jason Smithers, MD • Steven J. Fishman, MD

**B**etter understanding of vascular anomalies has come in the past several decades with improved knowledge about the growth of blood vessels (angiogenesis) and the development of a more logical classification system. Based on their biologic and clinical behavior, vascular anomalies can be broadly divided into two groups: vascular tumors and vascular malformations. Vascular tumors, of which the infantile hemangioma is the most common example, are true neoplasms that arise from endothelial hyperplasia. Conversely, vascular malformations are congenital lesions of vascular dysmorphogenesis that arise because of errors of embryonic development. These lesions exhibit normal endothelial cell turnover. Evaluation of vascular anomalies has historically been hindered by confusing and misused terminology and nomenclature. Along with the rarity and often complex nature of some of these disorders, this confusion has combined to make diagnosis and treatment of vascular anomalies inconsistent. The fact that these lesions do not fit neatly into the realm of any one medical or surgical specialty further complicates the picture. In this chapter, we outline the proper classification and nomenclature of vascular anomalies. This classification provides a basis for understanding the pathophysiology, diagnosis, and treatment of these disorders.<sup>1-3</sup>

## CLASSIFICATION AND NOMENCLATURE

A biologic classification system of vascular anomalies has been devised based on physical characteristics, natural history, and cellular features (Table 74-1).<sup>4,5</sup> This system was accepted in 1996 by the International Society for the Study of Vascular Anomalies. It divides these anomalies into vascular tumors and vascular malformations. Examples of vascular tumors include infantile hemangioma, kaposiform hemangioendothelioma (KHE), and tufted angioma (TA). Vascular malformations can be divided based on vascular channel type (capillary, lymphatic, venous, arterial, or combined) or by flow (slow or fast). Examples of slow-flow lesions are capillary malformations (CMs), lymphatic

malformations (LMs), and venous malformations (VMs). Fast-flow lesions include arteriovenous fistulas (AVFs) and arteriovenous malformations (AVMs).

Although now more clear, the nomenclature and classification of vascular anomalies have historically been confusing because the same or similar terms have been used to describe vastly different lesions. Unfortunately, the persistent use of the historic terms continues to confuse proper diagnosis and treatment of many patients. The various vascular anomalies often have a similar appearance whether involving the skin, mucosa, or viscera. These lesions can be flat or raised and can have pink, red, purple, or blue coloration. For centuries, these cutaneous vascular nevi were named based on their resemblance to common foods such as “cherry,” “strawberry,” or “port-wine stain.” The term *nevus* generically refers to any circumscribed malformation of the skin, especially if colored by hyperpigmentation or increased vascularity. In the 19th century, Virchow<sup>6</sup> was the first to describe the histologic features of vascular nevi and initiated the term *angioma*. The term *angioma* became a base term used to describe all such nevi regardless of natural history or other clinical features. He labeled the infantile hemangioma as “angioma simplex.” This same lesion has also been historically referred to as “capillary hemangioma” and “strawberry hemangioma.” Virchow’s “angioma cavernosum” actually was used to label two distinct lesions, infantile hemangiomas (when located deep to the skin) and VMs, because they have similar appearances on physical examination. Another example is Virchow’s designation of the “angioma racemosum,” which referred to what is called today an AVM and which also has been historically called an “arteriovenous hemangioma.”

Wegener, a student of Virchow, described the histology of LMs, which he called “lymphangiomata.”<sup>7</sup> The term *cystic hygroma*, referring to LMs, unfortunately also continues to have common usage. Although in the classic sense, the suffix “-oma” refers to a swelling of any cause, in contemporary usage this term connotes neoplastic tumors. Thus, both the terms *cystic hygroma* and *lymphangioma* should be abandoned in favor of LM (macrocystic and microcystic, respectively). The problems with this

**Table 74-1** Classification of Vascular Anomalies

Vascular Tumors	Slow-Flow Vascular Malformations	Fast-Flow Vascular Malformations	Combined Vascular Malformations
Hemangioma	Capillary malformation (CM)	Arteriovenous fistula (AVF)	Klippel-Trénaunay syndrome, a capillary lymphaticovenous malformation (CLVM)
Kaposiform hemangioendothelioma (KHE)	Venous malformation (VM)	Arteriovenous malformation (AVM)	Parkes Weber syndrome, a capillary arteriovenous malformation (CAVM)
Tufted angioma (TA)	Lymphatic malformation (LM)		

jumble of descriptive and histologic terms are obvious. The same lesion can often have several different names, and the same name can refer to several different lesions. Use of the term *hemangioma* is the most classic case. The term *hemangioma*, combined with descriptive modifiers such as “strawberry,” “cavernous,” and “lympho-,” is used to describe tumors, birthmarks, and vascular malformations. Thus, vascular anomalies with quite distinct features, whether congenital or acquired, whether they spontaneously regress or progress over time, become lumped under the umbrella of *hemangioma*. This faulty designation leads to improper diagnosis and treatment for patients. Moreover, it leads to misguided interdisciplinary communication and research efforts. A good example of this problem is provided by cavernous hemangiomas, which are truly VMs but which have often been treated with therapies directed at inhibition of angiogenesis, as if they were vascular tumors.

The nomenclature and the biologic classification of vascular anomalies have provided a useful clinical framework for the diagnosis and treatment of these lesions. Nevertheless, patients with vascular anomalies often provide complex exceptions to these designations. Lesions that are congenital malformations may not become apparent until adulthood, because of either anatomic location or progressive expansion over time. Likewise, neoplastic lesions, such as infantile hemangiomas, often have a premonitory cutaneous sign at birth. Additionally, hemangiomas, when they have a significant fast-flow component, can be difficult to distinguish from AVMs. Lastly, at times, vascular malformations exhibit enlargement and even endothelial hyperplasia triggered by clotting, ischemia, or partial resection. This hyperplasia leads to their propensity for recurrence after treatment. For these reasons, several regional and international centers have developed an interdisciplinary vascular anomaly team that serves as a referral center. These centers combine the medical, surgical, and radiologic expertise required to diagnose and manage effectively these often complex disorders.

## VASCULAR TUMORS

### Infantile Hemangiomas

Hemangiomas are the most common tumor of infancy, occurring in the skin in up to 4% to 10% of white infants, with a female-to-male ratio of 3 to 5:1.<sup>8</sup> The

incidence may be significantly higher in premature infants.<sup>9</sup> They are much more common in whites than dark-skinned individuals. Infantile hemangiomas have a unique and characteristic life cycle of rapid growth in the first year of life (proliferative phase) followed by spontaneous slow regression from ages 1 to 7 years (involuting phase). Once involuted, they never recur.

### Pathophysiology

The proliferating phase of hemangiomas is characterized by angiogenesis in the tumor.<sup>10,11</sup> The tumor is composed of plump, rapidly dividing endothelial cells, forming a mass of sinusoidal vascular channels. Enlarged feeding arteries and draining veins vascularize the tumor. Markers for mature endothelium, CD31 and von Willebrand's factor, are present on these neoplastic endothelial cells. In addition, a specific marker for endothelial cells of hemangiomas that is not found in other vascular anomalies is GLUT-1 (an erythrocyte-type glucose transporter).<sup>12</sup> Proangiogenic factors, such as fibroblast growth factor (FGF) and vascular endothelial growth factor (VEGF), are prominent during the proliferative phase. Increased levels of these peptides may be found in the urine of patients with hemangiomas. Additional factors that are required for angiogenesis include increased local levels of matrix metalloproteinases, which are necessary for remodeling of the extracellular matrix.

The involuting phase of hemangiomas is marked by reduced angiogenesis and endothelial cell apoptosis.<sup>13</sup> Levels of FGF and VEGF decrease and those of tissue inhibitors of metalloproteinases increase to suppress new blood vessel formation. The endothelial cells of the tumor flatten, the vascular channels dilate, and the tumor takes on a lobular architecture with replacement by fibrofatty stroma. In the end, with the involuted phase, all that remains is a residuum of fibrofatty tissue with tiny capillaries and mildly dilated draining vessels.

The triggers for angiogenesis and tumor formation are unknown. Viral causes have been postulated, but none have been elucidated. Human herpesvirus 8, which is associated with Kaposi's sarcoma, is not seen in hemangiomas. This polyomavirus can induce vascular tumors in mice and rats but leads to malignant growth and not to spontaneous regression. Almost certainly, some alteration occurs on a genetic level, but no specific genetic mutations have been found and no

**Figure 74-1.** This infant has multiple cutaneous hemangiomas. Many of these patients also have internal hemangiomas in the liver, gastrointestinal tract, and brain.

evidence exists for inheritance.<sup>14,15</sup> No animal model exists for a spontaneously regressing hemangioma, such as the common hemangioma of infancy.

### Clinical Presentation

Hemangiomas first appear in the neonatal period, with a median age at onset of 2 weeks. A premonitory cutaneous sign is present at birth in 30% to 50% of cases. Hemangiomas are most often single cutaneous lesions and have an anatomic predilection for the head and neck region (60%). They occur in the trunk in 25% of cases and on the extremities in 15% of cases. Internal and visceral lesions are uncommon. Up to 20% of patients can have multiple tumors (Fig. 74-1). In these patients, internal hemangiomas can be found in the liver, gastrointestinal tract, and brain. Rare congenital hemangiomas are fully developed at birth and do not usually exhibit postnatal tumor growth. These are the rapidly involuting congenital hemangioma (RICH) and the noninvoluting congenital hemangioma (NICH).<sup>16-19</sup> An understanding of these recently discovered entities is still in its infancy.

The proliferative phase of hemangiomas is marked by rapid growth, for the first 6 to 8 months, which typically plateaus by age 10 to 12 months. Tumors that involve the superficial dermis are first seen as a red, raised lesion (previously named “capillary” or “strawberry” hemangiomas; Fig. 74-2). Superficial tumors that are larger or that exhibit more rapid growth can cause ulceration of the skin and bleeding in 5% of cases. Tumors in the lower dermis, subcutaneous tissue, or muscle appear bluish with slightly raised overlying skin and have frequently incorrectly been called “cavernous” hemangiomas. With experience, history and physical examination can establish an accurate diagnosis for 90% of these tumors.

The involuting phase of hemangiomas occurs from age 1 to 7 years, during which time the tumor slowly regresses, although it may grow in proportion with the child (Fig. 74-3). This phase is notable for the fading color of the tumor to a dull purple and the softening of

**Figure 74-2.** Infantile hemangioma, proliferative phase.

the tumor mass. The skin usually becomes pale in the center of the tumor first, spreading outward. Both the deep color and the bulk of the tumor show continued gradual improvement until the regression is entirely complete by age 10 to 12 years. In the final involuted phase of the tumor, 50% of patients have nearly normal skin in the area of the prior lesion. Patients that had larger tumors may have lax or redundant skin and yellowish discoloration. Scars will persist if parts of the tumor were previously ulcerated.

The differential diagnosis of cutaneous hemangiomas consists primarily of other vascular anomalies. Capillary malformations that involve the skin can be mistaken for superficial hemangiomas and vice versa. Deeper hemangiomas can be confused with VMs or LMs, because they may all appear as bluish masses through the skin (Fig. 74-4). Hemangiomas with fast-flow vascularity of the tumor parenchyma could be mistaken for AVMs, but the age at onset and history generally distinguish the two. Congenital hemangiomas, such as RICH or NICH, can be confused with vascular malformations that are congenital by definition. Pyogenic granulomas are first seen in childhood, often

**Figure 74-3.** Posterior cervical hemangioma (left) has undergone involution (right).

**Figure 74-4.** A right parotid hemangioma is seen in this infant.

associated with minor trauma, and rarely appear before age 6 months (mean age, 6 to 7 years).<sup>20,21</sup> Finally, other tumors such as TA, hemangiopericytoma, and fibrosarcoma should be considered.<sup>22</sup> If any concern exists for malignancy, further evaluation with imaging or biopsy is mandated.

The primary local complications that can occur with cutaneous hemangiomas are ulceration, bleeding, and pain. Ulceration is seen in about 5% of cases. Severe complications also are possible, depending on size and location of the tumor. Lesions of the cervico-facial region may produce airway obstruction as they

**Figure 74-5.** This left periorbital hemangioma was causing visual impairment.

grow during the proliferative phase. Very large hemangiomas, notably of the liver, can lead to high-output congestive heart failure secondary to fast flow and vascular shunting within the tumor. Facial lesions can result in tissue necrosis with cosmetic consequences when involving the eyelid, nose, lip, or ear. Periorbital and eyelid lesions also may cause visual impairment or obstruction that leads to deprivation amblyopia (Fig. 74-5). Distortion of the cornea can alternatively cause astigmatic amblyopia. Subglottic hemangiomas may occur with stridor and lead to airway obstruction with continued growth. Gastrointestinal hemangiomas are very rare but can cause gastrointestinal bleeding.

### Other Manifestations

Hemangiomatosis consists of multiple disseminated hemangiomas. The cutaneous tumors are usually tiny (<5 mm) and, when five or more are present, visceral lesions should be sought as well. Screening patients with ultrasonography or magnetic resonance imaging (MRI) or both may be indicated for these patients.

Infantile hepatic hemangiomas must be differentiated from “hepatic hemangiomas” that are first seen in adulthood.<sup>23</sup> Adult “hepatic hemangiomas,” which are sometimes called “cavernous hemangiomas,” are VMs. Conversely, hepatic hemangiomas of infancy are true tumors and have a pattern of involution similar to that of cutaneous hemangiomas. Contrary to popular belief, not all liver hemangiomas are life threatening. Indeed, the “classic triad” of heart failure, anemia, and hepatomegaly is unusual. Recently, it has been recognized that hepatic hemangiomas present in several different patterns: focal, multifocal, or diffuse.<sup>24,25</sup> Focal lesions are single, generally large masses on antenatal imaging studies and/or present as a mass in early infancy. They may cause moderate thrombocytopenia that generally resolves spontaneously. This is in contrast to the profound thrombocytopenia seen with Kasabach-Merritt phenomenon (KMP). These single large lesions often do not exhibit growth after birth and are thought to represent RICH lesions, which are histologically distinct from the typical hemangioma. They are fully grown at birth and regress much faster than the typical hemangioma. However, a subset of focal hepatic RICH-type hemangiomas will have macrovascular shunts from the hepatic arteries and/or portal veins to the hepatic veins. These shunts can cause a large steal, accounting for blood-flow demands above and beyond the hypervascular tumor parenchyma. This may result in high-output cardiac failure. These shunts may close as the tumor involutes. However, cardiac strain may mandate interruption of the shunts, which can be performed by embolization. A skilled pediatric interventional radiologist may be able to embolize the shunts without disrupting the major hepatic vessels.

Multifocal hepatic hemangiomas are histologically identical to the typical cutaneous hemangioma. Smaller enlarging lesions, detected by imaging stimulated by the presence of cutaneous hemangiomas, may often remain asymptomatic. However, some will also

have associated macrovascular shunts that may cause cardiac failure. These shunts may close with corticosteroid therapy, but embolization may be necessary in those severe cases in which there is insufficient time to wait for involution.

The most dangerous hepatic hemangiomas are the diffuse type, presenting with innumerable compacted nodular lesions replacing normal liver parenchyma, and causing massive hepatomegaly, abdominal compartment syndrome, and respiratory compromise. Massive hemangiomas (e.g., those causing hepatomegaly) may induce profound acquired hypothyroidism.<sup>26</sup> Hemangiomas have been found to express type 3-iodothyronine deiodinase that inactivates circulating thyroid hormones. Lesions of sufficient size can break down active thyroid hormones more rapidly than the endocrine axis can replace them. Therefore, patients with large hemangiomas should be screened by measuring thyroid-stimulating hormone levels. When untreated, hypothyroidism in infancy will lead to severe mental retardation. For these unusual cases, aggressive exogenous thyroid replacement and close endocrinologic consultation are mandated. The condition is self-limiting after tumor involution.

The differential diagnosis of hepatic hemangiomas includes AVMs and malignant tumors such as hepatoblastoma and metastatic neuroblastoma. The diagnosis is established by imaging with ultrasonography, MRI, or computed tomography (CT). If typical imaging findings of one of the hemangioma patterns are not found, percutaneous biopsy may be indicated to ensure a malignancy is not present.

Although other congenital anomalies are rarely associated with infantile hemangiomas, a few have been reported, most commonly associated with larger or midline hemangiomas. Cervicothoracic hemangiomas can be seen in conjunction with sternal non-union.<sup>27</sup> Tumors of the lumbosacral area have been noted to occur along with spinal dysraphism abnormalities such as meningocele and tethered spinal cord.<sup>28,29</sup> Hemangiomas of the pelvis and perineum have been reported in association with urogenital and anorectal anomalies. Craniofacial hemangiomas have been rarely associated with congenital ocular abnormalities such as micro-ophthalmia, cataracts, and optic nerve hypoplasia; posterior fossa cystic malformations; hypoplasia or absence of the carotid and vertebral vessels; and malformation of the aortic arch.<sup>30,31</sup>

### Imaging

Proper radiologic diagnosis of vascular anomalies is dependent on specific expertise and clinical experience with the radiologic features of these lesions.<sup>32</sup> Ultrasonography and especially MRI are the principal useful modalities. Ultrasonography of proliferative-phase hemangiomas demonstrates a mass with dense parenchyma exhibiting fast-flow vascularity.<sup>33,34</sup> This distinguishes deep infantile hemangiomas from VMs that exhibit slow flow and larger blood-filled spaces. MRI of proliferating hemangiomas shows a lobulated

solid mass of intermediate intensity with T1-weighted spin-echo sequences and moderate hyperintensity on T2-weighted spin-echo images. Flow voids that represent fast flow and shunting are seen in and around the tumor. For the involuting phase, MRI demonstrates decreased flow voids and vascularity with the mass, taking on a more lobular and fatty appearance.<sup>35</sup>

### Treatment

The majority of infantile hemangiomas do not require any specific treatment other than observation and reassurance of the parents.<sup>36</sup> Even though the tumor may exhibit rapid growth and the skin is fiery red, these tumors will spontaneously regress with either no or minimal evidence of occurrence. Reasons for treatment or referral to a vascular anomalies center are the following: dangerous location (impinging on a vital structure such as the airway or eye), unusually large size or rapid growth, and local or endangering complications (skin ulceration or high-output heart failure). Few prognostic indicators exist for these potential complications. Regularly scheduled follow-up is essential. Serial photographs are very helpful in documenting progression and subsequent improvement.

Because hemangiomas are tumors of pure angiogenesis, pharmacologic therapy involves angiogenesis inhibition.<sup>37</sup> The first-line antiangiogenic therapy for hemangiomas exhibiting appropriate risk factors or complications is systemic corticosteroids.<sup>38</sup> Oral prednisone is used at a dose of 2 to 3 mg/kg/day. Doses up to 5 mg/kg/day have been administered for life-threatening complications with large hemangiomas causing airway obstruction or heart failure.<sup>39</sup> The overall response rate is 80% to 90%, with initial improvement in the color and tension of the mass usually noted within 1 week. The corticosteroids are maintained with a very gradual taper every 2 to 4 weeks, with the goal of discontinuation around age 10 to 11 months. Live vaccines such as those for polio, measles, mumps, rubella, and varicella should be withheld while children are on prednisone. Hemangiomas will demonstrate rebound growth if corticosteroids are tapered or stopped too quickly. A return to the initial dosage and a slower tapering will usually resolve this problem.

Potential complications of corticosteroid use in infants and children include impaired linear growth and weight gain in about 30% of cases. All children will have “catch-up” growth and return to pretreatment growth curves by age 14 to 24 months. Cushingoid facies occur in almost all patients and normalizes on tapering of the corticosteroids. In rare circumstances, corticosteroids may induce hypertension or hypertrophic cardiomyopathy, both of which are indications to wean or change therapy.<sup>40</sup>

Intralesional corticosteroids are used for hemangiomas that cause local deformity or ulceration, especially for facial lesions of the eyelid, nose, cheek, or lip.<sup>41</sup> A total of three to five injections (at a dose of 3 to 5 mg/kg per injection) are typically given at intervals of 6 to 8 weeks. The response rate approaches that of systemic corticosteroids. Subcutaneous atrophy is a potential

complication of corticosteroid injection, but it is usually temporary. Cases have been reported of blindness after intralesional corticosteroid injection for periorbital hemangiomas. This has been presumed to be secondary to particle embolization of the retinal artery through feeding vessels.<sup>42</sup> Manual compression around the periphery of the tumor is recommended during injection.

Recombinant interferon, previously considered as a second-line agent, has fallen out of favor, except in very limited circumstances, because of the severe potential complication of spastic diplegia that can occur in 5% to 12% of treated infants.<sup>43,44</sup> Spasticity usually resolves if the drug is terminated quickly. Children receiving interferon should be monitored carefully by a neurologist. On the other hand, experience is growing with low-dose, high-frequency antiangiogenic regimens of vincristine as second-line therapy after corticosteroids. A recent report of propranolol used to treat infantile hemangioma may indeed revolutionize medical therapy.<sup>45</sup>

Although it has popular appeal, laser therapy is not often beneficial for infantile hemangiomas.<sup>46</sup> The flash-lamp pulse-dye laser penetrates the dermis to a depth of only 0.75 to 1.2 mm. Most cutaneous hemangiomas are deeper and therefore not affected by laser treatment. Additionally, laser therapy carries risks of scarring, skin hypopigmentation, and ulceration, which may lead to a poor result compared with observation alone. A few specific indications for laser treatment of hemangiomas are worth mentioning. One instance in which the laser is beneficial is the treatment of telangiectasia, which often remains during the involuted phase of hemangioma. Also, the use of an endoscopic continuous-wave CO<sub>2</sub> laser has been shown to be a good technique for controlling proliferative-phase hemangiomas in the unilateral subglottic location.<sup>47</sup> Finally, intralesional photocoagulation with bare fiber neodymium:yttrium-aluminum-garnet (Nd:YAG) laser can be useful for hemangiomas in certain locations, such as the upper eyelid, when visual obstruction is a concern.

Indications for surgical resection of infantile hemangiomas vary with patient age. During the proliferative phase in infancy, well-localized or pedunculated tumors can be expeditiously resected with linear closure, especially for tumors complicated by bleeding and ulceration. Sites that are most amenable to resection in this stage are the scalp, trunk, and extremities. Other modalities to treat ulceration in hemangiomas include wound care with dressing changes, topical antibiotics, and topical corticosteroids, which can accelerate healing.<sup>48</sup> Tumors of the upper eyelid that obstruct vision and that do not respond to pharmacologic therapy also may require surgical excision or debulking. Focal lesions of the gastrointestinal tract that cause bleeding and for which medical management fails also may require resection by means of enterotomy or endoscopic band ligation. Preoperative localization with capsule endoscopy or intraoperative endoscopy (or both), may be necessary to identify lesions of the small intestine.<sup>49</sup>

Surgical resection is considered during the involuting phase in early childhood for hemangiomas that are large and protuberant and, therefore, likely to create

excess and lax overlying skin.<sup>50</sup> Indications are the following: (1) when it is obvious that resection would be necessary sooner or later; (2) when the surgical scar would be identical, regardless of timing of operation; and (3) when the surgical scar is easily hidden. Lesions of the nose, eyelids, lips, and ears require special expertise. It is often preferable to perform the operation for these indications in patients at preschool age before the children become aware of and focus on body differences that may lead to low self-esteem.

After complete involution of the hemangioma, cosmetic distortion is the primary indication for operative management. Fibrofatty residuum and redundant skin can be excised in staged operations, if necessary. Occasionally, extensive scarring from tissue destruction may necessitate reconstructive procedures. Finally, for the difficult-to-treat and life-threatening large hemangiomas, especially in the liver, angiographic embolization may be required to manage high-output cardiac failure.

Arterial catheterization in infants carries significant risks and generally should be limited to those situations with cardiac compromise in which the capacity and intent to perform simultaneous embolization exists. In these rare cases, antiangiogenic pharmacotherapy remains as the first line and should continue along with angiographic procedures. Repeated embolization procedures may be required. Successful embolization is dependent on occlusion of macrovascular shunts within the tumor rather than on occlusion of feeding vessels.<sup>51,52</sup>

### Tufted Angioma and Kaposiform Hemangioendothelioma

These vascular tumors of childhood are more aggressive and invasive than are infantile hemangiomas. TA and KHE probably exist within the same spectrum, because they share many overlapping clinical and histologic features.<sup>53,54</sup> Both tumors typically present at birth, although they occur postnatally as well. Male and female infants are affected equally. The tumors are unifocal and are most often located on the trunk, shoulder, thigh, or retroperitoneum. TA appears as erythematous macules or plaques, and histology reveals small tufts of capillaries. KHE is a more extensive tumor with deep red-purple skin discoloration and overlying and surrounding ecchymosis. Generalized petechiae may be apparent and coincide with profound thrombocytopenia secondary to the Kasabach-Merritt Phenomenon (KMP). Imaging of KHE depicts an enhancing lesion with poorly defined margins that extend across tissue planes. This is contrasted to hemangiomas, which are well circumscribed and respective of tissue planes. Biopsy is usually not necessary, but histology reveals infiltrating sheets of slender endothelial cells.

### Kasabach-Merritt Phenomenon

KMP was first reported in 1940 as a case of profound thrombocytopenia, petechiae, and bleeding in conjunction with a "giant hemangioma."<sup>55</sup> As with many terms in the field of vascular anomalies, the term has

been often misused in connection with other varieties of coagulopathy and vascular lesions, most prominently VMs. However, the profound and persistent thrombocytopenia that occurs with KMP does not occur with either VMs or infantile hemangioma. The only known true associations are with TA and KHE.<sup>56,57</sup> The platelet count with this disorder is typically less than 10,000/mm<sup>3</sup> and may be accompanied by decreased fibrinogen levels and a mildly elevated prothrombin time (PT) and partial thromboplastin time (PTT). Bleeding can result from this platelet-trapping coagulopathy at many sites (including intracranial, gastrointestinal, peritoneal, pleural, and pulmonary). Treatment of KHE with KMP is primarily medical, because the tumor is usually too large and extensive to be resected. Corticosteroids and interferon alpha have been effective in about 50% of cases. Vincristine also is beneficial, but no single agent has been shown to be consistently successful. Platelet transfusions are ineffective and should be avoided unless active bleeding occurs. Heparin stimulates tumor growth and worsens the thrombocytopenia of KMP and should likewise be avoided. Mortality rates with KMP and KHE or TA remain high at 20% to 30%. The natural history of these tumors is one of continued proliferation into early childhood followed by subsequent but incomplete regression. These tumors usually persist, albeit in a smaller form.<sup>58</sup> Fortunately, they are usually asymptomatic in later stages, although they may cause musculoskeletal pain.

## VASCULAR MALFORMATIONS

### Pathophysiology

Vascular malformations are congenital lesions of vascular dysmorphogenesis that can be local or diffuse. They are classified, based on the appearance of the abnormal channels, as resembling capillaries, lymphatics, veins, arteries, or a combination thereof. The majority of vascular malformations are sporadic, although some rare varieties are familial.<sup>59</sup> They can be quite complex and associated with underlying soft tissue and skeletal abnormalities. Vasculogenesis refers to the process of blood vessel formation from mesodermally derived endothelial precursor cells. The destiny of endothelial precursors to create different types of blood vessels appears to be imprinted early in embryogenesis. Unique cell-surface markers are seen on these endothelial cells.<sup>60</sup> Arterial endothelial cells express ephrin-B<sub>2</sub>, and venous endothelial cells express ephrin-B<sub>4</sub>.<sup>61</sup> Although the understanding of vasculogenesis and the pathogenesis of VMs is still limited, the molecular processes are beginning to be understood. VMs probably result from genetic mutations that lead to dysfunction in the regulation of endothelial proliferation and apoptosis, cellular differentiation, maturation, and cell-to-cell adhesions.<sup>62</sup>

Hereditary hemorrhagic telangiectasia (HHT or Rendu-Osler-Weber disease) was the first vascular anomaly to be elucidated at the genetic level.<sup>63</sup> This autosomal dominant disease generally is first seen in the third and fourth decades of life with telangiectasia,

AVFs, and AVMs that occur in the skin, mucous membranes, lung, liver, and brain. Two primary causative genes, both on chromosome 9, involve the binding and signaling of transforming growth factor- $\beta$ . Endoglin is the affected gene for HHT type 1 and codes for an endothelial glycoprotein. HHT type 2 involves mutation of an activin receptor kinase.

Lymphatic vessels are thought to develop from preexisting veins and express a unique receptor for vascular endothelial growth factor (VEGF3 or Flt-4).<sup>64,65</sup> Genetic studies with mice have shown that VEGF3 knockout mice die on embryo day 9 with major venous anomalies before any lymphatic sprouting has occurred.<sup>62</sup> Conversely, transgenic mice that overexpress the ligand for VEGF3 (VEGF-C) develop distended lymphatic channels.<sup>66</sup> LMs, especially posterior cervical LMs, are one of the components of several sporadic chromosomal syndromes, including trisomies 13, 18, and 21, as well as Turner's, Roberts', and Noonan's syndromes. As with the other vascular malformations, the majority of VMs are sporadic as well. However, some families have demonstrated an autosomal dominant pattern of inheritance.<sup>67</sup> Studies of these families have shown a mutation in the gene for TIE-2, a receptor expressed by endothelial cells.<sup>68</sup> Defective smooth muscle cells in the vascular wall are thought to be responsible for some VMs. These examples support the concept of genetic mutations as being the causative mechanism for vascular malformations.

### Capillary Malformations

Capillary malformations (CMs), which have been previously referred to as "port-wine stains," are present at birth as permanent, flat, pink-red cutaneous lesions (Fig. 74-6). The most common location is the

**Figure 74-6.** This capillary malformation is seen along this baby's right temporal lobe.

head and neck region. It is rare to have multiple CMs. These lesions can be localized or exhibit an extensive, geographic pattern. The histology of cutaneous CMs consists of dilated capillary- to venule-size vessels located in the superficial dermis. These abnormal vessels gradually dilate over time, leading to a darker color and, occasionally, nodular ectasias. In the newborn nursery, CMs can be confused with nevus flammeus neonatorum, commonly called an “angel’s kiss” when located on the face or a “stork bite” when in the posterior cervical location. However, these nevi fade with time, whereas a CM does not.

CMs can be associated with underlying soft tissue and skeletal overgrowth as well as other internal abnormalities. CMs of the occiput can signal underlying encephalocele or ectopic meninges. When located over the spine, underlying spinal dysraphism is a concern. Sturge-Weber syndrome represents a classic case of underlying anomalies associated with CMs of the face. In this syndrome, facial CMs affect the trigeminal dermatomes and are associated with ipsilateral ocular and leptomeningeal vascular anomalies. Ocular lesions lead to an increased risk for retinal detachment, glaucoma, and blindness. Leptomeningeal involvement can manifest as seizures, hemiplegia, and impaired motor and cognitive function. MRI reveals the central nervous system abnormalities, showing pial vascular enhancement and gyriform calcifications.<sup>69</sup>

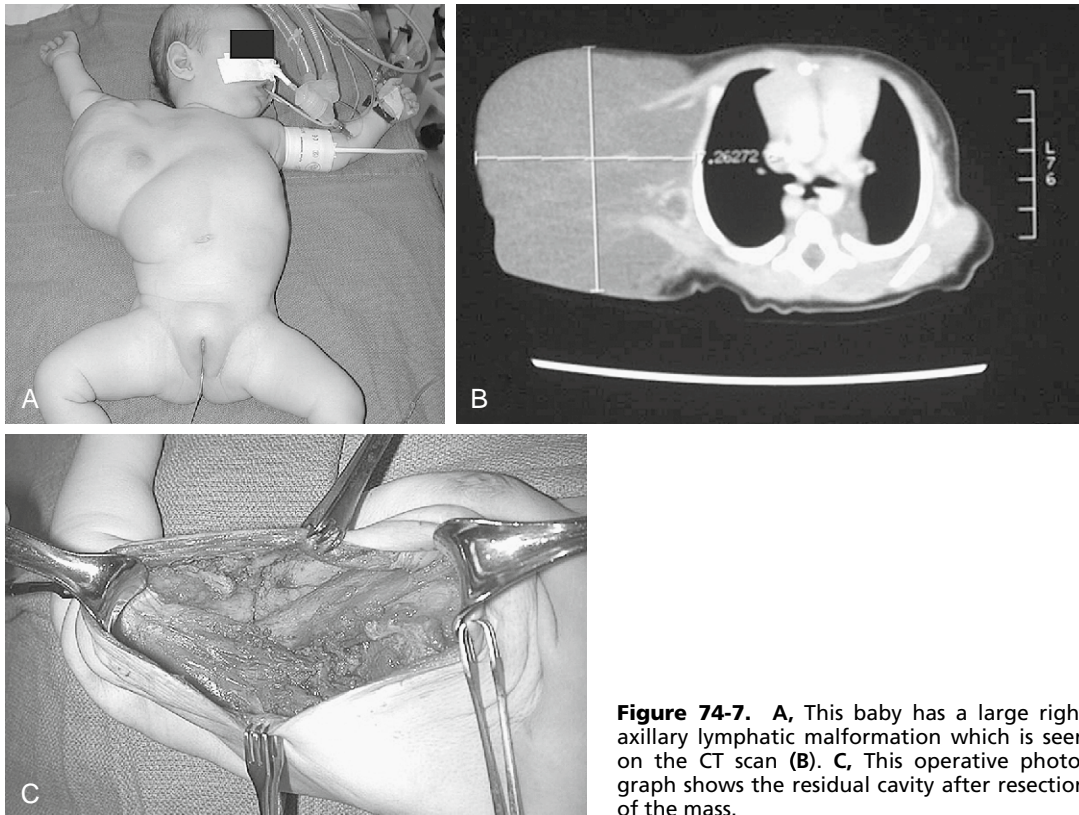

Treatment of CMs is indicated primarily for cosmetic purposes. Flash-lamp pulsed-dye laser therapy causing

photothermolysis of the CM will improve the appearance by lightening the color of the lesion in 70% of patients.<sup>70</sup> The timing of therapy remains controversial, and repeated treatments are usually needed.<sup>71</sup> Ablative and orthopedic surgical procedures can be tailored to treat cosmetic and functional problems related to soft tissue and bony hypertrophy.

## LYMPHATIC MALFORMATIONS

### Clinical Presentation

LMs occur as a wide spectrum from localized masses to areas of diffuse infiltration to chylous fluid accumulations in various body cavities. LMs are usually noted at birth but can be seen at any age or even prenatally by fetal ultrasonography.<sup>72,73</sup> The skin and soft tissues are most commonly affected. LMs can involve the subcutaneous tissues, muscle, bone, and, more rarely, internal organs such as the gastrointestinal tract and lungs. Anatomic sites frequently seen are the axilla and thorax, cervicofacial region, mediastinum, retroperitoneum, buttock, and anogenital regions (Fig. 74-7). As with CMs, underlying localized soft tissue and skeletal hypertrophy can often be associated with LMs. The abnormal lymphatic spaces can be either macrocystic, microcystic, or a combination. According to previous terminology, macrocystic LMs were referred to as “cystic hygromas” and microcystic LMs

**Figure 74-7.** A, This baby has a large right axillary lymphatic malformation which is seen on the CT scan (B). C, This operative photograph shows the residual cavity after resection of the mass.

**Figure 74-8.** This teenager has lymphangiomatous involvement of the dermis, which produces puckering of the skin and vessels that can weep clear fluid. This is termed *lymphangioma cutis*.

as “lymphangiomas.” However, these names should be abandoned.

LMs appear as soft compressible masses, similar to VMs, and may have a bluish hue, although not to the same extent as VMs. Involvement of the dermis (lymphangioma cutis) may produce puckering of the skin or vesicles that weep clear yellowish fluid (Fig. 74-8). Diffuse infiltration of the subcutaneous tissue can produce extensive lymphedema that also falls within the spectrum of LMs. One unique factor among the vascular anomalies is that LMs are at risk for infection that can lead to cellulitis or even systemic illness. Similarly, infections located elsewhere in the body or viral illnesses can cause increased size and tension of LMs. The cystic components of LMs also are subject to intralesional bleeding secondary to trauma or abnormal venous connections. The vesicles from cutaneous involvement also can leak thin sanguineous fluid or appear as red, purple, or black nodules.

**Figure 74-9.** This neonate was born with a large lymphangioma of the face. This tumor is often associated with macrocheilia, macroglossia, and macromala. Staged resections are usually necessary.

LMs at various anatomic locations are prone to unique associated anomalies. Periorbital LMs can lead to proptosis. Facial LMs can cause the associated deformities of macrocheilia, macroglossia, and macromala (Fig. 74-9). Overgrowth of the mandible, sometimes massive, can be seen with cervicofacial LMs.<sup>74</sup> Congenital airway obstruction is rare but also possible. Lesions of the tongue and floor of the mouth, conversely, may more commonly produce obstruction of the oropharynx. LMs of the cervical and axillary regions can signal associated LMs of the mediastinum. Anomalies of the central conducting lymphatic channels, the thoracic duct and cisterna chyli, can lead to very problematic and recurrent chylous effusions that affect the pleural, pericardial, and/or peritoneal cavities. In addition, LMs of the gastrointestinal tract can lead to loss of chyle and subsequent protein-losing enteropathy. In the pelvis, associated problems include recurrent infection and bladder outlet obstruction. LMs of the extremities are seen in conjunction with overgrowth and limb-length discrepancy. A rare but very difficult problem arises with Gorham’s syndrome, in which soft tissue and skeletal LMs lead to progressive osteolysis and “disappearing bone disease.”<sup>75</sup> Pathologic fractures and vertebral instability can become manifest with this often fatal syndrome.

## Imaging

Well-localized and cystic LMs are easily characterized by ultrasonography and CT (see Fig. 74-7). MRI, however, provides the most reliable diagnosis and is superior in documenting the full extent of more complex LMs as well as their macrocystic and microcystic components. LMs are hyperintense on T2-weighted sequences because of their high water content. Within the cysts, fluid-fluid levels denote layering of protein or blood, or both. Cystic rims and intralesional septa are highlighted by contrast enhancement. Adjacent enlarged or anomalous venous channels may be apparent as well. The differential diagnosis of these cystic lesions in the infant includes teratoma and infantile fibrosarcoma. For lymphatic anomalies of the thoracic duct and chylous effusions, contrast lymphangiography, although technically difficult to perform, can be helpful to locate the abnormal lymphatic channels or site of leakage.<sup>76</sup>

## Treatment

The indications for treatment of LMs vary with the extent and location of the lesions.<sup>77</sup> Surgical resection provides the only method for potential “cure,” but this is possible only for lesions that are well localized. Focal and macrocystic lesions are amenable to ablation by both sclerotherapy and resection. In contrast, more diffuse and predominantly microcystic LMs are difficult to eradicate by any method. For local intralesional bleeding that causes sudden enlargement of LMs and pain, conservative management with rest and pain medications is sufficient. Similarly, the enlargement of LMs that coincides with systemic viral or bacterial

infections can be managed expectantly, as it usually resolves. Conversely, bacterial infections within LMs causing cellulitis require treatment with antibiotics. Infected LMs become more tense and swollen, producing erythema, pain, and toxicity. The incidence of this complication is around 17%. Treatment consists of systemic antibiotics, and hospitalization for intravenous antibiotics is often necessary. The antibiotic regimen is directed toward oral pathogens for LMs of the head and neck and toward enteric pathogens for lesions of the trunk, pelvis, and perineum.

Indications for ablative or excisional therapy include recurrent complications with infection, cosmesis, deformity, dysfunction, and leakage into body cavities or from the skin. Intralesional sclerotherapy is most beneficial for LMs with macrocystic components. The commonly used agents are ethanol, sodium tetradecyl sulfate, and doxycycline that produce scarring and collapse of the cysts. For simple, well-localized macrocystic LMs, sclerotherapy can indeed be curative. For more diffuse and complex LMs, sclerotherapy procedures are staged and can lead to significant improvement. Re-expansion of the lesions, however, is the typical course. Weeping or bleeding from cutaneous vesicles can be controlled with local injection sclerotherapy, although leakage generally resumes in 6 to 24 months. Complications of sclerotherapy to be avoided include injury to adjacent nerves, necrosis of overlying skin, and cardiotoxicity related to the overall dose.

Surgical resection for complex LMs also can be of significant benefit (see Fig. 74-7). A staged approach is often required.<sup>78</sup> The operations may be long and tedious and require meticulous, thorough dissection to preserve vital structures. General guidelines for surgical resection are as follows: each operation should (1) focus on a defined anatomic region, removing as much lesion as possible, including neurovascular dissection, but without injuring vital structures; (2) limit blood loss to less than the patient's blood volume; and (3) allow prolonged closed suction drainage of the resection cavity. The recurrence rate after "macroscopically complete excision" ranges from 15% to 40%. This recurrence is thought to be secondary to regrowth and re-expansion of unexcised lymphatic channels. Some have considered that sclerotherapy of the resection cavity after operation may be helpful in this regard. After resection, it is common for cutaneous vesicles to occur within the surgical scar. These can be controlled to some extent with local intravesicular sclerotherapy. Alternatively, additional staged excision, pulling uninvolved dermis over the resection bed, may prevent this annoying result.

Some other caveats of surgical treatment for LMs deserve mention. Cervicofacial LMs will often require staged orthognathic procedures to improve bite and speech impediments related to maxillary and mandibular overgrowth. Tracheostomy may be needed in cases of oropharyngeal and airway obstruction (Fig. 74-10). When considered necessary, tracheostomy should precede any attempts at sclerotherapy for cervicofacial LMs. Reactive inflammatory swelling can be dramatic in the initial period after sclerotherapy and can exacerbate partial oropharyngeal obstruction. Lesions

**Figure 74-10.** This baby has undergone a tracheostomy due to oropharyngeal obstruction from this large cervicofacial lymphatic malformation.

of the cervical and axillary regions often involve the brachial plexus. Nerve stimulators can be a useful adjunct to prevent injury in these cases. Resection of thoracic and mediastinal LMs to treat recurrent pleural and pericardial effusions involves dissection and skeletonization of the great vessels and vagus and phrenic nerves. For pelvic and anorectal LMs, detailed knowledge of the anatomy of the ischioanal fossa and sciatic nerve is paramount. Preoperative sclerotherapy to shrink lesions is often useful as well, but discernment is necessary, because scarring can impede the preservation of important nerves. Finally, for the specific type of cutaneous LM, "lymphangioma circumscriptum," wide resection and closure with split-thickness skin grafts can be curative.

## VENOUS MALFORMATIONS

### Clinical Presentation

As one might expect from the embryonic relation of veins and lymphatics, VMs share many clinical features with LMs. VMs, often incorrectly called "cavernous hemangiomas," are slow-flow lesions consisting of venous channels that can develop anywhere in the body. They are most common in the skin and soft tissues. VMs may be seen at birth or become apparent later, depending on the anatomic location. They comprise a wide spectrum, including simple varicosities and ectasias, discrete spongy masses, and complex channels that can permeate any tissue or organ system. VMs are probably the most common of the vascular malformations, and they are more likely to be multiple

**Figure 74-11.** This adolescent has a venous malformation in the subcutaneous tissue of his back.

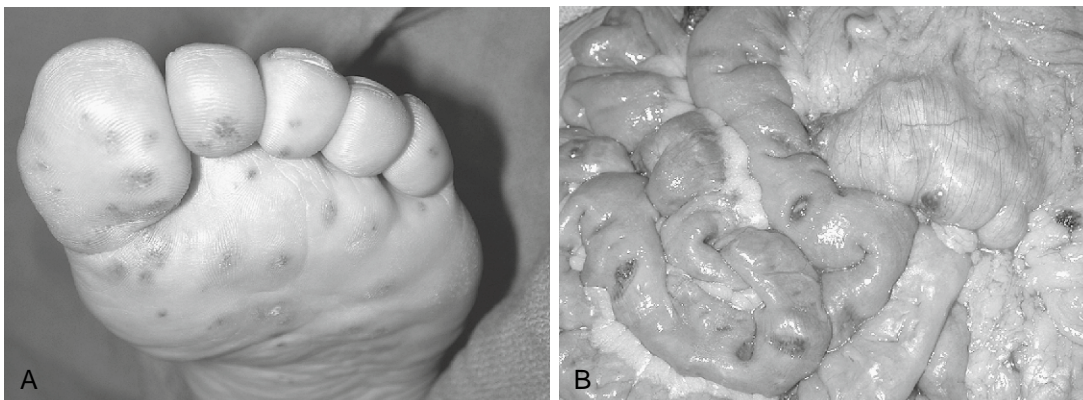

as well. They tend to enlarge slowly with normal growth of the patient but can dilate and become symptomatic at any time. As with other vascular malformations, the proportional growth that occurs may become exaggerated during puberty. On examination, these soft, bluish, compressible lesions will expand with dependent position and Valsalva maneuver (Fig. 74-11). Episodes of phlebothrombosis secondary to stasis may lead to acute pain and swelling. Associated local overgrowth and limb-length discrepancy are not uncommon. Involvement of bones and joints may lead to pathologic fractures, hemarthroses, and subsequent arthritis.

VMs of the gastrointestinal tract are often multiple and can affect every part of the tract from mouth to

anus. They are more commonly found in the left colon and rectum when associated with VMs of the pelvis and perineum. Gastrointestinal bleeding, typically chronic, can result. Blue rubber bleb nevus syndrome (or Bean's syndrome) represents a specific rare disorder consisting of multifocal VMs that affect the skin and gastrointestinal tract primarily.<sup>79</sup> The skin lesions are unique in that they are often quite numerous and resemble tiny "blue rubber nipples." These skin lesions are classically located on the palms and soles of the feet (Fig. 74-12). As with other gastrointestinal VMs, chronic bleeding and anemia can result. Intussusception of polypoid VMs can be another presentation. Diagnosis of gastrointestinal VMs is generally based on endoscopic findings.

VMs of the liver deserve specific mention. Historically called by the misnomer "hepatic hemangiomas," these lesions typically are first seen in adulthood, most often as an incidental finding of abdominal imaging obtained for other reasons. The majority of these lesions are asymptomatic, although they can be quite large or even massive. Reported cases of spontaneous or traumatic rupture have had devastating consequences, but this is exceedingly rare. The most common indications for treatment of these VMs are persistent discomfort from very large lesions and the inability to exclude malignancy. In experienced hands, surgical resection is safe and effective. The technique of enucleation is preferred.<sup>80</sup>

Large VMs also can be complicated by localized intravascular coagulopathy caused by stasis and stagnation of blood within the malformation, leading to consumption of coagulation factors. The clotting profile consists of prolonged PT, decreased fibrinogen, and elevated D-dimers. The PTT is often normal. Thrombocytopenia occurs, with a typical platelet range of 100,000 to 150,000/mm<sup>3</sup>. The distinction between this coagulopathy and KMP is important. KMP only occurs with two specific vascular tumors, TA and KHE, and has a much more profound thrombocytopenia, with a platelet range of 2,000 to 10,000/mm<sup>3</sup>. Also, lesions causing KMP are treated with antiangiogenic agents, whereas VMs will not respond to pharmacotherapy.

**Figure 74-12.** Blue rubber bleb nevus syndrome. **A**, Classic cutaneous venous malformations are seen on the sole of the foot. **B**, Venous malformations of the small intestine and colon were found at operation.

Histologically, VMs most often consist of sinusoidal vascular spaces with variable communications with adjacent veins (the dilated venous channels of VMs are thin walled when compared with normal veins). Staining with smooth muscle actin reveals abnormal smooth muscle architecture that may be responsible for the gradual expansion seen over time with these lesions. Moreover, calcified phleboliths may provide evidence of prior clot formation within the VMs. A variant of VMs, glomovenous malformation (also incorrectly called “glomangioma”), has the additional presence of ball-shaped glomus cells that line the vascular channels.

## Imaging

Radiologic modalities useful for the diagnosis of VMs include ultrasonography, MRI, and venography. MRI is most informative and demonstrates hyperintense lesions with T2-weighted sequences. Contrast enhancement of the vascular spaces distinguishes VMs from LMs, as does the presence of pathognomonic phleboliths. Intralesional bleeding within LMs causing contrast enhancement can be an exception to this rule. In contrast to AVMs, VMs do not demonstrate evidence of arterial flow on MRI.

## Treatment

The indications for treatment of VMs are appearance, pain, loss of function, and bleeding. Unfortunately, cure for VMs, as with LMs, is difficult to achieve for all but the most localized and therefore less problematic lesions. For extensive VMs of the extremities, conservative management with the use of graded compression stockings can achieve significant improvement in size and symptoms. Patient satisfaction with this modality depends on a proper customized fit, but can be elusive, especially for children and teenagers. To prevent phlebothrombosis of VMs with resultant pain and swelling, low-dose aspirin may be beneficial.

Intralesional sclerotherapy is the mainstay of treatment for most VMs.<sup>81</sup> Sclerosing agents, most commonly ethanol and sodium tetradecyl sulfate, cause direct endothelial damage, thrombosis, and scarring. For small VMs, the injection process is similar to that of simple varicosities. Larger lesions are accessed by direct puncture, and therapeutic agents are injected under fluoroscopy with the use of tourniquets and compression of venous drainage to prevent systemic administration of the sclerosants. General anesthesia is required in most instances. Staged therapy and occasional embolization of large venous channels are useful for more complex VMs. The more complex lesions are best treated by a skilled interventional radiologist who has experience with vascular anomalies. Potential local complications of sclerotherapy are blistering, skin necrosis, and damage to adjacent nerves. Systemic complications include hemolysis, sudden pulmonary hypertension, and cardiac and renal toxicity. These can usually be avoided with proper dosage and

sclerosant selection. For example, ethanol is a strong sclerosant that carries a higher risk of damage to local tissues and adjacent structures.

VMs have a propensity for recanalization and, therefore, re-enlargement. Cure with sclerotherapy is rare. Results from treatment are often stated in terms of patient satisfaction from decreased pain and appearance, given that recurrence is so prevalent. Surgical resection is typically reserved for well-localized lesions but is marked by procedural morbidity and recurrence. Preoperative sclerotherapy is recommended preceding operations for extensive VMs to shrink the lesion and decrease bleeding during the resection.

Unifocal gastrointestinal lesions can be excised. Diffuse colorectal malformations causing significant bleeding may be treated with colectomy, anorectal mucosectomy, and coloanal pull-through.<sup>82</sup> For multifocal VMs of the blue rubber bleb nevus syndrome, complete surgical resection of the lesions, combined with endoscopy of the entire gastrointestinal tract at the time of operation, provides the only chance for possible cure. Bowel resections for these lesions are rarely indicated. Rather, wedge excision and polypectomy by intussusception of successive lengths of intestine are the preferred methods of resection.<sup>83</sup>

## ARTERIOVENOUS MALFORMATIONS

### Clinical Presentation

AVMs are fast-flow vascular malformations characterized by abnormal connections or shunts between feeding arteries and draining veins without an intervening capillary bed. These shunts define the nidus of the malformation. This lesion tends to be localized but can be extensive as well. AVMs are familiar to neurosurgeons as one of the more common vascular anomalies that occur in the central nervous system. Indeed, intracranial AVMs are more frequent than AVMs of the skin and soft tissues within the head and neck region. Other common sites of involvement are the extremities, trunk, and viscera. These congenital malformations exhibit a peculiar but characteristic natural history of progression in stages (Table 74-2). At birth, they appear as a pink cutaneous blemish that can be confused with both CMs and the premonitory sign of an infantile hemangioma. However, fast flow across arteriovenous shunts is present beneath the innocent-appearing surface. This fast flow becomes more evident in childhood, and the lesion develops into a mass. AVMs grow in proportion with the child, but puberty, pregnancy, or local trauma tends to trigger more rapid expansion. The lesion becomes more obviously warm to touch and may develop a bruit or thrill. With continued expansion, the lesion becomes more red and prominent. Because of expansion and local steal phenomenon, skin ischemia can develop, leading to pain, ulceration, and bleeding (Fig. 74-13). For large AVMs, high-output cardiac failure can result.

**Table 74-2** Schobinger Clinical Staging System for Arteriovenous Malformations

Stage	Clinical Findings
I (Quiescent)	Pink to bluish stain, cutaneous warmth, and arteriovenous shunting by Doppler ultrasound imaging
II (Expanding)	Same as stage I, plus enlargement, pulsation, thrill, bruit, and tortuous and tense veins
III (Destructive)	Same as stage II, plus skin ulceration, bleeding, persistent pain, or tissue necrosis
IV (Decompensating)	Same as stage III, plus cardiac failure

## Imaging

Ultrasonography and Doppler imaging are excellent tools to elucidate the fast flow of these lesions and to distinguish them from VMs. Although hemangiomas can be characterized by fast flow as well, the history and age at onset should distinguish them from AVMs. MRI and MR angiography are the most useful tools to demonstrate the full extent of these lesions. They appear as hyperintense masses with contrast enhancement and flow voids seen on flow-sensitive sequences. Superselective angiography has its role at the time when treatment is planned.

## Treatment

The majority of AVMs will require treatment at some point because of the natural history of continued expansion that leads to local tissue ischemia and pain.<sup>84,85</sup> The mainstays of treatment for these lesions are angiographic embolization alone or in combination with surgical excision. However, in the early stages, the full extent of the AVMs may not be appreciated, such that local recurrence would complicate embolization or resection. Therefore, resection of AVMs during infancy and early childhood is rarely advocated. At the same time, the very well localized stage I AVMs may be amenable to excision. The usual recommendation is to observe AVMs in the early stages and monitor them carefully through regularly scheduled annual examinations. Intervention is delayed until symptoms develop indicative of stage III: local pain, ulceration, and bleeding. For treatment initiated at any stage, it is critical that the proximal feeding arteries *not* be embolized or ligated. Although ligation may provide temporary improvement for complications such as bleeding, these feeding arteries provide the only avenue for subsequent successful embolization. The nidus of the AVMs will recruit other nearby arteries after the primary feeding vessels are occluded, and the AVMs will recur and continue to progress.

Embolization must be directed to the nidus itself and to the AVFs at the epicenter of the lesion. Direct puncture sclerotherapy of the AVM nidus can be a useful adjunct to embolization, especially when the feeding arteries are too tortuous or have been previously

**Figure 74-13.** A facial arteriovenous malformation (stage III) with ulceration of the skin is seen in this patient.

ligated. Repeated and staged embolization procedures are typically necessary for these lesions but often only provide temporary improvement. The reason for this problem is the quantity and microscopic nature of the AVFs that comprise the nidus of AVMs. It is difficult to achieve complete occlusion for the entirety of these microscopic shunts. Nonetheless, patients often have significant improvement in their symptoms, and cures with embolization alone have been reported.

The preferred strategy of treatment of AVMs typically consists of surgical resection performed 2 to 3 days after preoperative embolization of the nidus. Angiographic embolization facilitates the operation by decreasing bleeding but does not reduce the extent of tissue that should be resected. Whenever possible, the goal should be complete excision to normal margins. Both the nidus of the AVMs and the involved skin are removed. The most important factor for success that should be given close attention is the decision regarding extent of resection. Review of radiologic imaging is necessary, including the earliest available MR images and angiograms before any other treatment. Intraoperatively, observation of the pattern of bleeding at the resection margins also can guide the extent of excision, as can intraoperative frozen section pathology. Primary closure is sometimes not possible without tissue transfer techniques. Vacuum-assisted closure devices also can be useful in wounds with large soft tissue loss precluding linear closure. The best results are seen with AVMs that are well localized. Yet, even for these cases it is prudent to monitor these patients for years to

evaluate for signs of recurrence. Unfortunately, most AVMs are extensive and often not amenable to surgical options. For these difficult lesions, embolization is used for palliation. For difficult AVMs of the extremities, if distal in location, amputation should be considered as an option.

## COMBINED VASCULAR MALFORMATIONS

As with other vascular malformations, combined malformations are classified as either slow flow or fast flow. These more complex disorders, as a rule, are associated with soft tissue and skeletal overgrowth. They tend to be named for the person or persons who first described them. However, these eponyms often create confusion because of misuse. Thus, it is preferred to use the anatomic terms that best describe the anomalous vascular channels that are present.

### Klippel-Trénaunay Syndrome

Klippel-Trénaunay syndrome is a slow-flow combined vascular malformation involving abnormal capillaries, lymphatics, and veins.<sup>86-88</sup> This capillary lymphaticovenous malformation (CLVM) usually involves one or more extremities, most often a lower limb, and is associated with prominent soft tissue and bony hypertrophy (Fig. 74-14). This syndrome is sporadic and obvious at birth, although a wide range of severity occurs. The CM component can be multiple and typically is seen as a large geographic pattern affecting the extremity, buttock, and trunk. It is macular at birth and develops hemolympathic vesicles over time. The lymphatic anomalies have a variable presentation, including hypoplasia, lymphedema, and macrocystic LMs. The venous component consists of anomalous lateral superficial veins in the extremity that are persistent embryonic vessels. These veins are usually dilated and have incompetent valve systems. Anomalous deep system veins may be hypoplastic or even absent. Thrombophlebitis of the anomalous veins occurs with a frequency of 20% to 45%, and pulmonary emboli are reported in 4% to 25% of cases.

Limb hypertrophy is obvious at birth and occurs in peculiar patterns. It tends to be progressive over time. The spectrum of deformities includes enlargement of hands and feet, both ipsilateral and contralateral to the limb affected by CLVMs. Although the affected extremity is generally larger, it is occasionally smaller. With CLVMs of the legs, pelvic involvement with LMs and VMs also can occur but is often asymptomatic. Alternatively, problems with recurrent infections, hematuria, hematochezia, and bladder outlet obstruction may occur. With CLVMs of the superior trunk and arms, the mediastinum or retropleural space can harbor the vascular malformations as well.

Imaging plays an important role in the evaluation of patients with Klippel-Trénaunay syndrome. Plain radiographs are used to document limb-length discrepancies serially. MRI provides the foundation for

**Figure 74-14.** Patient with Klippel-Trénaunay syndrome or capillary lymphaticovenous malformation (CLVM) and associated soft tissue and skeletal overgrowth of the lower extremity.

describing the type and extent of each of the vascular malformation components. Hypertrophic fatty tissue is often seen on MRI in areas of overgrowth. One common pattern seen with LMs of the lower extremity is to find macrocystic lesions in the pelvis and thigh and microcystic LMs affecting the abdominal wall, buttock, and distal extremity. These LMs can be localized to the subcutaneous tissues or extend into the intramuscular compartments. MR venography can elucidate the anatomy of the deep system veins. Identification of a subcutaneous vein coursing along the lateral calf and thigh (the marginal vein of Servelle) is pathognomonic for Klippel-Trénaunay syndrome. Venography is considered for some patients to map the venous drainage of the extremity before resection of any anomalous superficial veins if concern exists regarding patency of the deep veins based on MR venography.

In general, treatment for Klippel-Trénaunay syndrome is conservative, because it is not a curable disease. However, operative therapies do have a place to manage some of the specific problems that are encountered, which are primarily overgrowth.<sup>89</sup> Gross foot enlargement that impairs ambulation and the ability to wear shoes requires orthopedic corrective procedures and partial amputations to permit the use of custom footwear. Leg-length discrepancy should be followed up annually by an orthopedic surgeon to document and predict severity. Shoe lifts are recommended to prevent limping and scoliosis if the discrepancy is greater than 1.5 cm at age 2 years. Sometimes, epiphysiodesis of the distal femoral growth plate is performed around age 12 years to correct overgrowth. Correction for arm-length discrepancies is unnecessary. Staged contour resection can be used to treat areas of soft tissue overgrowth and lymphedema. Symptoms of pain and deformity secondary to venous anomalies can often be improved with compression

stockings. Alternatively, sclerotherapy can treat certain components of CLVMs such as focal VMs, macrocystic LMs, and bleeding capillary lymphatic vesicles. Recurrence after sclerotherapy, however, is often a problem. Surgical resection of anomalous veins producing pain or potential sources of pulmonary emboli also is an option. Perioperative management during significant resections should include consideration for anticoagulation and temporary inferior vena cava filter placement to help prevent deep venous thrombosis and pulmonary embolization.

### Maffucci Syndrome

Maffucci syndrome consists of exophytic VMs of the soft tissue and bones, bony exostoses, and endochondromas. It is sporadic and not usually evident at birth. It can be unilateral or bilateral. The bony lesions and endochondromas manifest first in childhood, and the venous anomalies appear later. Spindle cell hemangi endotheliomas commonly occur and denote reactive vascular proliferation within the preexisting VMs, rather than true tumors.<sup>90</sup> The endochondromas can undergo malignant transformation in 20% to 30% of cases, leading to chondrosarcomas.<sup>91</sup> This fact suggests that a tumor suppressor gene may be involved in the pathogenesis.

### Bannayan-Riley-Ruvalcaba Syndrome

Bannayan-Riley-Ruvalcaba syndrome is an autosomal dominant syndrome caused by mutations of the tumor suppressor gene *PTEN* (phosphatase tensin homolog) on chromosome 10.<sup>92</sup> It is primarily an overgrowth syndrome that has vascular malformations as a minor component. Typically, cutaneous CMs, VMs, or AVMs are found. The more prominent clinical features are macrocephaly, multiple lipomas, hamartomatous

polyps of the ileum and colon, and Hashimoto's thyroiditis.

### Proteus Syndrome

This syndrome is probably diagnosed more often than it actually occurs. It is named after a Greek god who was able to assume any shape or form.<sup>93</sup> This overgrowth disorder is sporadic and progressive over time. Vascular, skeletal, and soft tissue anomalies tend to be asymmetric and variably expressed. Common features include lipomas or lipomatosis, macrocephaly, and gigantism of the hands or feet or both.

### Parkes Weber Syndrome

Parkes Weber syndrome is a sporadic combined fast-flow vascular malformation affecting the limb and trunk, with the lower extremity being the most common site.<sup>94,95</sup> Capillary arteriovenous fistulas (CAVF) and capillary arteriovenous malformations (CAVM) are combined with hypertrophy of the bone and muscle of the affected limb. CAVM is obvious at birth, appearing as overgrowth with a large geographic macular pink stain. In contrast to CLVM seen with Klippel-Trénaunay syndrome, the limb hypertrophy is symmetric along the length and substance of the extremity. The macular stain associated with CAVM has much greater cutaneous warmth than do typical CMs. The findings of bruits or thrills on examination confirm the diagnosis.

MRI demonstrates symmetric muscular and bony overgrowth, with generalized enlargement of the normal named arteries and veins within the affected limb. Angiography depicts the discrete AVFs. In rare cases, superselective embolization is used to occlude the arteriovenous shunts if symptoms of ischemia, pain, or high-output congestive heart failure occur.

# HEAD AND NECK SINUSES AND MASSES

Stephanie Acierno, MD, MPH • John H. T. Waldhausen, MD

Lesions of the head and neck in children can be subdivided by etiology as resulting from infection, trauma, or neoplasm, or being of congenital origin. The more common benign neoplasms, including hemangiomas, lymphangiomas, and cystic hygromas, are discussed in Chapter 74. Malignant neoplasms of childhood (e.g., neuroblastoma, lymphoma, and rhabdomyosarcoma), which occur as a primary or metastatic mass in the head and neck, lesions of the thyroid and parathyroid, and traumatic injuries of the head and neck, also are discussed in other chapters. In this chapter, common congenital head and neck malformations are described and inflammatory lesions are reviewed.

## LESIONS OF EMBRYONIC ORIGIN

Congenital cysts and sinuses that appear in the neck result from embryonic structures that have failed to mature or have persisted in an aberrant fashion.<sup>1,2</sup> Successful treatment of a child with a mass or sinus in the head or neck requires accurate identification of the lesion as well as a planned course of therapy. Both diagnosis and therapy depend on a working knowledge of the embryologic origin and differentiation of the head and neck structures.<sup>3,4</sup> This knowledge is particularly important because complete surgical resection of cartilaginous remnants, remnants of the branchial arch and cleft structures, and midline fusion abnormalities is imperative to avoid recurrence. Congenital lesions of the head and neck, in descending order of frequency, are thyroglossal duct cysts, preauricular pits and sinuses, branchial cleft anomalies, dermoid cysts, and median cervical clefts.

### Thyroglossal Duct Cyst

One of the most common lesions in the midline of the neck is a thyroglossal duct cyst. Thyroglossal duct remnants are found in 7% of the population, although few become symptomatic.<sup>4,5</sup> Although they are embryonic in origin, it is rare for these lesions to be found in the newborn period.<sup>1</sup> More commonly, they are noted in

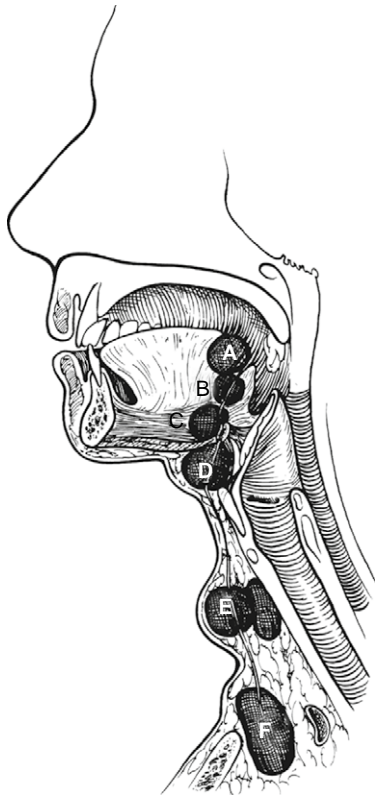

preschool-age children.<sup>1</sup> Thyroglossal duct cysts also are common in young adults and, with the exception of thyroid goiter, are the most common midline neck masses in this age group.<sup>6</sup>

### EMBRYOLOGY

The embryogenesis of the thyroglossal duct is intimately involved with that of the thyroid gland, the hyoid bone, and the tongue.<sup>7</sup> The foramen cecum is the site of the development of the thyroid diverticulum.<sup>7</sup> In the embryo, this structure develops caudal to the central tuberculum impar, which is one of the pharyngeal buds that leads to the formation of the tongue.<sup>7</sup> As the tongue develops, the thyroid diverticulum descends in the neck, maintaining its connection to the foramen cecum. During this time, the hyoid bone is developing from the second branchial arch. The thyroid gland develops between weeks 4 and 7 of gestation and descends into its pretracheal position in the neck.<sup>8</sup> As a result of these multiple events occurring simultaneously, the thyroglossal duct may pass in front of or behind the hyoid bone, but most commonly it passes through it. Usually, the duct disappears by the time the thyroid reaches its normal position by 5 to 8 weeks' gestation.<sup>5,9</sup> Thyroglossal duct cysts never have a primary external opening because the embryologic thyroglossal tract never reaches the surface of the neck.<sup>8</sup> Usually the thyroglossal tract becomes obliterated. If it persists, a cyst can be located anywhere along the migratory course of the thyroglossal tract in the neck (Fig. 75-1). Occasionally, the cysts attach to the pyramidal lobe of the thyroid or may be intrathyroidal.<sup>10</sup> Complete failure of migration of the thyroid results in a lingual thyroid, which develops beneath the foramen cecum at the base of the tongue.<sup>11</sup> In this instance, no thyroid tissue is found in the neck.<sup>11</sup>

### CLINICAL PRESENTATION

Two thirds of thyroglossal duct anomalies are discovered within the first 3 decades of life.<sup>5</sup> Classically, the thyroglossal cysts are located in the midline at or just below the hyoid bone (Fig. 75-2). Suprahyoid thyroglossal cysts must be distinguished from submental dermoid cysts and from submental lymph nodes.<sup>12</sup>

**Figure 75-1.** Thyroglossal duct cysts can be located anywhere from the base of the tongue to behind the sternum. A and B, Lingual (rare). C and D, Adjacent to hyoid bone (common). E and F, Suprasternal fossa (rare). (From Welch KJ, Randolph JG, Ravitch MM, et al [eds]: *Pediatric Surgery*, 4th ed. Chicago, Year Book Medical, 1986, p 549.)

Rarely, the cysts are suprasternal in location. The initial sign is usually a painless mass in the midline of the neck, with 66% found adjacent to the hyoid bone.<sup>9</sup> On physical examination, the thyroglossal duct cyst is smooth, soft, and nontender. To distinguish this lesion from the more superficial dermoid lesion, one should palpate the lesion while the child sticks out his or her tongue. Owing to its attachment to the foramen cecum, the thyroglossal duct cyst does not fully

**Figure 75-2.** A classic thyroglossal duct cyst located in the midline just below the hyoid bone. Markings on the neck represent the thyroid, cricoid and tracheal cartilages.

move when the tongue protrudes. This maneuver is more reliable than asking the child to swallow and determining whether the mass moves with swallowing. Owing to the communication to the mouth via the foramen cecum, thyroglossal cysts can become infected with oral flora. One third of patients will present with a concurrent or prior infection and a fourth will present with a draining sinus from spontaneous or surgical drainage of an abscess.<sup>9</sup> Some patients may present with a foul taste in the mouth from spontaneous drainage of the cyst via the foramen cecum.

The preoperative evaluation for a patient with a suspected thyroglossal duct cyst should include a complete history and physical examination. Patients with findings suggestive of hypothyroidism should undergo thyroid function testing and additional imaging to exclude a median ectopic thyroid. The incidence of ectopic thyroid tissue in or near the duct is reported to be from 10% to 45%. Some clinicians have advocated preoperative thyroid scanning or ultrasonography to eliminate the possibility of an ectopic thyroid gland masquerading as a thyroglossal duct cyst.<sup>13-17</sup> Ultrasonography appears to be very accurate and avoids the need for irradiation and possible sedation in younger children.<sup>16</sup> The anatomic location also may be useful in differentiating cysts and ectopic thyroid. Ninety percent of ectopic thyroid tissue lies at the base of the tongue, and thyroglossal duct cysts are rarely found there. Abnormal thyroid function tests, a suggestive history, or a solid mass evident on an ultrasound image should prompt a preoperative thyroid scan to ensure the lesion is not the only thyroid gland present, which occurs in less than 1% to 2% of patients with thyroglossal duct cysts.<sup>9,15,18</sup> If ectopic thyroid tissue is found, the management becomes controversial, but some clinicians suggest a trial of medical suppression to decrease the size of the mass.

## TREATMENT

Elective surgical excision is advised to avoid the complications of infection and because of the small risk (<1%) of cancer developing in the cyst.<sup>15</sup> The cyst and its cephalad tract are completely excised to the base of the tongue (Fig. 75-3). In 1920, Sistrunk described excision of the central portion of the hyoid bone as necessary treatment to prevent cyst recurrence.<sup>19</sup> The operation must include resection of the central portion of the hyoid bone.<sup>20,21</sup> Several other studies have shown that multiple smaller tracts can connect through the hyoid bone to the floor of the mouth, requiring wide resection of tracts above the hyoid.<sup>20-22</sup> If these suprahyoid tracts remain, the incidence of recurrence increases.<sup>23</sup> The best chance for successful resection is adequate wide resection at the initial procedure.<sup>22</sup>

As for all neck surgery, the patient should be supine with the neck slightly hyperextended (Fig. 75-4). The thyroglossal cyst is exposed through a transverse incision. The cyst has a characteristic appearance that is distinctly different from that of thyroid tissue. The dissection should continue cephalad to the hyoid, resecting a block of tissue along the proximal tract. Transecting the hyoid is simplified by using angled scissors, similar to Potts scissors, or by using a

**Figure 75-3.** Complete excision of a previously infected thyroglossal duct cyst. Surrounding skin was removed because of changes related to a previous infection. Note the well-defined tract leading toward the hyoid bone and the floor of the mouth. The operation was completed by excising the central portion of the hyoid bone and suture ligating the tract.

side-cutting bone cutter. The base of the tract at the floor of the mouth is ligated with absorbable suture. The wings of the hyoid are not approximated. The incision is copiously irrigated, and the wound is closed in layers. If the floor of the mouth is entered inadvertently, this can be repaired with absorbable suture.

Occasionally, the dissection may be made easier by having the anesthesiologist place his or her finger at the base of the child's tongue to identify the cephalad extent of the dissection. With complete excision, including the central portion of the hyoid bone, the risk of recurrence is low, 2.6% to 5.0%.<sup>5,9,23,24</sup> Risk factors for recurrence include simple cyst excision alone (recurrence rates of 38% to 70%), intraoperative cyst rupture, presence of a cutaneous component, and postoperative wound infections.<sup>5,9,25</sup> As mentioned, the cyst is usually connected to the foramen cecum by single or multiple tracts that pass through the hyoid. On histologic examination, the duct lining is stratified squamous epithelium or ciliated pseudostratified

**Figure 75-4.** Positioning a child for a cervical operation. Hyperextension of the head with support under the shoulders and stabilization with a bean bag keeps the child in a stable position and facilitates exposure. The head of the bed should be elevated 30 degrees to decrease venous pressure in the neck.

columnar epithelium, with associated mucus-secreting glands.<sup>9</sup> The cyst contains a characteristic glairy mucus. Less than 1% have malignant tissue, which is most often papillary thyroid carcinoma.

Infected cysts or sinuses should be managed by initially treating the infection. The usual route of infection is via the mouth. Thus, the common organisms are *Haemophilus influenzae*, *Staphylococcus aureus*, and *Staphylococcus epidermidis*.<sup>9</sup> Needle aspiration may be required to decompress the cyst and allow for identification of the organism, but formal incision and drainage should be avoided. This may seed ductal cells outside of the cyst and increase recurrence rates.<sup>9</sup> If incision and drainage is required, the incision should be placed so that it can be completely excised during a formal Sistrunk procedure once the infection clears.

If a solid mass is found during thyroglossal duct cyst excision, it should be sent for frozen section to exclude median ectopic thyroid. If it is normal thyroid tissue and there is additional functional thyroid tissue in the normal location, a Sistrunk procedure with excision of the mass should be performed.<sup>9</sup> If there is no other thyroid tissue present, management is controversial. One option is to leave the tissue in situ or reposition it into the strap muscles. This is attempted to prevent the patient from becoming permanently hypothyroid. However, most patients still require thyroid hormone therapy for hypothyroidism or to control the size of the ectopic thyroid. Because of this likely need for long-term therapy and possible malignant degeneration, some surgeons advocate complete excision of the ectopic thyroid tissue regardless of the presence of additional thyroid tissue.<sup>9</sup>

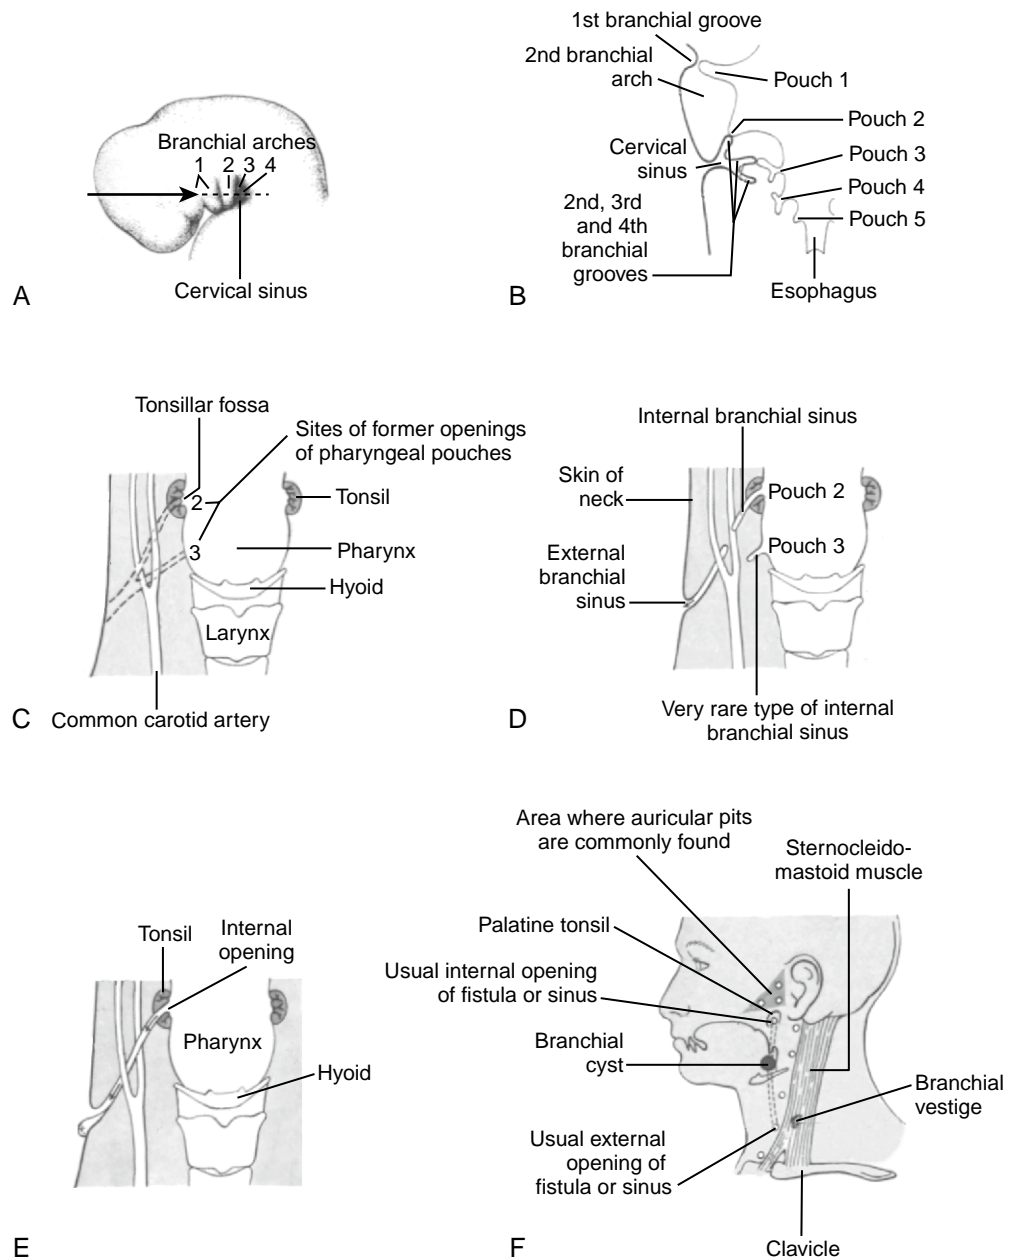

## Remnants of Embryonic Branchial Apparatus

Branchial anomalies comprise approximately 30% of congenital neck masses and can present as cysts, sinuses, or fistulas.<sup>5,26</sup> They are equally common in males and females and present in childhood or early adulthood.

### EMBRYOLOGY

During weeks 4 to 8 after fertilization, four pairs of well-developed ridges (branchial arches) dominate the lateral cervicofacial area of the human embryo.<sup>27</sup> These four pairs are accompanied by two rudimentary pairs, which are analogous to the gill apparatus of lower forms.<sup>2,27</sup> No true gill mechanisms are found in any stage of the human embryo. These pharyngeal arches and clefts are formed without a true connection between the outer ectodermal clefts and the inner endodermal pharyngeal pouches (Fig. 75-5). The mature structures of the head and neck are derivatives of several branchial arches and their intervening clefts.<sup>27,28</sup> The branchial clefts and pouches are gradually obliterated by mesenchyme, but branchial cleft anomalies result if that process is incomplete.<sup>26</sup>

Each arch transforms during gestation into a defined anatomic pattern. Understanding this pattern and its relationship to normal neck structures is key in

**Figure 75-5.** **A**, The head and neck region of a 5-week-old embryo. **B**, Horizontal section through the embryo illustrating the relationship of the cervical sinus to the branchial arches and pharyngeal pouches. **C**, The adult neck region, indicating the former sites of openings of the cervical sinus and the pharyngeal pouches. The *dotted lines* indicate possible courses of branchial fistulas. **D**, The embryologic basis of various types of branchial sinuses. **E**, A branchial fistula resulting from persistence of parts of the second branchial cleft and the second pharyngeal pouch. **F**, Possible sites of branchial cysts and openings of branchial sinuses and fistulas. A branchial vestige also is illustrated. (From Moore KL: *The Developing Human: Clinically Oriented Embryology*. Philadelphia, WB Saunders, 1977.)

the diagnosis and treatment of these anomalies. Each anomaly is classified by the cleft or pouch of origin, which can be determined by the internal opening of the sinus as well as its relationship to nerves, arteries, and muscles. Careful attention to these relationships is necessary to prevent injury to surrounding tissues and ensure complete resection.<sup>26</sup>

### **PATHOLOGY**

Branchial anomalies are lined with either respiratory or squamous epithelium. Sinuses and fistulas usually have the former and cysts have the latter.<sup>26</sup> One also can see lymphoid tissue, sebaceous glands, salivary tissue, or cholesterol crystals. Squamous cell cancer has been reported in adults, but it is rare and can be difficult to distinguish a primary branchiogenic lesion from a metastatic lesion from an occult primary lesion.<sup>5</sup>

### **CLINICAL PRESENTATION**

Complete fistulas are more common than external sinuses. Both are more common than branchial cysts, at least during childhood.<sup>29,30</sup> In adults, cysts predominate.<sup>29</sup> By definition, all branchial remnants are truly congenital and are present at birth.<sup>30,31</sup> Cysts are remnants of sinuses without an external opening and usually appear later in childhood than do sinuses, fistulas, and cartilaginous remnants, which are often found at birth.<sup>5,31</sup> Sinuses have the persistence of the external opening only, whereas fistulas involve the persistence of the branchial groove with breakdown of the branchial membrane.<sup>5</sup> Commonly, the tiny external opening of the fistula and the external sinuses remain unnoticed for some time. Spontaneous mucoid drainage from the ostium along the border of the sternocleidomastoid

usually heralds its presence and initiates the parent's concern and the reason for the child's referral. The first clinical presentation may be an infected mass as a result of the inability of the thick mucoid material to drain spontaneously. Infection is, however, less common in fistulas and external sinuses than in cysts.<sup>1</sup> The cutaneous openings are occasionally marked by skin tags or cartilage remnants. The tract itself may be palpable as a cord-like structure ascending in the neck when the child's neck is hyperextended and the skin is taut. Compression along the tract may produce mucoid material exiting from the ostium.

The evaluation of these lesions starts with a thorough history and physical examination. Palpating the tract and observing the mucoid discharge can be confirmatory. Although colored dye or radiopaque material may be injected to delineate the tract, these manipulations generally are unnecessary. Upper endoscopy can be helpful to locate the pharyngeal opening. Both the pyriform sinus and tonsillar fossas should be examined. Cysts may be more difficult to diagnose. They lie deep to the skin along the anterior border of the sternocleidomastoid muscle.<sup>1</sup> They can usually be distinguished from cystic hygromas, which are subcutaneous and can be transilluminated. Ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) can help define the lesion and can be particularly helpful in narrowing the differential diagnosis, but CT is most often used and can demonstrate a fistula in 64% of cases.<sup>32</sup> A barium esophagogram has 50% to 80% sensitivity for third and fourth branchial fistulas.<sup>33</sup> Whereas fine-needle aspiration is necessary in adults to rule out metastatic carcinoma, it is not necessary in children, and incisional biopsy should be avoided.<sup>26</sup>

## TREATMENT

The goal of treating all congenital neck sinuses, cysts, and fistulas is usually complete excision, done electively, when no inflammation is present.<sup>34</sup> Timing of resection is controversial, with some advocating for early resection to prevent infection while others support waiting until 2 or 3 years of age.<sup>26,35,36</sup> As with thyroglossal duct cysts, if the lesion is infected at clinical presentation, antibiotic therapy and warm soaks to encourage spontaneous drainage of mucoid plugs should precede definitive excision. Approximately 20% of lesions will have been infected at least once before surgery.<sup>35</sup> Attempts at complete excision in an inflamed, infected field increase the risk of nerve injury and incomplete resection. Aspiration or a limited incision and drainage procedure is sometimes necessary to resolve the infection. Complete surgical excision is delayed until the inflammation subsides and the surrounding skin is supple. Endoscopic cauterization of fourth branchial cleft sinuses has been described either at the time of initial abscess drainage or 4 to 6 weeks later. Recurrence with this technique seems to be uncommon.<sup>37</sup>

Surgical resection is performed under general anesthesia with the patient positioned as shown in [Figure 75-4](#). A small transverse elliptical incision is made

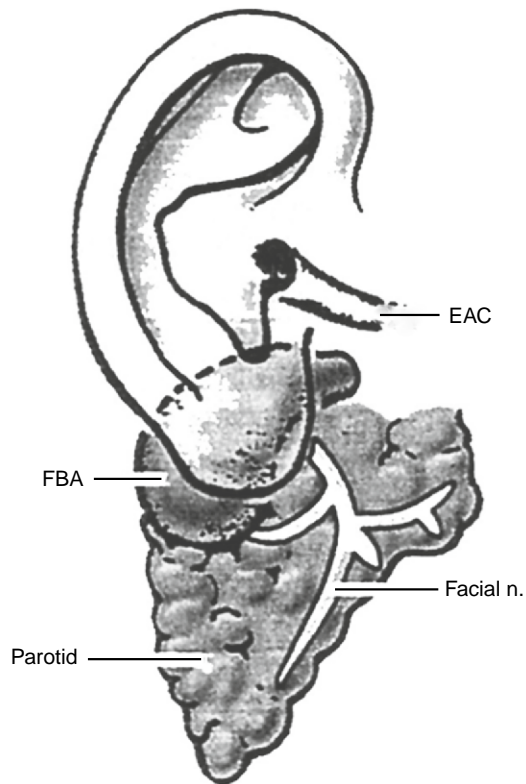

around the external opening and deepened beneath the cervical fascia. The initial dissection is along the inferior border of the incision so that the ascending tract is identified from below and is not injured. Placement of a 2-0 or 3-0 monofilament suture or probe within the tract can facilitate this dissection. Dissection proceeds cephalad, staying on the tract until visualization of the most superior portion of the tract becomes difficult. At this level, a second, more cephalad, parallel "stair step" incision or extension of the original incision may be necessary for adequate exposure. If a second, more cephalad incision is needed, the tract is pulled subcutaneously through the second incision and the dissection is continued cephalad between the bifurcation of the carotid artery to the point where the tract inserts into the pharynx. The fistula is suture ligated with absorbable suture material. The incision is closed in layers with absorbable sutures. No drains are needed if resection is complete. Recurrences are rare and imply that a portion of the epithelium-lined tract was overlooked. The incidence of recurrence is higher in cases of previously infected lesions. The specific embryology, anatomic presentation, and treatment for each type of branchial anomaly will now be discussed.

## First Cleft Anomalies

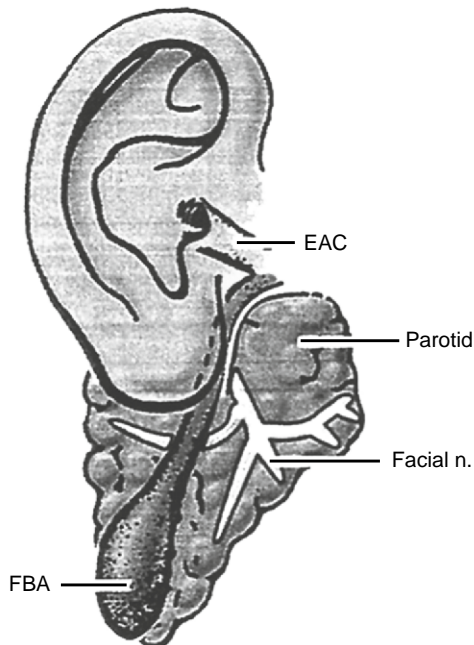

The first branchial arch forms the mandible and contributes to the maxillary process of the upper jaw.<sup>28,31,38</sup> Abnormal development of the first branchial arch results in a host of facial deformities, including cleft lip and palate, abnormal shape or contour of the external ear, and malformed internal ossicles.<sup>28,31</sup> The first branchial cleft contributes to the tympanic cavity, eustachian tube, middle ear cavity, and mastoid air cells. Microtia and aural atresia occur with failure of the first branchial cleft to develop.<sup>27,28</sup>

First branchial anomalies are rare and account for less than 1% of branchial cleft malformations.<sup>26</sup> Cysts are seen as swellings posterior or anterior to the ear or inferior to the earlobe in the submandibular region. External openings, if found, are located inferior to the mandible in a suprahyoid position. One third open into the external auditory canal.<sup>6</sup> The tract may be intimately associated with, or course through, the parotid gland. This and the proximity of the seventh cranial nerve make resection difficult, particularly in the younger patient who is likely to have a tract deep to the facial nerve.<sup>32</sup> First cleft anomalies are classified as type I or type II ([Figs. 75-6 and 75-7](#)).<sup>5,26</sup> Type I lesions are duplications of the external auditory canal, have only ectoderm, course lateral to the facial nerve, and present as swellings near the ear. Type II consist of both mesoderm and ectoderm, can contain cartilage, pass medial to the facial nerve, and present as swellings inferior to the angle of the mandible or anterior to the sternocleidomastoid in a preauricular, infra-auricular, or postauricular position. First branchial anomalies are more common in females than males and are often misdiagnosed, leading to delay in excision.<sup>39</sup> Presentation can include cervical, parotid, or auricular signs.

**Figure 75-6.** Type I first branchial cleft anomaly (FBA). Note that the anomaly, located in the parotid gland, has no connection to the external auditory canal (EAC). (From Mukherji SK, Fatterpekar G, Castillo M, et al: Imaging of congenital anomalies of the branchial apparatus. *Neuroimaging Clin North Am* 10:75-93, 2000.)

**Figure 75-7.** Type II first branchial cleft anomaly (FBA). The anomaly connects with the external auditory canal (EAC) and extends deep into the parotid gland. (From Mukherji SK, Fatterpekar G, Castillo M, et al: Imaging of congenital anomalies of the branchial apparatus. *Neuroimaging Clin North Am* 10:75-93, 2000.)

Cervical signs include drainage from a pit-like depression at the angle of the mandible. Parotid signs result from rapid enlargement due to inflammation. Auricular signs can consist of swelling or otorrhea.

Resection of first arch anomalies often requires at least partial facial nerve dissection and superficial parotidectomy. It is important to resect any involved skin or cartilage of the external auditory canal (Fig. 75-8). If it extends medial to the tympanic membrane, a second procedure may be necessary to remove the medial component. Tracts that go to the middle ear are more likely to travel deep or split around the facial nerve.<sup>39</sup> Recurrence is common, and more than two procedures are often required for complete resection.<sup>40</sup> Each repeat surgery places the facial nerve at greater risk from prior scarring, emphasizing the importance of complete resection at the first attempt.<sup>26</sup>

### Second Cleft Anomalies

The second arch forms the hyoid bone and the cleft of the tonsillar fossa.<sup>1,2</sup> The second pouch gives rise to the tonsillar and suprtonsillar fossa.<sup>26</sup> The external ostium of the second branchial cleft is along the anterior border of the sternocleidomastoid muscle, generally at the junction of the lower and middle thirds.<sup>29</sup> Because of its embryonic origin, the second cleft tract penetrates platysma and cervical fascia to ascend along the carotid sheath to the level of the hyoid bone. Remnants may be found anywhere along this course. The residual tract then turns medially between the branches of the carotid artery, behind the posterior belly of the digastric and stylohyoid muscles, and in front of the hypoglossal nerve to end in the tonsillar fossa (Fig. 75-9).<sup>29</sup> Although the internal opening can be anywhere in the nasopharynx or oropharynx, it is most commonly found in the tonsillar fossa. Figure 75-10 demonstrates the four types of second arch anomalies. Type I anomalies lie anterior to the sternocleidomastoid muscle and do not come into contact with the carotid sheath. Type II lesions are the most common, passing deep to the sternocleidomastoid and anterior or posterior to the carotid sheath. Type III anomalies pass between the internal and external carotid arteries, ending adjacent to the pharynx. Type IV lesions are medial to the carotid sheath adjacent to the tonsillar fossa.

Second branchial cleft anomalies represent 95% of all branchial cleft anomalies. About 10% of second branchial remnants are bilateral.<sup>29</sup> These anomalies commonly present as a fistula or cyst in the lower, anterolateral neck. Fistulas are commonly diagnosed in infancy or childhood after presenting with chronic drainage from an opening anterior to the sternocleidomastoid muscle in the lower third of the neck. Cysts usually present during the third to fifth decades of life with an acute increase in size after an upper respiratory tract infection.<sup>5,26</sup> The dissection of the tract follows the course as described above with care taken during the resection to protect the spinal accessory, hypoglossal, and vagus nerves. A finger or bougie in the oropharynx can help identify the opening in the

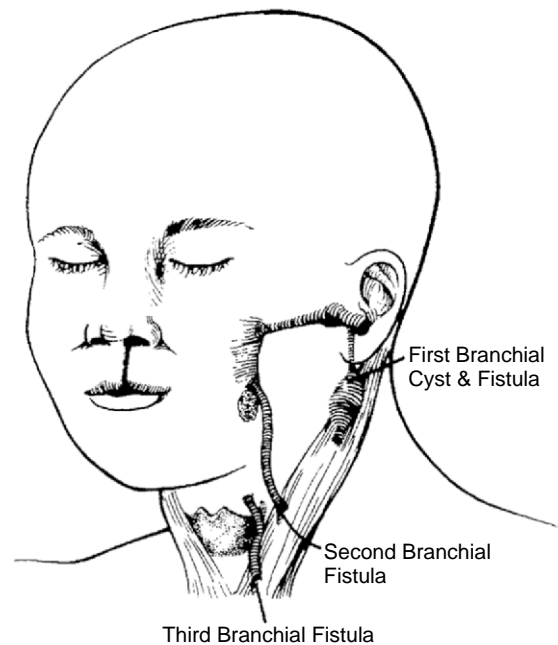

**Figure 75-8.** **A,** This young child presented with drainage from a first branchial cleft fistula. The ostium is marked with an *arrow*. **B,** In the operative photograph, the fistula has been dissected from its external opening (*arrow*) and is seen progressing toward the external auditory canal. The left ear (*asterisk*) has been elevated to improve visualization.

tonsillar fossa. The tract must be carefully ligated at this entry point.

### Third and Fourth Cleft Anomalies

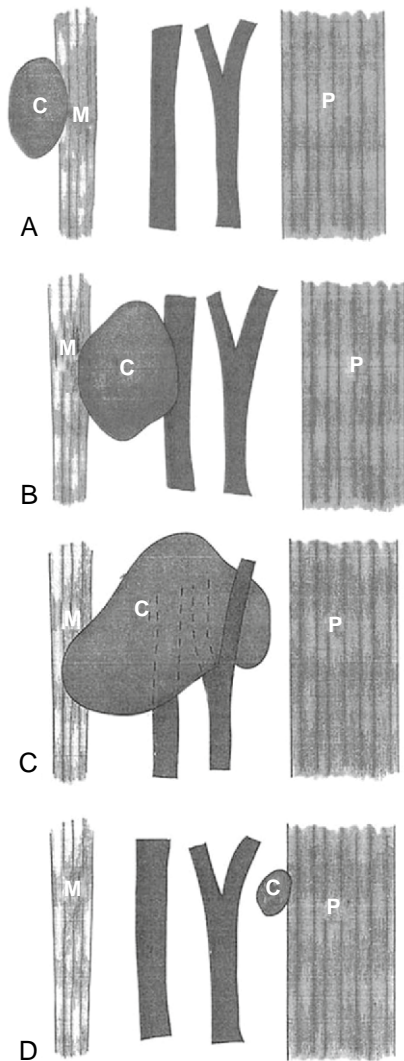

Third and fourth branchial anomalies are rare. The third and fourth pouches form the pharynx below the hyoid bone; thus, these anomalies enter into the pyriform sinus. The third cleft migrates lower in the neck to form the inferior parathyroid glands and the thymus.<sup>7,29</sup> The descent of the fourth cleft stops higher in the neck to form the superior parathyroid glands. The fourth pouch has added significance because its ventral portion develops into the ultimobranchial body, which contributes thyrocalcitonin-producing parafollicular cells to the thyroid gland.<sup>7</sup> It is unusual to find cysts and sinuses from the third branchial cleft.<sup>2,28</sup> When found, they are in the same area as those of the second cleft but ascend posterior to the carotid artery rather than through the bifurcation (Fig. 75-11).<sup>28</sup> The fistula pierces the thyrohyoid membrane and enters the pyriform sinus.

Fourth branchial fistulas are difficult to differentiate from other associated anomalies. Also, fourth pouch cysts are highly unusual and must be differentiated from laryngoceles. These tracts originate at the apex of the pyriform sinus, descend beneath the aortic arch, and then ascend anterior to the carotid artery to end in the vestigial cervical sinus of His (Fig. 75-12).<sup>41</sup> Other anomalies arising from the third and fourth branchial pouches may appear as cystic structures in the neck. Thymic cysts may occur as a result of incomplete degeneration of the thymal pharyngeal duct or of progressive cystic degeneration of epithelial remnants of Hassall corpuscles.<sup>41</sup> Most are found on the left side of the neck. Parathyroid cysts may be

**Figure 75-9.** A child with a cleft lip and remnants of the first three branchial systems. Note the important relation to the sternocleidomastoid muscle and the fistula's origin. (From Welch KJ, Randolph JG, Ravitch MM, et al [eds]: *Pediatric Surgery*, 4th ed. Chicago, Year Book Medical, 1986, p 543.)

located anywhere around the thyroid gland or in the mediastinum. These are usually not associated with biochemical abnormalities, although reports of hyperparathyroidism secondary to functioning cysts have been seen. The etiology of these cysts is not clear, but they may be embryologic remnants of third and fourth branchial pouches or may represent cystic

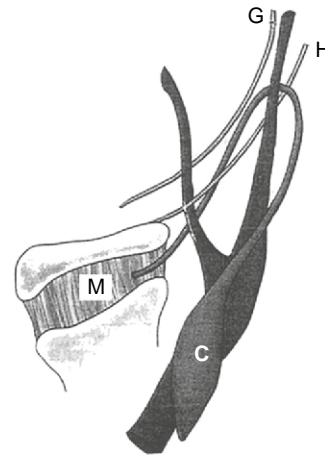

**Figure 75-10.** Types I to IV second branchial cleft anomalies. **A**, Type I: the cyst (C) is superficial to the sternocleidomastoid muscle (M). **B**, Type II: the cyst is adjacent to the carotid sheath. **C**, Type III: the cyst passes between the internal and external carotid arteries to the lateral wall of the pharynx (P). **D**, Type IV: the cyst is deep to the carotid sheath abutting the pharynx. (From Mukherji SK, Fatterpekar G, Castillo M, et al: Imaging of congenital anomalies of the branchial apparatus. *Neuroimaging Clin North Am* 10:75-93, 2000.)

degeneration of adenomas or gradual enlargement of microcysts.<sup>41</sup>

Both third and fourth cleft lesions can present at any age. In the neonate, both can present as tracheal compression or airway compromise owing to rapid enlargement. They can also present as cold nodules within the thyroid or as a thyroid abscess. Other initial presentations include recurrent upper respiratory tract infections or neck pain.

Surgical therapy for third and fourth arch anomalies is similar to that for anomalies of the second arch, with a few notable exceptions. Endoscopy should be used to find the pyriform sinus entry point to allow cannulation of the tract to aid with dissection. Fourth arch anomaly resections require ipsilateral

**Figure 75-11.** Third branchial cleft anomaly. The cyst (C) is posterior to the sternocleidomastoid muscle (M), and the tract ascends posterior to the internal carotid artery. It then passes medially between the hypoglossal (H) and glossopharyngeal (G) nerves. It pierces the thyroid membrane (M) to enter the pyriform sinus. (From Mukherji SK, Fatterpekar G, Castillo M, et al: Imaging of congenital anomalies of the branchial apparatus. *Neuroimaging Clin North Am* 10:75-93, 2000.)

**Figure 75-12.** Fourth branchial cleft anomaly. The cysts (C) are located anterior to the aortic arch on either side. The tract hooks either the subclavian artery or the aortic arch, depending on the side, and ascends to loop over the hypoglossal nerve (H). (From Mukherji SK, Fatterpekar G, Castillo M, et al: Imaging of congenital anomalies of the branchial apparatus. *Neuroimaging Clin North Am* 10:75-93, 2000.)

hemithyroidectomy for complete excision, and partial resection of the thyroid cartilage may be necessary to expose the pyriform sinus.<sup>42</sup>

## Preauricular Pits, Sinuses, and Cysts

### EMBRYOLOGY

Preauricular pits, cysts, and sinuses are not of true branchial cleft origin.<sup>43</sup> They represent ectodermal inclusions, which are related to embryonic ectodermal mounds (auditory hillocks) that essentially form the auricles of the ear.<sup>28,44</sup> The sinuses are often short

and end blindly. They never connect internally to the external auditory canal or eustachian tube.<sup>43</sup> They characteristically end in thin strands that blend with the periosteum of the external auditory canal. Some authors propose that they are a marker of teratogenic exposure.<sup>44</sup> Preauricular cysts are located in the subcutaneous layer superficial to the parotid fascia and may seem deeper if they become infected. These cysts and sinuses are lined with stratified squamous epithelium. They do not contain hair-bearing follicles, owing to their origin from the ectoderm associated with external ear formation.<sup>34</sup>

### CLINICAL PRESENTATION

The estimated incidence of preauricular sinuses is 0.1% to 0.9% in the United States and as high as 4% to 10% in Africa.<sup>44</sup> These cysts and sinuses are commonly noted at birth and are more common on the right side.<sup>44</sup> The parent may remark about the familial and bilateral nature of these lesions.<sup>29</sup> Preauricular sinuses usually do not drain. In those situations, excision is not required. However, parents may report that sebaceous-like material drains from the sinus. The presence of drainage is an indication for surgical excision. Sinuses that drain are often connected to subcutaneous cysts that have an increased likelihood of staphylococcal infection. Ideally, these lesions should be completely excised before becoming infected (Fig. 75-13). Prior infection increases the difficulty of complete surgical excision, which increases the risk of recurrence.

### TREATMENT

Complete surgical excision of the sinus tract and subcutaneous cyst to the level of the temporalis fascia is the treatment of choice in the uninfected draining sinus. It is important to avoid rupture of the sinus and to perform a complete excision to decrease the risk of recurrence.<sup>45</sup> If infection supervenes, the lesion is treated with antibiotics and warm soaks to encourage drainage and control of the surrounding inflammation. Occasionally, as with infected branchial cysts, incision and drainage or needle aspiration may be required to control the infection. Surgical excision is often done through an elliptical incision with a small, chevron-shaped skin flap surrounding the sinus. The cyst is then dissected from the subcutaneous tissue and removed in its entirety.<sup>43</sup> The cyst or sinus may have multiple branches, making complete resection difficult. Removal of a small bit of adjacent cartilage reduces the risk of missing one of these branching tracts.<sup>44</sup> The incidence of recurrence is as high as 40%, owing to these multiple branches. As a result, some clinicians have advocated an extended preauricular incision to enhance exposure.<sup>45</sup> Postoperative wound infection also is common.

### Branchio-oto-renal Syndrome

Branchio-oto-renal syndrome (Melnick-Frazier syndrome) is an autosomal dominant disorder that can occur with branchial fistulas and preauricular pits.

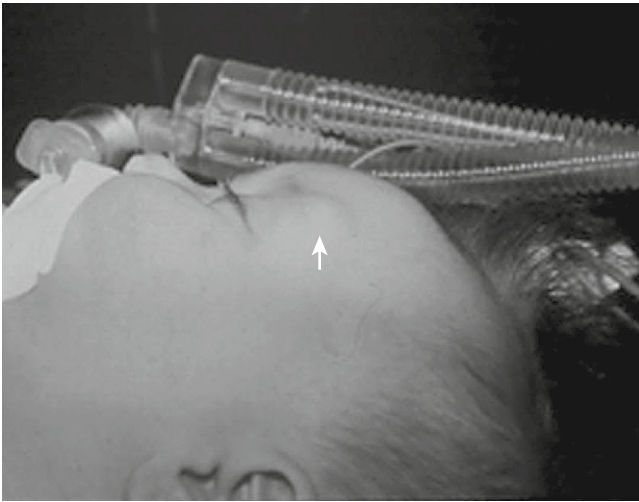

**Figure 75-13.** An infected preauricular cyst. The pit anterior to the helix is difficult to see. Note the swelling and skin changes anterior to the tragus. Preauricular sinuses that drain sebaceous material should be excised electively. Warm compresses and antibiotics allowed the inflammation to diminish. The cyst and sinus were then completely excised.

It occurs in 2% of profoundly deaf students and has been mapped to chromosome 8q13.3, which has roles in cochlear and vestibular development and renal morphogenesis.<sup>46</sup> The typical phenotype includes cup-shaped pinnae; preauricular pits; branchial fistulas; conductive, sensorineural, or mixed hearing impairment; and renal anomalies ranging from mild hypoplasia to agenesis. Hearing loss and preauricular pits are the most common associations, and 50% of patients have branchial cleft fistulas.<sup>46</sup>

### Dermoid and Epidermoid Cysts

Dermoid cysts embryologically represent ectodermal elements that either were trapped beneath the skin along median or paramedian embryonic lines of fusion or failed to separate from the neural tube.<sup>47-50</sup> Dermoids are differentiated from epidermoids histologically by the accessory glandular structures found in dermoids.<sup>47</sup> Dermoids contain sebaceous glands, hair follicles, connective tissues, and papillae.<sup>47</sup> Both contain sebaceous material within the cyst cavity.

Most dermoid or epidermoid cysts are diagnosed before the patient is 3 years of age.<sup>5</sup> The most common location for dermoids in children is along the supraorbital palpebral ridge (Fig. 75-14). This lesion commonly appears as a characteristic swelling in the corner of the eyebrow and is most commonly first noticed at birth or within the first 1 to 3 months of life. Although commonly attached to the underlying bony fascia, this lesion is movable and nontender. Occasionally, the mass may be dumbbell shaped and penetrate through the orbital bone. Dermoids may

**Figure 75-14.** This infant presented with the classic finding of a dermoid cyst located along the supraorbital palpebral ridge (arrow).

occur along the midline or atypical locations such as the medial orbital wall, nose, floor of the mouth, or submental and submaxillary areas.<sup>51</sup> Midline cysts can be confused with midline thyroglossal duct cysts. Dermoids, however, are more superficial and remain mobile when the tongue is forcibly protruded and will lack a deep-seated tract to the hyoid bone or other neck structures. Nasal dermoids may present as a cyst or sinus anywhere from the glabella to the base of the columella.<sup>51</sup> Any midline scalp lesion suspected of being a dermoid should undergo preoperative radiographic evaluation to evaluate for intracranial extension. This is especially important for nasal dermoids, which have been reported to extend to the cribriform plate in 12% to 45% of cases.<sup>51</sup> The best way to evaluate for deep extension of a midline lesion is controversial. Both CT and MRI may be used in a complementary fashion, with CT better for evaluating bony abnormalities and MRI better for defining soft tissue structures. Some clinicians argue that CT alone is adequate; however, false-negative results have been reported.<sup>51</sup> Dermoids and epidermoid cysts gradually increase in size owing to the accumulation of sebum.<sup>49</sup> Infection is rare, but the cysts can rupture, resulting in granulomatous inflammation.<sup>5,49</sup> Fine-needle aspiration may also be helpful in distinguishing an infected thyroglossal duct cyst from a ruptured dermoid.<sup>49</sup>

Surgical excision is the treatment of choice for all dermoids and epidermoids, especially those that are symptomatic, enlarging, or have ruptured. This has been most commonly performed as an open operation, although increasing experience with removing these lesions is accruing by using endoscopic minimally invasive techniques.<sup>52</sup> Proponents of the open technique report good cosmetic results with minimal complications, whereas early reports with the endoscopic technique have reported a few partial facial nerve injuries especially early into the surgeon's learning curve.<sup>53</sup> It is important to completely remove the

capsule and avoid intraoperative rupture to decrease the risk of recurrence. Infection is possible secondary to repeated local trauma. Malignant degeneration of dermoids also is possible but rare.<sup>23</sup> Complete surgical excision is curative.

## Midline Cervical Clefts

Midline cervical clefts are rare congenital cervical anomalies that present at birth as a cutaneous ulceration with overhanging skin or cartilage tag in the anterior lower midline of the neck (Fig. 75-15). There may be a tract that extends downward into the skin connecting to the sternum or mandible, or it can end blindly. The embryologic origin is unknown but thought to be a "mesodermal fusion abnormality" involving the branchial arches.<sup>9</sup> Most are sporadic but can be found with cleft abnormalities of the tongue, lower lip, or mandible. Early surgical excision at the time of diagnosis is recommended to avoid neck contractures or growth deformities of the sternum or mandible. This is achieved through complete excision of the skin lesion and the subcutaneous sinus to reduce the rate of recurrence. Stair-step incisions or a series of Z-plasty incisions may be required.<sup>9</sup>

## Torticollis

### ETIOLOGY

Torticollis in childhood may be congenital or acquired. Congenital torticollis resulting from fibrosis and shortening in the sternocleidomastoid muscle is the most common type.<sup>54-56</sup> The shortening of the

**Figure 75-15.** Congenital midline cervical cleft. (From Foley DS, Fallat ME: Thyroglossal duct cysts and other congenital midline cervical anomalies. *Semin Pediatr Surg* 15:70-75, 2006.)

sternocleidomastoid muscle characteristically pulls the head and neck to the side of the lesion. The resulting “mass” represents the fibrous tissue palpable within the muscle. The etiology of this “fibrous tumor” is debatable.<sup>57</sup> The significant incidence of breech presentations and other abnormal obstetric positions has been used to support both the injury and the tumor etiology. Those who favor tumor see the abnormal presentation as the result of the fixed abnormal head position, whereas those who favor trauma see the difficult extraction as the cause of injury.<sup>55,58</sup> No single theory completely explains this condition.

The etiology of acquired torticollis includes cervical hemivertebra and imbalance of the ocular muscles. In children in whom no identifiable muscular etiology is found, a high likelihood exists of Klippel-Feil anomalies or other neurologic disorders as the cause.<sup>59</sup> Acquired torticollis also should raise the suspicion of otolaryngologic infection, gastroesophageal reflux (Sandifer’s syndrome), or the possibility of a neoplastic condition as the underlying cause.<sup>60,61</sup>

Pathologically, the basic abnormality in congenital torticollis is endomysial fibrosis—the deposition of collagen and fibroblasts around individual muscle fibers that undergo atrophy.<sup>57</sup> The sarcoplasmic nuclei are compacted to form “muscle giant cells,” which appear to be multinucleated. The severity and distribution of fibrosis differ widely from patient to patient. Some cases of fibrosis occur bilaterally. The fact that mature fibrous tissue is present even in the neonate suggests that the disease begins well before birth and probably does not result from a difficult delivery.

## DIAGNOSIS

In a series of 100 infants with torticollis, 66% had a “tumor” in the muscle and the other 34% had fibrosis but no tumor.<sup>24,62</sup> A more recent series of 624 cases from China noted only 35.4% with a tumor.<sup>63</sup> In the typical case, the mass is not found in the neonatal period but is noted at the first “well-baby” checkup, some 6 weeks after birth. The infant has the characteristic posture, with the face and chin rotated away from the affected side and the head tilted toward the ipsilateral shoulder. Acquired torticollis may develop at any age. It is important to keep in mind the various causes of the acquired lesion. Its appearance depends on the severity of the lesion, the distribution of the fibrosis, and the child’s growth pattern. With time, facial and cranial asymmetry develop and a notable flattening of the facial structures on the side of the lesion occurs. This may become irreversible by age 12 years, although there have been reports of excellent results when the surgical procedure is performed after age 10 years.<sup>64,65</sup>

## TREATMENT

Experience with this condition has shown that 80% to 97% of affected infants do not require operative treatment.<sup>63,64</sup> The key to successful treatment is early recognition and prompt physical therapy.<sup>56,66</sup> The longer the shortening of the muscle persists, the more facial and cranial asymmetry develops, and the more the

deeper cervical tissues become involved in the process. Ultrasonography may be used not only as a diagnostic tool but also to help determine which children may be more likely to need surgical therapy. In a study from China, the cross-sectional as well as longitudinal extent of fibrosis in the sternocleidomastoid muscle correlated well with the need for surgical intervention.<sup>67</sup>

In most instances, complete correction can be achieved by early range-of-motion and stretching exercises and positional changes with the infant in the crib. The parents should be taught to perform these exercises with the infant multiple times each day. One parent holds the child’s shoulder down against a firm surface, and the other rotates the head toward the opposite shoulder. When the child’s head is rotated toward the opposite shoulder, the muscle is gently kneaded along its entire course. Often one parent can accomplish the stretching exercises by placing the infant on his or her lap, turning the infant’s head, and gently extending the head and neck over the parent’s knees. An additional maneuver is rearranging the infant’s room, changing objects in the crib, and encouraging the infant to look toward the side opposite the involved muscle. One study showed a mean duration of 4.7 months for successful non-operative resolution.<sup>68</sup> Some clinicians have used botulinum toxin injections in select patients who have failed to improve after 6 months of aggressive physical therapy, avoiding surgery in 74% to 95% of subjects.<sup>69,70</sup>

Some clinicians have suggested that the criterion for operation, regardless of age, is the development of facial hemihypoplasia.<sup>66</sup> In children with significant torticollis, facial hemihypoplasia is invariably present, not always with a linear relation between the two conditions.<sup>66</sup> The muscle can be divided anywhere, but transection in the middle third, through a lateral collar incision, is the simplest and provides the most aesthetically acceptable scar.<sup>66,71</sup> Through this incision, one can divide the fascia colli of the neck, which is often tight and may need to be divided anteriorly as far as the midline and posteriorly to the anterior border of the trapezius. Intensive physiotherapy, including full rotation of the neck in both directions and full extension of the cervical spine, is instituted as soon as possible. Occasionally, in an older child, a splint is used to provide overcorrection and stretching of the muscle.<sup>66,71</sup>

## INFLAMMATORY LESIONS

### Cervical Adenopathy

Enlarged cervical lymph nodes are by far the most common neck masses in childhood. In most instances they are the result of nonspecific reactive hyperplasia.<sup>1</sup> The etiology is often viral or is related to an upper respiratory tract or skin infection. The adenitis resolves spontaneously. Many patients are initially seen with bilateral enlarged nodes. Because the anterior cervical nodes drain the mouth and pharynx, almost all

**Figure 75-16.** Acute suppurative cervical adenitis. Skin is shiny and taut over the centralized abscess cavity.

upper respiratory and pharyngeal infections have some effect on the anterior cervical nodes. Enlarged cervical lymph nodes are frequently palpable in children between ages 2 and 10 years. Palpable nodes are uncommon in infants. A mass in a child younger than 2 years old is more likely to be a cystic hygroma, thyroglossal duct cyst, dermoid cyst, or branchial cyst. The mass can often be diagnosed on clinical findings.<sup>72</sup>

Because the head contains so many structures through which bacteria or viruses may enter the body, the cervical lymph nodes frequently become involved in these cervicofacial infections and inflammatory diseases. Cervical nodes also may be the first clinical manifestations of various tumors, particularly those of the lymphoma group.<sup>1</sup> The most frequent inflammatory lesion of the cervical lymph nodes is suppurative lymphadenitis (Fig. 75-16). Others of importance are cat-scratch disease, atypical mycobacterial lymphadenitis, and tuberculous lymphadenitis. Less common but important considerations in the differential diagnosis of cervical adenitis include Kawasaki's disease and acquired immunodeficiency syndrome (AIDS).

### Acute Suppurative Cervical Lymphadenitis

The most common cause of acute lymphadenopathy is a bacterial infection arising in the oropharynx or elsewhere in the drainage area.<sup>73</sup> The most common organisms are penicillin-resistant *Staphylococcus aureus* and *Streptococcus hemolyticus*, although cultures of the pus often yield a mixture of both or prove to be sterile.<sup>73</sup> *Staphylococcus* may be more prevalent in infants.<sup>74</sup> Anaerobes, although common in the oropharynx, are not common pathogens in cervical adenitis. The diagnosis is usually apparent. Fever is variable and usually mild. Initial treatment with antibiotics is often followed by resolution without suppuration. Without treatment, the node often enlarges and becomes

fluctuant, eventually leading to thinning of the overlying skin and abscess formation. Needle aspiration can be both diagnostic and therapeutic. Aspiration of the purulent material confirms the diagnosis. The material obtained can be cultured (Fig. 75-17). Frequently, needle aspiration and drainage of the purulent material coupled with judicious antibiotic therapy may alleviate the necessity of formal incision and drainage. Occasionally, repeated aspirations may be necessary.

If the child appears toxic or is quite young, hospitalization and intravenous antibiotics, including a  $\beta$ -lactamase-resistant antibiotic, may be helpful, but formal incision and drainage is often required. The node can be incised and the cavity packed loosely with a Silastic drain. The parent can be taught to perform irrigations through the drain, which encourages drainage of the residual debris. Usually, apparent improvement is evident in 2 to 3 days, although antibiotic therapy should be continued for 10 days. Complete resolution of the adenopathy may take weeks.

### Chronic Lymphadenitis

Children occasionally have impressively enlarged nodes that do not seem to be acutely infected. The nodes are not as inflamed or as tender as those in acute bacterial adenitis. Progression to fluctuation is unlikely. The child with this type of lymphadenopathy must be evaluated for tuberculosis, atypical mycobacterial infection, and cat-scratch disease. Most children should receive a full 2-week course of an oral anti-staphylococcal antibiotic. The same physician should examine the child on a number of occasions to assess the results of therapy. A single dominant lymph node present for longer than 6 to 8 weeks that has not responded to appropriate antibiotic therapy, should be completely excised, fully cultured, and submitted for histologic examination to exclude the diagnosis of malignancy. Nodes present in the supraclavicular space

**Figure 75-17.** Aspiration of purulent material confirms the diagnosis of suppurative lymphadenitis. Frequently, repeated aspirations may be necessary to remove the majority of debris and can often obviate the need for formal incision and drainage.

and posterior triangle tend to be more of a concern for malignancy than those found in the submandibular or anterior triangle.

### *Mycobacterial Lymphadenitis*

#### CLINICAL PRESENTATION

The prevalence and the relative incidence of infections caused by different mycobacteria vary with the success of preventive health measures in particular populations.<sup>75</sup> In developed countries, bovine mycobacteria have been eliminated from milk. Most mycobacterial lymphadenitis is caused by the atypical mycobacteria of the *Mycobacterium avium-intracellulare-scrofulaceum* (MAIS) complex.<sup>75</sup> Internationally adopted terminology defines this group of 10 to 15 mycobacteria, which produce a specific and localized form of lymphadenitis.<sup>20,47,75</sup> The portal of entry is primarily through the mucous membranes of the pharynx. Lymphadenitis resulting from infection with *M. tuberculosis* is thought to be an extension of a primary pulmonary infection and usually involves the supraclavicular nodes.<sup>76</sup> Infection with the atypical strains usually involves higher cervical nodes, most commonly the submandibular or submaxillary.<sup>76</sup> This finding is consistent with the etiology being a primary infection and not pulmonary disease. Infection is most commonly seen between ages 1 and 5 years; occurrence before age 1 year is rare. The disease involves unilateral nodes, and dissemination is rare. Atypical mycobacteria enter from the environment and are not contagious, although the reservoir may be the mouth and oropharynx of apparently healthy children.<sup>74</sup> Person-to-person spread of disease has not been documented, and isolation is not necessary.

Infection with atypical mycobacteria is generally limited to the lymph nodes. Pediatric patients with atypical mycobacterial lymphadenitis are usually asymptomatic. The nodes are usually nontender. Spontaneous regression of the atypical lymph node infection may occur but is likely to lead to breakdown of the nodes, resulting in sinus or fistula formation. Children with tuberculous scrofula usually are symptomatic. Most have pulmonary tuberculosis when the diagnosis is made.<sup>77</sup> It is rare for the infection to progress from cervical adenopathy to pulmonary disease if the initial chest radiographs are clear. Degeneration of nodes with abscess and fistula formation is unusual.

#### DIAGNOSIS

In children, tuberculous or atypical mycobacterial lymphadenitis presents as a clinical picture of chronic lymph node hypertrophy.<sup>78</sup> Pulmonary tuberculosis on chest radiograph helps to identify the cause of the cervical swelling. Patients with MAIS usually have a normal chest radiograph. Skin testing helps differentiate these diseases. All children with tuberculosis should show positive test results to second-strength purified protein derivative (PPD). Children with atypical mycobacterial infection have either a negative or a doubtful skin test. If the initial PPD is inconclusive, second-strength PPD may help confirm the

mycobacterial etiology. A history of familial exposure to tuberculosis should suggest tuberculosis as more likely than atypical mycobacteria. Although specific skin tests for atypical mycobacteria often provide positive results, it is difficult to obtain the appropriate antigen. Final diagnosis may depend on culture results or histopathology after excision of the involved nodes.<sup>79</sup>

#### TREATMENT

It is important to distinguish tuberculous from MAIS lymphadenitis because the treatment is significantly different. In tuberculous infections, antituberculous chemotherapy is required, usually resulting in marked resolution of the lymphadenopathy within a few months. Chemotherapy is continued for 2 years.<sup>77</sup> Surgical intervention in a human tuberculosis infection is confined to an excisional biopsy of a node if the diagnosis cannot be made on other grounds. Most children with tuberculous lymphadenitis respond well to chemotherapy with standard drugs.

Treatment of MAIS infections is primarily surgical.<sup>80</sup> Careful, thorough excision of the group of affected nodes (the one or two sentinel nodes) and adjacent smaller nodes is required. This procedure should ideally be performed before extensive ulceration of the overlying skin occurs. Standard chemotherapy for tuberculosis is of no value in MAIS infections except in patients in whom a draining sinus develops after primary excision of infected nodes.<sup>81</sup> Children with atypical mycobacterial infection respond well to complete surgical excision without drug therapy. Some authors report successful treatment with antibiotics alone (e.g., clarithromycin, ethambutol, and rifampin) in patients whose lesions were too close to the facial nerve or other key structures.<sup>82</sup>

#### *Cat-Scratch Disease*

The incidence of cat-scratch disease varies greatly in different parts of the world. In developed countries, cat-scratch disease is the most common cause of non-bacterial chronic lymphadenopathy.<sup>83</sup> *Bartonella henselae*, a gram-negative rickettsial organism, is responsible for most cases of cat-scratch disease.<sup>84</sup> The disease is usually transmitted via a superficial wound caused by a cat, dog, or monkey.<sup>85</sup> A healthy kitten is the most frequent vector. The disease begins as a superficial infection or pustule forming in 3 to 5 days and is followed by regional adenopathy in 1 to 2 weeks. Generally, only one node is involved. Nodal involvement corresponds to the inoculation site and the nodes that drain it. The axilla is the most commonly involved area.<sup>1</sup> The diagnosis can be made by a commercially available indirect fluorescent antibody test for detection of antibody. Histology findings are characteristic but not pathognomonic. Polymerase chain reaction studies for *B. henselae* on a fine-needle aspirate may be useful when the diagnosis is in question, although this technique is not readily available in all hospitals.<sup>86</sup> Complete excision of the involved node may be needed to confirm the diagnosis. Patients usually have

tender lymphadenopathy and few systemic symptoms. On rare occasions, complications include encephalitis, retinitis, and osteomyelitis. The delay between inoculation and subsequent lymphadenopathy can approach 30 days.<sup>85</sup> Treatment of cat-scratch disease is most often symptomatic because the disease is usually self-limited. Lymphadenopathy resolves spontaneously over a period of weeks to months with only occasional suppuration. Specific antimicrobial therapy against *B. henselae* has not proved efficacious, although it is susceptible to many common antibiotics. Azithromycin, rifampin, ciprofloxacin, and trimethoprim-sulfamethoxazole may be useful if antibiotics are needed.<sup>87,88</sup>

## Lesions of the Salivary Glands

Surgical lesions of the salivary glands in children are unusual. In this section we address benign and inflammatory conditions in these glands.

### Ranula

In children, prominent, glistening, cystic masses occasionally develop below the tongue in the floor of the mouth. These cystic lesions generally arise from the sublingual glands and are known as ranulas (Fig. 75-18).<sup>89</sup> Most are simple cysts that result from the partial obstruction of the sublingual salivary duct. The traditional ranula is a simple cyst lined with salivary ductal epithelium. Occasionally, the sublingual duct can become completely occluded. The duct may rupture, which leads to the formation of a pseudocyst. The pseudocyst forms because amylase-containing secretions extravasate and erode or “plunge” into the neck muscles. This leads to the condition known as “plunging ranula.”<sup>90,91</sup> This lesion lacks a true epithelial lining.<sup>90</sup>

**Figure 75-18.** A simple cystic ranula, located below the tongue, is arising from the sublingual glands.

Many surgeons suggest marsupialization at the initial procedure for a simple ranula.<sup>92,93</sup> By incising the cyst and draining the contents, the mass rapidly decreases in size. Suturing the epithelium back on itself allows the partially occluded duct to drain. Marsupialization alone has a fairly high recurrence rate, and complete resection or marsupialization with packing may be preferable.<sup>92,93</sup> Concurrent resection of the ipsilateral sublingual gland has been shown to decrease the rate of recurrence (1.2% compared with 66%).<sup>93,94</sup> Recent trials with picibanil (OK-432) similar to therapy for lymphangioma have been described with some success in Japan.<sup>95</sup>

The complex or plunging ranula requires a more extensive dissection into the neck to totally excise the pseudocyst and the atrophied sublingual gland.<sup>91</sup> This may be accomplished using an intraoral approach but may require a cervical incision. Dissection may be tedious in this inflamed area because the hypoglossal and lingual nerves run beneath the sublingual gland and become entrapped in the mass.

### Parotid Hemangioma

This is the most common benign neoplasm affecting the major salivary glands and is seen most often in female infants at birth or within the first few months of life.<sup>96</sup> It is usually confined to the intracapsular component of the gland and rarely involves the overlying subcutaneous tissues and skin. A surface sentinel lesion may be present. It appears as a spongy mass anterior to the ear. The diagnosis is usually evident on physical examination. Rarely is a cutaneous component present in the hemangioma. Growth may be rapid in the first few weeks of life. Ultrasonography is helpful, and MRI can be useful in establishing the diagnosis. Most parotid hemangiomas involute by age 4 to 6 years, and only 10% need surgical intervention. One series demonstrated that parotid hemangiomas, like other hemangiomas, respond to medical therapy with corticosteroids or interferon in 98% of cases, with surgical therapy being delayed until the involuting or involuted phase for reconstruction only.<sup>97</sup> Surgical resection puts the seventh nerve at risk so it must be conducted with great care.

### Sialadenitis

Inflammation and swelling of the salivary glands are not common in children. Sialadenitis may appear as an acute suppurative infection, a chronic infection, or a granulomatous replacement of the gland. Acute suppurative sialadenitis is most frequently seen in infants. The organism most often involved is *S. aureus*, followed by *Streptococcus* and group D pneumococcus.<sup>98</sup>

The pathophysiology of chronic sialadenitis may involve duct ectasia, stricture, and sialolithiasis. Sialectasis, a sacular dilation of the small, intercalated ducts that connect acini with the striated ducts, is a common congenital abnormality of the gland. Sialolithiasis occurs much more commonly in the submandibular than in the parotid gland. Culture of material from the

duct may not reveal pathogenic organisms. Recurrent bacterial infection without demonstrable obstruction is the primary problem in some cases.

#### CLINICAL PRESENTATION

Sialadenitis is characterized by episodes of pain that may last from 1 to 7 days. Swelling and pain are isolated to the anatomic distribution of the gland and do not involve the overlying skin and subcutaneous tissue. Secretions are thick and flocculent. Bilateral involvement may occur over time, although each acute episode tends to be unilateral.

#### DIAGNOSIS

Salivary gland abnormalities may follow diseases such as mumps. Tenderness may occur, with cystic or solid swelling of the gland. The pus may be seen draining from Warthin's duct. Plain radiographs are useful in detecting radiopaque stones, which are seen four

times more frequently in the submandibular than in the parotid gland.<sup>98</sup> Sialography remains the definitive study for ductal abnormalities, although it is associated with some discomfort and may require general anesthesia in younger children. High-resolution ultrasonography may demonstrate ductal ectasia.<sup>98</sup> CT has been used in children to evaluate vascularity and abscess formation. MRI may be useful in imaging the course of the facial nerve through the parotid gland.<sup>99</sup> Incisional biopsy is rarely indicated. The utility of fine-needle aspiration is questionable.<sup>100</sup>

#### TREATMENT

Antibiotics may be useful in both acute and recurrent sialadenitis. Nonspecific therapy with sialagogues, with massage of the gland, may be helpful. Sialolithotomy or dilation with removal of demonstrated calculi is usually curative. Radical surgical treatment is rarely necessary in children.

# PEDIATRIC AND ADOLESCENT GYNECOLOGY

Julie Strickland, MD

From birth through adulthood, many gynecologic conditions may come to the surgeon's attention. Acute gynecologic problems may mimic urologic or general surgical diseases. Surgeons who care for children must be equipped to diagnose and treat a variety of developmental and acquired disorders of the vulva, vagina, upper female genital tract, and ovary. It is important to begin with an understanding of the normal anatomy and developmental changes of the genital tract. Knowledge of examination techniques and modifications necessary in children to obtain diagnostic information can facilitate accurate diagnoses. Consequently, the proper use and interpretation of radiologic and endoscopic techniques is essential in the care of female children and adolescents.

## NORMAL GENITAL ANATOMY

The genital tract undergoes visible morphologic changes from infancy through childhood and adolescence.<sup>1,2</sup> At birth, owing to the influence of maternal circulating estrogens, the labia majora are anteriorly placed and edematous. The mons pubis has a flattened triangulated look. The labia majora are thickened and cover the introital opening. The clitoral proportion is larger. The vestibule and hymen are pale and thickened and may occlude visualization of the vaginal canal without manipulation. The vagina is rugated and moist, and vaginal secretions may be present. The cervix is visible, and the uterus may contain functioning endometrial tissue, leading to the occurrence of estrogen-withdrawal bleeding in infancy.

During early childhood, the vulva remodels with thinning and attenuation of the labia majora and minora. The vestibule takes on an erythematous color with prominent vascular markings. It may now lie unopposed by the labia, allowing for easy visualization of the vaginal orifice with minimal retraction. The hymen of a prepubescent female is normally easily visualized and is thin, often translucent, and inelastic. Normal variations in the shape and amount of hymenal

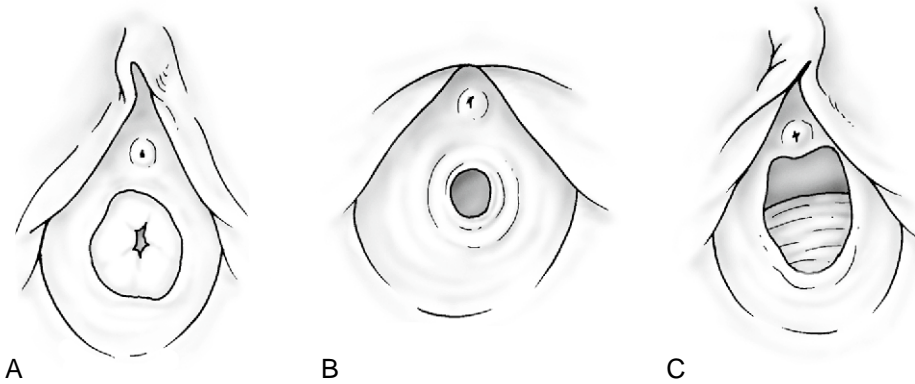

tissue have been described, (Fig. 76-1). Knowledge of these variations becomes important in the evaluation of penetrating injuries and anomalies<sup>3-5</sup> The vagina has an erythematous appearance and is inelastic and without rugations. Normally, the pH is mildly basic and a mixture of bacterial flora is present. The cervix is flush with the vaginal vault and may be difficult to identify. The uterine fundus is poorly developed, with the cervicovaginal ratio being 3:1. No endometrium is visualized on sagittal imaging.

With the onset of puberty, the mons, labia majora, and labia minora all begin to develop. The vestibule begins to lose its erythematous appearance and lies opposed by the labia majora. The hymen thickens and becomes elastic and redundant.<sup>6</sup> The vagina grows in length and develops rugations. The cervix develops a well-defined junction from the uterus, and the uterine fundus develops a rounded appearance. Evidence of an endometrial lining begins to be seen before menarche.

Folliculogenesis of the ovary, with small cyst formation, can be imaged as early as 16 weeks of gestation.<sup>7</sup> Three to 5 percent of children have small incidental ovarian cysts detected on ultrasound evaluation.<sup>8</sup> Follicular growth and atresia occurs throughout childhood, with increased follicular activity and size coinciding with advancing age.<sup>9</sup> Ovarian volume and position change with age, with the ovaries intra-abdominal in childhood and assuming a pelvic position at puberty.

## GENITAL EXAMINATION

The genital examination of a child can be anxiety provoking to both the child and her parents. It is important to have a calm, professional attitude and establish rapport with the patient and her family. Examinations are not very successful if they are hurried, forced, or exceed the developmental understanding of the child. An adequate light source and proper positioning are usually all that is needed to accomplish an examination

**Figure 76-1.** A to C, Normal anatomic variations of the hymen. (Adapted from Pokorny SF, Stormer J: Atraumatic removal of secretions from the prepubertal vagina. *Am J Obstet Gynecol* 156:581-583, 1987.)

**Figure 76-2.** Examination of the genitalia by labial traction. Gently grasping the posterior labia majora and pulling anteriorly and superiorly allows visualization of the genital structures.

in a prepubertal child.<sup>10</sup> For visualization of the vulva, introital opening, and lower vagina, gentle downward traction on the labia in a lithotomy position is usually successful (Fig. 76-2). Placing the child on the mother's lap can sometimes facilitate the examination in young children. The knee-chest position may offer a clearer view of the hymen and lower vagina (Fig. 76-3).<sup>11</sup> A magnifying glass, colposcope, or otoscope may be helpful to see the detail of the lower vagina.<sup>12</sup> The office use of speculums is discouraged in prepubertal

**Figure 76-3.** Knee-chest positioning. The lower vagina and hymen can occasionally be viewed more successfully by using the knee-chest position.

children. Comprehensive vaginal inspection, when necessary, is ideally done through endoscopic instruments under sedation.<sup>13,14</sup> By gently occluding the vaginal orifice, the entire vaginal canal can be visualized with hydrodistention. Speculum examinations of the vagina are usually well tolerated in postpubertal girls when a narrow-caliber straight blade speculum is gently inserted. Bimanual examinations can be accomplished through a rectal approach or, in adolescents, with a single digit inserted into the vaginal fornix. Imaging with ultrasound or, occasionally, magnetic resonance imaging (MRI) is adjuvant to examination and provides additional information on the status of the upper genital tract.<sup>15</sup>

### Vulvar Abnormalities

Vulvar pruritus, pain, and discharge are common complaints in children. An etiology can be obtained in most cases with careful external inspection and, if necessary, blind vaginal cultures. Biopsy is seldom indicated. Most often, symptoms involve irritation or eruption of the vulvar skin related to hygienic practices. Atopic or irritant dermatitis are the most common diagnoses.<sup>16</sup> Infections are more associated with acute inflammation with erythema and the presence of a vaginal discharge.<sup>17</sup> Common respiratory pathogens such as *Streptococcus pyogenes* and *Haemophilus influenzae* may cause acute genital symptoms.<sup>18,19</sup> When a bacterial infection is suspected, cultures of the vagina may be obtained by using moistened urethral swabs, feeding tubes, or catheters. A double-catheter system with a butterfly catheter within a small rubber catheter can be used to collect upper vaginal secretions.<sup>20</sup>

Recurrent or persistent vaginitis despite treatment should alert the clinician to the presence of a retained foreign body in the vagina. Occasionally, foreign bodies also may cause vaginal bleeding and become symptomatic as a protruding mass.<sup>21,22</sup> The most common foreign body is toilet paper shreds.<sup>21</sup> Pelvic ultrasonography may reveal the bladder-indentation sign, suggesting a foreign body.<sup>23</sup> When a foreign body is suspected, vaginal lavage can be attempted in the office by using warm-water saline in a venous catheter or straight urinary catheter. Vaginoscopy under sedation may be necessary to retrieve an object. Endoscopic

**Figure 76-4.** Lichen sclerosus diagnosed in a 5-year-old. A sharp demarcation of hypopigmented, thin epithelium is seen. This lesion is often associated with fissures and purpura.

instruments such as cystoscopes or hysteroscopes allow easy location of the object with minimal trauma to the genital area.<sup>14</sup>

Vulvar dermatoses may lead to acute vulvovaginal symptoms. Lichen sclerosus has the hallmark characteristic of a loss of skin markings with a sharply demarcated pale epithelial ring encircling the introitus but sparing the vagina (Fig. 76-4). Signs of inflammation and trauma may be present, with purpura, fissures, and secondary infection associated with scratching. Lichen sclerosus may be confused with sexual abuse in some cases. Mainstays of treatment include avoidance of trauma with loose clothing, mild soaps, and the generous use of emollients. Early treatment with ultrapotent corticosteroids may be effective in reducing symptoms of lichen sclerosus and minimizing long-term scarring. In 20% of patients, ultrapotent corticosteroids have been shown to reverse skin changes.<sup>24</sup> Tacrolimus has been reported to offer similar benefit to pediatric patients.<sup>25</sup> Other dermatologic conditions such as psoriasis, eczema, and allergic dermatitis also may mimic vulvovaginitis.<sup>14</sup>

Labial agglutination or adhesions occur relatively frequently in prepubescent girls (Fig. 76-5). Adhesions are thought to occur because of irritation or trauma to the unestrogenized labia, leading to a midline fusion of the labia. Adhesions can be associated with an increase in urinary tract infections, perineal wetness, symptomatic vulvitis, and an inability to access the urethra and vaginal orifice. When symptomatic, the treatment of choice is an estrogen-based cream applied under traction to the adhesion site.<sup>26,27</sup> Surgical separation is seldom indicated because of the efficacy of topical hormonal therapy but may be necessary in unusually dense adhesions or those that have required previous separation.<sup>26,27</sup> Even with recurrent or persistent labial agglutination, estrogen therapy was effective in over one third of cases in one study.<sup>28</sup> Long-acting local anesthetics, such as EMLA cream, may allow office separation in some girls.<sup>29</sup> Manual separation of the adhesions without anesthesia should

**Figure 76-5.** A 2-year-old child with labial (minora) adhesions is seen.

be avoided because of the discomfort and the high risk of recurrence.

## Genital Bleeding

Unexplained bleeding from the genital area in a prepubescent child is always abnormal (Table 76-1). Bleeding is most commonly extragenital, resulting from hematuria, rectal fissures, and vulvar epithelial irritation. Prolapse of the urethra may occur and be associated with bleeding or even gangrenous changes. A red, granular lesion is seen protruding from the urethral meatus (Fig. 76-6). Topical treatment with estrogen-based cream usually relieves the symptoms. If symptoms persist, excision of the redundant tissue may be necessary. Vaginal bleeding may be associated with precocious puberty or autonomous production or exogenous sources of hormonal stimulation. It is important to perform a detailed physical examination searching for evidence of breast development, estrogenization of the genital tract, or the presence of an

**Table 76-1** Causes of Genital Bleeding in Prepubescent Girls

Genital trauma: Accidental, sexual abuse
Genitourinary: Urethral prolapse, urinary tract infections
Gastrointestinal: Inflammatory bowel disease, rectal fissure, hemorrhoids
Vulvovaginitis: Acute dermatitis, pinworms, $\beta$ -hemolytic <i>Streptococcus</i> , <i>Shigella</i>
Foreign body
Vulvar dermatosis: Lichen sclerosus
Condylomata acuminata
Hemangiomas
Tumors: Malignant or benign endocrine abnormalities: isosexual precocious puberty, pseudoprecocious puberty, exogenous hormonal stimulation

**Figure 76-6.** Urethral prolapse was found in this 6-year-old child with a history of recurrent painless genital bleeding.

abdominal mass. In the absence of a satisfactory explanation for the source of bleeding, vaginoscopy should be performed to evaluate the vaginal canal and cervix for the presence of a foreign body, trauma, infection or, rarely, primary and metastatic tumors of the lower genital canal.

Acute genital bleeding in children requires immediate evaluation for the presence of serious injury or sexual abuse.<sup>30</sup> If the source of bleeding is not readily apparent, if the entire lesion cannot be identified, or if the patient is not tolerant of the examination, vaginoscopy under sedation is indicated.<sup>31</sup> Straddle injuries are common during childhood from accidental falls onto blunt objects, resulting in soft tissue trauma from striking the pubic symphysis or rami. Straddle injuries are usually anterior, involving the mons, clitoris, and labia and sparing the vaginal ring or perineal body (Fig. 76-7). They may result in hematoma formation, linear lacerations, or abrasions. Vulvar hematomas can be extensive but are usually self-limited. In the absence of acute ongoing hemorrhage, small or moderate hematomas can be managed conservatively with bed rest, ice, and pain control. Evacuation of extremely large hematomas causing distortion of the pelvic midline occasionally is necessary to facilitate recovery. Evacuation with debridement should be performed with the child under anesthesia by incising the medial mucosal surface and placing absorbable sutures for hemostasis and closure of dead space.<sup>32</sup> Drainage of the urinary bladder may be necessary because of edema, resulting in urinary retention.

**Figure 76-7.** An extensive vulvar hematoma is seen after a straddle injury. (Courtesy of Diane Merritt, MD.)

Penetrating injuries can occur through accidental impalements onto irregular objects, but the possibility of sexual abuse must always be strongly considered (Figs. 76-8 and 76-9). In the prepubertal child, lacerations involving or occurring above the hymenal ring require vaginoscopy under general anesthesia. Because of the inelasticity of the vaginal epithelium, penetrating injuries can result in disruption of the vagina, with possible internal hemorrhage and hematoma formation.<sup>33</sup> All injuries that cannot readily be explained by the presenting history should be referred to child protection. Surgeons should familiarize themselves with the legal and social resources for sexual abuse diagnosis and care that are available within their communities.

**Figure 76-8.** A 9-year-old girl has a penetrating posterior vaginal injury sustained after falling onto an open cabinet. A urinary catheter has been inserted in the urethra.

**Figure 76-9.** An 8-year-old victim of acute sexual assault has small bowel herniating through the apex of the avulsed vagina. Note the abundant, although transected, amount of hymenal tissue (*arrows*) present, indicating that she had not had significant stretch trauma to her hymen before this episode of rape. (From Pokorny SF, Pokorny WJ, Kramer W: Acute genital injury in the prepubertal girl. *Am J Obstet Gynecol* 166:1461-1466, 1992.)

Introital masses in children occasionally come to the attention of surgeons. Masses of the introitus or vagina are most commonly epithelial inclusion cysts of the hymen or lower vagina and often spontaneously resolve. In young girls, the rare possibility exists of embryonic rhabdomyosarcoma, a malignant primary tumor that appears as indolent, grape-like masses protruding from the vagina (Fig. 76-10). Other possibilities include condylomata acuminata, ectopic ureter, and an obstructive vaginal anomaly. Occasionally, the Bartholin gland or periurethral gland may occlude or form an abscess, leading to an acquired lateral mass. It is important that the origin of the mass be fully evaluated, with evaluation under anesthesia as necessary. Transperineal ultrasonography may be helpful to delineate the mass further. In cases that are unclear, biopsy or excision (or both) are essential.

## UTEROVAGINAL ANOMALIES

Developmental abnormalities causing agenesis or obstruction of the genital tract can occur in children. These can often be recognized in the newborn period with routine examination, but the majority are diagnosed in the adolescent period with the lack of anticipated menses or with symptoms of obstruction.

Imperforate hymen is the most commonly diagnosed obstructive anomaly, with an incidence of less

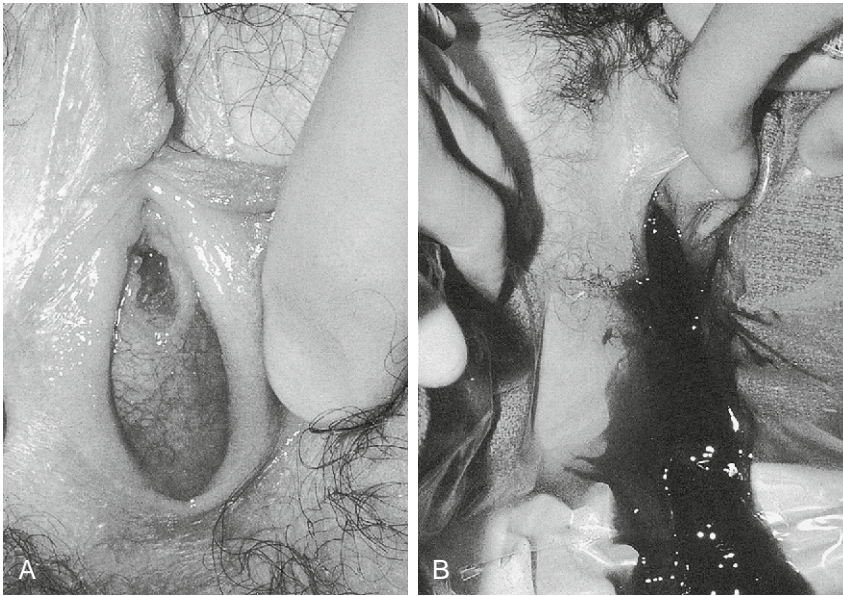

**Figure 76-10.** A 3-year-old with an extensive protruding vaginal mass diagnosed as embryonic rhabdomyosarcoma of the vagina. These rare tumors often begin as an indolent-appearing mass at the introitus. (Used with permission from the North American Society for Pediatric and Adolescent Gynecology, 1999.)

than 1%.<sup>4,34</sup> It arises as an isolated anomaly from failure of canalization of the urogenital sinus. Symptoms typically are first noted during late puberty with cyclic pelvic pain and introital distention, associated with the absence of menstruation. With the continued accumulation of menstrual blood, a pelvic mass and obstructive genitourinary or gastrointestinal symptoms may develop. Occasionally, presentation will be in the newborn period because of the accumulation of mucus, producing an abdominal mass (Fig. 76-11). Transabdominal ultrasonography reveals a dilated vaginal and uterine canal. If this is found during childhood and is asymptomatic, correction is usually deferred until the

**Figure 76-11.** Mucocolpos, leading to urinary obstruction in a 2-day-old infant.

**Figure 76-12.** A, Imperforate hymen in a 12-year-old girl with a 6-month history of recurrent abdominal pain. B, Evacuation of the menstrual obstruction at hymenotomy.

onset of puberty. Surgical excision of the hymen with evacuation of the retained menstrual fluid provides permanent correction (Fig. 76-12). This is performed by carefully identifying the anatomic landmarks, such as the urethra and the lateral hymenal borders. It is important to recognize that significant distention of the posterior vaginal wall may cause the hymenal membrane to be located in a more superior position. A cruciate incision is made into the membrane inferior

to the urethral meatus. After decompression, the individual flaps of tissue are then excised. The vaginal mucosa is sutured to the introital edge with interrupted absorbable sutures to avoid stenosis (Fig. 76-13). Needle aspiration without definitive surgical correction is contraindicated because of the possibility of bacterial seeding and abscess development.

A transverse vaginal septum also may exist at various levels of the vagina because of failure of unification

**Figure 76-13.** A, Imperforate hymen. B, A cruciate incision is made in the apex of the hymen after identifying the outer hymenal borders. C, The hymenal remnants are trimmed. D, Interrupted sutures are utilized for hemostasis.

**Figure 76-14.** The transverse vaginal septum is the result of failed unification or canalization of the urogenital sinus and the müllerian duct. It can arise anywhere in the vagina, but is most common in the upper vagina.

of the urogenital sinus and the müllerian ducts during embryogenesis. A vaginal septum may be complete or partial and may occur at any level in the vaginal canal (Fig. 76-14).<sup>35</sup> These lesions are most common in the upper vagina. Because the introitus may appear normal, the diagnosis may be delayed. MRI or ultrasonography is essential in defining this anomaly and indicating the thickness of the septum.<sup>36</sup> Before surgical exploration, it is important to ensure the presence of cervical tissue by imaging to differentiate this condition from true agenesis of the cervix. Surgical correction is dependent on the location and thickness of the septum, but most often entails excision of the septum with a vaginal-mucosal anastomosis. A thick septum may require preoperative vaginal dilation, mobilization of the upper vagina, or occasionally a skin graft to maintain vaginal patency. Circumferential stenosis is common at the anastomotic site, particularly with high or thick septa. Vaginal dilation may be required postoperatively. Occasionally, a uterine duplication is associated with hypoplasia of one cervix and obstruction. This condition is treatable with laparoscopic hemihysterectomy of the affected side.<sup>37</sup> True cervicovaginal agenesis is a rare disorder associated with an obstructed uterine canal, the absence of a patent cervix, and agenesis of the upper vagina (Fig. 76-15). The lower vagina may be patent. These patients are initially seen with cyclic or noncyclic abdominal or pelvic pain (or both) and a pelvic mass. This condition has a poor prognosis for reconstruction, with reports of significant morbidity from ascending infection and even death.<sup>38</sup> Hysterectomy is usually recommended, but the surgical creation of a vagino-uterine fistula has also been described.<sup>39,40</sup>

Occasionally, patients may be seen with a duplication of the uterus and cervix and a unilateral obstructing longitudinal septum of the vagina. Associated ipsilateral renal agenesis or hypoplasia is commonly found.<sup>41</sup> Menstruation occurs from the nonobstructed side, so the diagnosis may be made well past menarche. Pelvic ultrasonography and MRI are very reliable in distinguishing these disorders, especially when

**Figure 76-15.** A sonographic sagittal view of the pelvis of a 16-year-old girl with cervicovaginal agenesis and a resultant hematometra. Note the dilated vagina and uterus (UT).

obstruction is present (Fig. 76-16).<sup>36,42</sup> Surgical repair through a vaginal approach is performed at diagnosis, with full excision of the vaginal septum. Care must be taken to approximate the vaginal mucosa of the two cavities.

Mayer-Rokitansky-Küster-Hauser syndrome was first described in 1961 and includes primary amenorrhea in women with normal secondary sexual characteristics, uterine hypoplasia, and congenital absence of the vagina.<sup>43</sup> The incidence is approximately 1 in 5000.<sup>44</sup> Because of failure of development of the müllerian system, the uterus, cervix, and upper two thirds of the vagina fail to form. Renal and skeletal anomalies are commonly associated with this disorder. Although patients have primary amenorrhea, pubertal development and ovarian function are normal. The diagnosis can be made clinically on the basis of a normal phenotype and the genital findings cited earlier. An absent uterus with an elevated testosterone, poor breast development, virilization, or the lack of sexual hair

**Figure 76-16.** MR image of a 16-year-old girl with a complete uterine duplication and a blind right hemivagina. Note the obstructed and dilated right hemivagina (asterisk) and the resultant right-sided hematocolpos and hematometra.

**Figure 76-17.** Sequential vaginal dilators are often used to create a coital pouch in individuals with vaginal agenesis.

requires a full chromosomal and hormonal evaluation for the presence a disorder of sexual development.

Therapy for this condition is centered on creation of an adequate vaginal pouch to allow normal sexual functioning. The use of Lucite dilators, first popularized in the 1930s, has provided a highly effective nonsurgical alternative for many patients with agenesis (Fig. 76-17).<sup>45,46</sup> Through the use of successive pressure dilators placed at the hymenal ring, the vaginal vault can be lengthened and enhanced to provide an adequate vaginal capacity. This approach has the advantage of being patient controlled and associated with extremely low morbidity. Vaginal dilation can usually be accomplished over a 2- to 3-month period or even more rapidly in highly motivated individuals. Sexual satisfaction of young women treated with dilation has been shown to be comparable with a normal population.<sup>47</sup> In selected patients, surgical creation of an artificial vagina may be indicated.<sup>48</sup> Many surgical options have been described, with the split-thickness graft vaginoplasty being advocated most often for patients with agenesis.<sup>49</sup> In this approach, a split thickness of skin is harvested from an aesthetic place on the buttocks and sewn, dermal side exposed, over a vaginal mold (Fig. 76-18). The potential space above the levator plate is surgically dissected, followed by placement of a skin-covered vaginal mold. The vaginal mold is sutured in place. After initial epithelialization, the mold is removed and the patient is required to dilate the vagina for several months to maintain patency. Surgical outcome and patient satisfaction remains high for this type of vaginoplasty.<sup>50,51</sup> Other materials such as amnion, peritoneum, and absorbable adhesion barriers (INTERCEED, Ethicon, Somerville, NJ) have been described as an alternative to skin grafting.<sup>52,53</sup> Novel laparoscopic techniques using these alternatives have also been described.<sup>54</sup> New laparoscopic methods using a transperitoneal pulley system to advance the neovagina have shown rapid correction with high success rates.<sup>55</sup>

The use of sigmoid bowel pedicles pulled to the introitus for vaginal creation is less commonly utilized

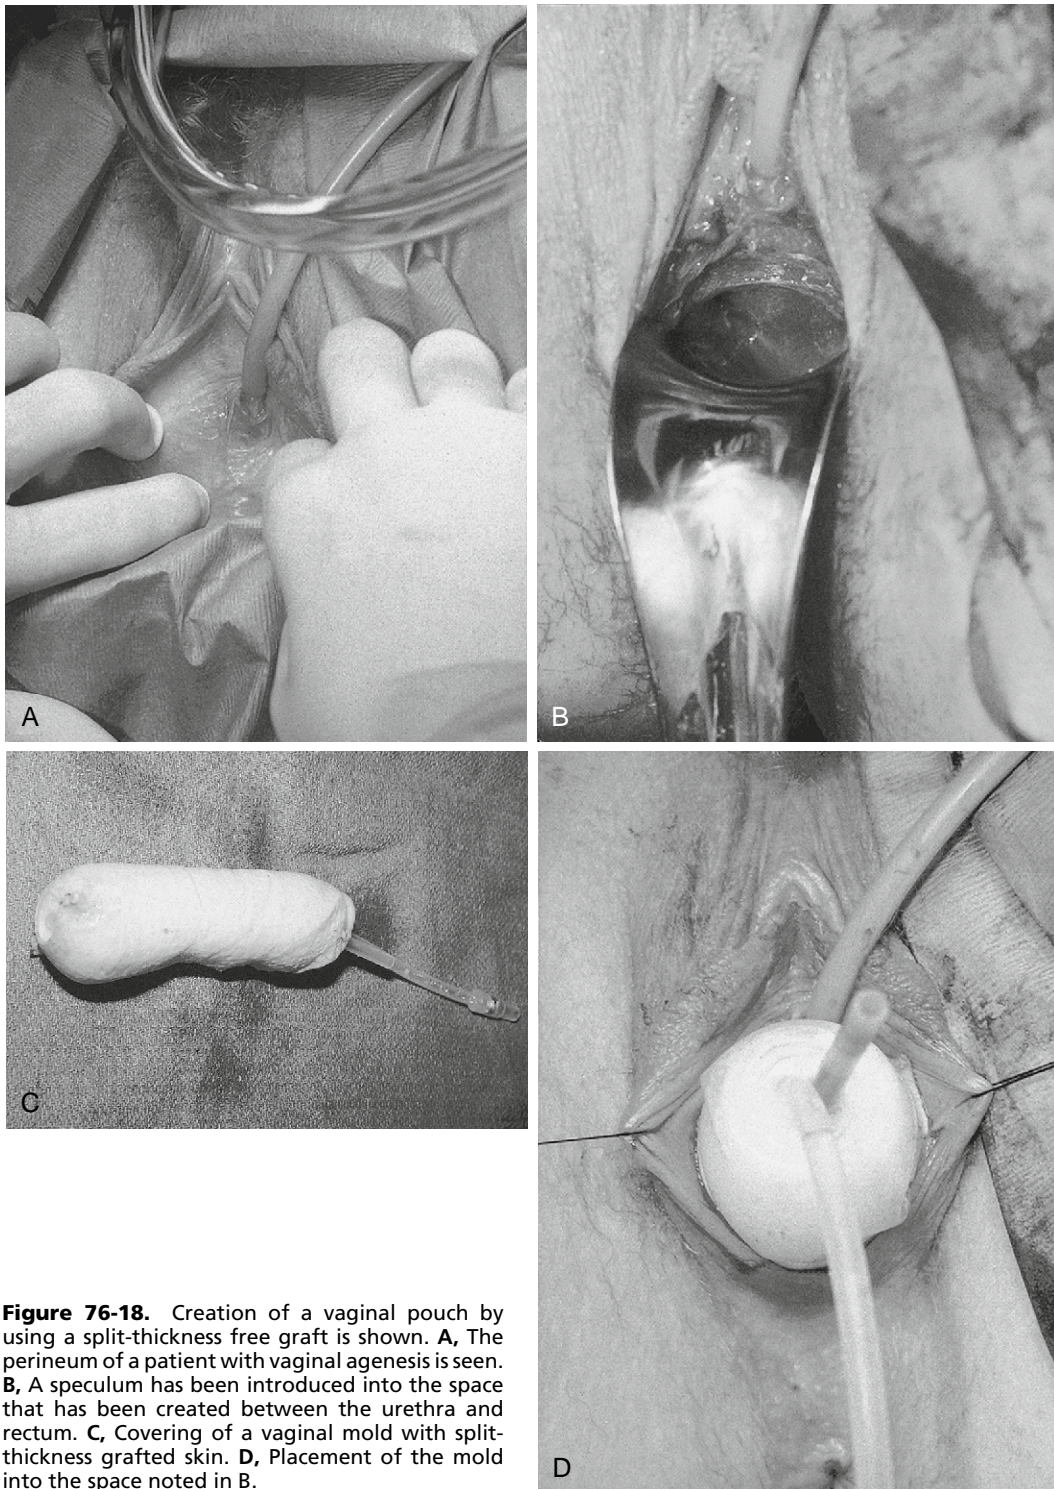

for this problem, but also may be associated with good long-term results.<sup>56</sup> Although this approach has the advantage of avoiding postoperative dilation, it is occasionally associated with prolapse, chronic vaginal discharge, and vaginitis, which limit its functional result.<sup>50,57,58</sup> Rarely, external interposition of gracilis muscle or vulvoperineal flaps are used to create a coital pouch.

## ADNEXAL DISEASE

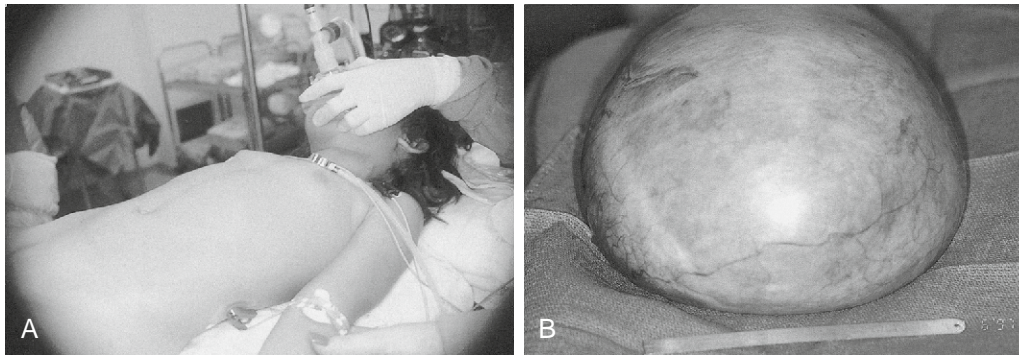

Surgical disorders of the adnexa are common, particularly in the adolescent period. Ultrasonography has increased the level of understanding regarding the development and natural history of ovarian cysts. New less-invasive surgical techniques allow more conservative management of adnexal disease in children.

Ovarian cysts may occur at any time from fetal life to adulthood. Simple cysts in the neonate are generally follicular and originate from the influence of maternal estrogens. Complex masses in this age group may represent in-utero or neonatal torsion.<sup>59</sup> The risk of malignancy is extremely small, but complications requiring surgical intervention can arise from torsion, hemorrhage, or mass effect. Both simple and complex masses are likely to resolve without therapy. Percutaneous aspiration is indicated for cysts larger than 5 cm to minimize the risk of torsion.<sup>60,61</sup> Indications for operative intervention include the presence of a complex mass that fails to resolve in the neonatal period, the recurrence of a cyst after aspiration, the development of acute abdominal symptoms, or a combination of these complications.<sup>61</sup> Treatment may consist of laparoscopic fenestration of simple cysts or cystectomy, if it can be done without loss of functional tissue.<sup>62</sup>

In childhood, small cysts representing follicular development and atresia are common and not associated with a pathologic state.<sup>8</sup> Management of ovarian cysts in children is based on size, the presence of symptoms, and cyst composition. Worrisome findings include cysts of larger than 5 cm, cysts with solid or complex internal echoes on ultrasonography, and fixed masses accompanied by systemic symptoms of disease or precocious development.<sup>63</sup> Occasionally, cysts may be associated with breast development or vaginal bleeding (Fig. 76-19). It is important to distinguish follicular development arising from true precocious puberty from autonomously active cysts. Recurrent gonadotropin-independent cysts are most commonly associated with McCune-Albright syndrome or, more rarely, with hormonally active stromal or germ cell tumors. The diagnosis of an ovarian tumor must be considered in children, especially in those with a large, persistent complex mass that has solid components (Table 76-2). The most common ovarian tumor of childhood is the mature cystic teratoma, followed by stromal tumors.<sup>64,65</sup> Malignant tumors are rare, comprising about 10% of all surgically treated masses.<sup>64,66</sup> In prepubertal girls, ovarian masses, when symptomatic or associated with worrisome radiologic signs, should undergo surgical exploration. In the absence of

Table 76-2		Neoplasms in Female Children and Adolescents		
Tumor Neoplasm	Appearance	Markers	Other Information	
Benign teratoma (dermoid)	Irregular, cystic and solid; or primarily cystic	None	Most common germ cell tumor 6%-8% malignant Malignant immature forms may be associated with other germ cell tumors	
Dysgerminoma	Thick, white, opaque; cytologic reactivity with alkaline phosphatase	None	Inspect other ovary 15%-20% bilateral, 95% cure (stage I) Chemotherapy for advanced disease	
Endodermal sinus tumor (yolk sac tumor)	Solid and cystic Schiller-Duval bodies	AFP	Primarily unilateral Surgery and chemotherapy for all stages 15% survival after stage I	
Embryonal carcinoma	Smooth with areas of hemorrhage and necrosis Schiller-Duval bodies	$\beta$ -hCG	Usually part of a mixed germ cell tumor 60% endocrinologically active (precocious puberty) Surgery and chemotherapy for all stages 50% survival (stage I)	
Choriocarcinoma	Syncytiotrophoblasts and cytotrophoblasts	$\beta$ -hCG	Rare primary tumor in pediatric age group Surgery and chemotherapy for all stages	
Mixed germ cell tumor	Predominantly solid, or cystic and solid, depending on composition	AFP	Most commonly composed of dysgerminoma and endodermal sinus tumor	
Sex cord stromal tumors	Granulosa-theca or Sertoli-Leydig cells	None	More common in younger patients Isosexual precocious puberty or androgenization	
Juvenile granulosa-theca cell tumor	Very vascular	None	Malignancy related to percentage of granulosa cells Pure thecomas benign Surgery alone for stage I Surgery and chemotherapy for advanced disease Variable malignant potential	
Sertoli-Leydig cell tumors (arrhenoblastoma)				
Epithelial tumors	Predominantly cystic		Commonly large size May have borderline variants Low malignant potential	
Serous cystadenoma				
Mucinous cystadenoma	Predominantly cystic with septations		From coelomic epithelium Rare in children and adolescents	
Serous or mucinous cystadenocarcinoma				
<b>Miscellaneous Tumors</b>				
Polyembryoma	Tissues resemble embryos with all three germ cell types (amniotic cavity, yolk sac, placental primordia)			
Gonadoblastoma			Predominantly dysgenetic gonads	
Mesothelioma				
Metastatic disease

malignancy, conservation of ovarian tissue should be attempted, whenever possible.

Ovarian cysts are extremely common in adolescence because of persistent anovulation or ovulation dysfunction. They may be associated with rupture, pain, and hemorrhage (Fig. 76-20). A mass in the pelvis may be present, or the cyst may be found as an incidental finding at the time of radiologic studies. Mature cystic teratomas are the most common neoplasm, followed by a cystadenoma. Malignant neoplasms are seen but comprise less than 4% of all surgically excised masses.<sup>64</sup> In adolescents, a variety of reproductive disorders such as endometriosis, pelvic inflammatory disease, disorders of the fallopian tube, congenital uterine anomalies, or disorders of pregnancy may have the appearance of ovarian cysts (Table 76-3). It is essential to elicit a full history, including the details of menstrual function and sexual activity. Pregnancy must be excluded, and the possibility of complications of a sexually transmitted infection considered. Diagnostic imaging is very helpful in the management of ovarian cysts.<sup>67</sup>

The conservative approach to the management of ovarian cysts in adolescents is based on the low rate of malignancy and the high rate of functional cysts and benign germ cell tumors. Recurrent observation is recommended as an initial therapy for adolescent women. Indications for surgical intervention include cysts larger than 10 cm, persistent complex masses, acute symptoms, or a high suspicion for malignancy, based on radiologic or clinical criteria. In the absence of findings suggestive of neoplasm, minimally invasive surgical techniques such as laparoscopy should be paired with cystectomy and ovarian conservation. Cystectomy is performed by incising the ovary on the antimesenteric portion of the ovary. Blunt dissection separates the cyst from the ovarian capsule, allowing the cyst wall to be removed in toto (Fig. 76-21). Electrocautery or sutures may be needed to obtain hemostasis. Closure of the cyst wall is not necessary. Although marked distortion of the ovarian capsule may be present, rapid involution occurs. The cyst may be removed using a laparoscopic

bag to prevent spillage of contents into the peritoneum. Laparoscopic management of cystic teratomas remains controversial because of concerns about the effects of rupture and spillage on long-term fertility. Recent studies, however, have found laparoscopic removal to be safe and efficient and without long-term sequelae, even in the presence of rupture and spillage (Fig. 76-22).<sup>68,69</sup> When malignancy is suspected, oophorectomy through a midline laparotomy incision allows proper staging with careful exploration, collection of pelvic cytology, and pelvic and periaortic lymph node sampling.

The ovaries or tubes may occasionally undergo torsion, with ischemia and ultimately necrosis of the adnexa (Fig. 76-23). Torsion of the ovary can occur at any age and is recognized by the acute onset of pain, nausea, vomiting, and a pelvic mass. Ovarian torsion is classically associated with the presence of an ovarian cyst or tumor but can be associated with normal ovaries.<sup>70</sup> Doppler-enhanced ultrasonography demonstrating the absence of blood flow has historically been used to predict ovarian torsion, but has been shown to be less predictive than ovarian enlargement.<sup>71,72</sup> Ovarian torsion is a surgical emergency. If a prompt diagnosis is made, the ovary may be salvaged with detorsion and cystectomy, even when it visually appears to have

**Figure 76-21.** Laparoscopic ovarian cystectomy. **A**, An incision is made on the antimesenteric portion of the ovary. **B**, The capsule is separated from the ovarian cyst with blunt and sharp dissection.

**Figure 76-22.** A 14-year-old presented with abdominal pain. Ultrasonography and CT showed calcifications within this left ovarian mass (**A**), indicating that it was a likely ovarian teratoma. **B**, Laparoscopic excision of the teratoma was initiated by incising the outer layer and peeling back the normal ovarian parenchyma (asterisk). **C**, The ovarian parenchyma (asterisk) has almost been completely stripped from the teratoma. **D**, The ovarian parenchyma was approximated after excision of the mass. The teratoma was placed into an endoscopic retrieval bag and exteriorized through the umbilicus after some morcellation. Histologic examination showed it to be a benign teratoma.

**Figure 76-23.** **A** and **B**, Right ovarian torsion in a 14-year-old girl with acute abdominal pain. The fallopian tube and ovarian vascular pedicle are twisted several times (arrow), resulting in acute venous congestion. Untwisting the pedicle allowed return of arterial flow and resolution of the venous congestion. Although the ovary appeared ischemic, it was not removed.

**Figure 76-24.** A, The peritoneal surface of a 14-year-old with endometriosis. Note the hypervascularity and subtle vesicular type lesions. B, The peritoneal surface of a 17-year-old with endometriosis. Note the classic “powder burn” appearance.

vascular compromise.<sup>73</sup> Oophorectomy is reserved for cases of delay associated with necrosis. Oophoropexy by side-wall fixation or shortening of the meso-ovarian ligament has been advocated by some to decrease the risk of subsequent contralateral torsion, although there is no evidence showing its efficacy.<sup>73</sup>

## ENDOMETRIOSIS

Endometriosis refers to the presence of endometrial glands and stroma functioning outside the uterine lining. Endometriosis has been traditionally thought to be a disease of women in their 20s and 30s, but is well described in the adolescent population. Common symptoms among adolescents, such as dysmenorrhea, chronic pelvic pain, and dysfunctional uterine bleeding, have been associated with a 38% to 47% prevalence of endometriosis.<sup>74,75</sup> As many as 75% of symptomatic adolescents with medically refractory pelvic pain are found to have endometriosis at laparoscopy.<sup>76</sup> Although symptoms can suggest the diagnosis, definitive diagnosis is made by laparoscopic visualization or biopsy (or both). Because few adolescents need laparoscopy during their adolescent years, the exact prevalence of endometriosis in adolescents remains unknown. Progression of disease and the types of lesions appear to change with age. Clear, vesicular-appearing lesions

and low-stage disease are more common in adolescence, with more classic hemosiderin “powder burn lesions” identified in older adults (Fig. 76-24).<sup>77,78</sup>

The treatment of endometriosis in adolescents is based on alleviation of symptoms and slowing the progression of disease. For patients undergoing surgical therapy, removal of all visible lesions by resection or destruction, with normalization of the pelvic anatomy, should be undertaken at the time of diagnosis. To accomplish this, CO<sub>2</sub> laser, cautery, coagulation, and the laparoscopic approach are all used. Menstrual suppression with oral contraceptives or progesterone-only medication (or both), along with nonsteroidal anti-inflammatory agents, are the mainstays of therapy. Gonadotropin-releasing agonists may be used on a short-term basis as an adjuvant to surgical therapy in adolescents but carries the risk of a detrimental effect on bone density. This therapy should be used cautiously in younger adolescents. Likewise, newer therapies advocated to control the symptoms of endometriosis such as the Levonorgestrel IUS (Schering Health, Berlin-Wedding, Germany) and aromatase inhibitors have not been studied in adolescents.<sup>79,80</sup> Noninterventional pain therapies may have a place in controlling the chronic pain associated with endometriosis. The long-term outcomes of infertility and chronic pain in those diagnosed with endometriosis as adolescents is not well described.

# BREAST DISEASES

Don K. Nakayama, MD, MBA

The embryonic breast is formed in three steps.<sup>1</sup> First, the ectoderm thickens into a pair of longitudinal streaks in the ventral surface of the embryonic torso that become the primitive mammary ridges or “milk lines.” Next, paired lens-shaped placodes appear as thickenings at specific locations along the milk lines, five in number in the mouse and a single pair in humans. Third, epithelial cells invaginate from the placode into the underlying mesenchyme to form the breast bud. A dense mesenchymal stroma coalesces around the bud, a situation that remains quiescent until the final stages of embryonic development. At this point epithelial cells begin to proliferate, sprouting from the mesenchyme and into a fat pad that has developed within the dermis.

Ductal branching follows entry of the bud into the fat pad forming a rudimentary ductal tree. Early lactiferous ducts are well established by 16 weeks. Ductal trees coalesce at the nipple that forms from differentiating epithelium at the skin. The nipple and areola form during late fetal development. A pigmented areola is first seen at 20 to 24 weeks, but a true nipple is not present until later in the perinatal period and is frequently inverted at birth. The buds respond to estrogenic hormonal stimulation by the maternal-placental-fetal unit during the last trimester, canalizing into ducts and enlarging en masse to form a true breast nodule during the final weeks of gestation.

Once perinatal maternal endocrine influences subside, the breast bud begins to involute in a process that resembles that seen in menopause.<sup>2</sup> Then it increases in size at a rate similar to somatic growth until puberty and undergoes robust branching, development of terminal duct lobular units, and stromal expansion that fills the entire mammary fat pad by adulthood.

## ANATOMY AND PHYSIOLOGY

The fetus is subject to relatively high levels of placental estrogens in the perinatal period, resulting in breast enlargement in both genders at birth. A bimodal surge in hypothalamic-pituitary-gonadal axis activity, originally in the first 2 days of life with a second peak at

2 months, causes a “minipuberty of early infancy” that may explain persistence of breast enlargement well into the first few months to a year of life. At 6 months, the hormonal levels fall to prepubertal levels. A sudden fall in estrogens may allow prolactin and oxytocin secretion and the release of small amounts of milk by the infant breast (“witch’s milk”). Sex hormone levels then remain low until puberty. Activation of the gonadotropin axis causes ovarian estradiol production in girls and, at a later age, testicular testosterone secretion in boys, with the resulting changes in body habitus and appearance of secondary sexual features. The testes are responsible for about 15% of estradiol production. Extragonadal aromatization then converts this compound into active estrogen.

The breast in the term neonate is a firm discrete nodule of white tissue up to 1 cm in diameter.<sup>3</sup> The nodule may persist well into the first year of life and may be more prominent at 6 months than earlier in infancy. The nodule begins to involute in late infancy. Throughout prepuberty, breast tissue is minimal and the nipple lies nearly flush with the skin contour in both boys and girls. The premature infant lacks this defined breast nodule and is particularly vulnerable to damage to the breast by an ill-placed surgical incision.

The onset of puberty is characterized by an increase in pulsatile secretion of gonadotropin-releasing hormone and gonadotropins, especially during sleep.<sup>4</sup> Thelarche is a response to the maturation of functional ovarian follicles.<sup>5</sup> Prolactin, glucocorticoids, and insulin have a permissive effect on breast development. With puberty, ovarian follicles initiate estrogen production. Estrogens circulate to the breast and stimulate ductal development and site-specific adipose deposition. Male adolescents fail to produce a significant breast mass, primarily because they lack significant levels of circulating estrogen. Once started, the process usually progresses smoothly to maturity in about 3 years. The breast stages; as defined by Marshall and Tanner, are as follows<sup>6</sup>:

Stage 1: Preadolescent; elevation of papilla only

Stage 2: Breast bud stage; elevation of breast and areola as a small mound, enlargement of areola diameter

**Table 77-1** Aberrations of Normal Development and Involution of the Breast (ANDI)

Stage (Peak Ages, Adult yrs, Newborn mos)	Aberration			
	Normal Process	Underlying Condition	Clinical Presentation	Disease State
Early reproductive period (Adult, 15-25; Newborn, -2 to Birth)	Lobule formation	Fibroadenoma	Discrete lump	Giant fibroadenoma, multiple fibroadenomas
	Stroma formation	Juvenile hypertrophy	Excessive breast development	
Mature reproductive period (Adult, 25-40; Newborn, Birth to 2)	Cyclical hormonal effects on glandular tissue and stroma	Exaggerated cyclical effects	Cyclical mastalgia and nodularity (generalized or discrete)	
Involution (Adult, 35-55; Infant, 2-24)	Lobular involution (including microcysts, apocrine change, fibrosis, adenosis)	Macrocysts	Discrete lumps	
		Sclerosing lesions	Radiographic abnormalities (mastalgia lumps)	
	Ductal involution (including periductal round cell infiltrates)	Duct dilation	Nipple discharge	Periductal mastitis with bacterial infection and abscess formation
	Epithelial turnover	Periductal fibrosis Mild epithelial hyperplasia	Nipple retraction	Epithelial hyperplasia with atypia

From Hughes LE: Aberrations of normal development and involution (ANDI): An update. In Mansell RE (ed): Recent Developments in the Study of Benign Breast Disease. London, Parthenon Publishing, 1994, pp 65-73, with permission.

Stage 3: Further enlargement of breast and areola, with no separation of their contours

Stage 4: Projection of areola and papilla to form a secondary mound above the level of the breast

Stage 5: Mature stage; projection of papilla only, resulting from recession of the areola to the general contour of the breast

The sequence of developmental changes that surround puberty is the onset of the adolescent growth spurt, breast development, appearance of pubic hair, and menarche. Thelarche has been shown to be influenced by diet (earlier among Korean girls eating a diet rich in shellfish and processed meat)<sup>7</sup> and environment (earlier among Mexican girls raised in valley ranches practicing modern agriculture compared with those raised in ranches using traditional methods).<sup>8</sup>

## PATHOPHYSIOLOGY

Female breast disease in pediatric age groups can be seen as an aberration of normal development and involution (ANDI).<sup>9</sup> ANDI links adult breast pathology to events in early breast development. Thus, many of the same disease processes observed in adults may be present in the pediatric age group. Under the ANDI concept, a fibroadenoma is not a typical benign tumor but a disorder of normal lobular development. Excessive stroma development results in juvenile hypertrophy. Benign conditions that result from breast involution may be encountered during infancy, such as periductal mastitis, nipple discharge, and nipple retraction. The complete ANDI

classification and associated pathology at each stage of breast development, modified to include events and conditions that involve the infant breast, is summarized in Table 77-1.

Breast cancer represents the extreme end of the spectrum of developmental disorders. It is a disorder of the mature breast, apparently the cumulative product of genetic and hormonal influences over time.<sup>10</sup> It is extremely rare in pediatric age groups, almost exclusively seen in late adolescence when encountered. Although risk factors for breast cancer certainly involve events during childhood and adolescence (e.g., early menarche) and genetic influences (e.g., familial breast cancer), breast cancer is not a childhood disease.

## DISORDERS OF DEVELOPMENT AND GROWTH

### Polythelia

Extra nipples and areolae may develop anywhere along the milk line from axilla to pubis. The most common location is on the chest below the actual breast.<sup>11</sup> In a minority, a true accessory breast develops. Unightly structures should be removed.

### Hypoplasia and Aplasia

Either breast aplasia or hypoplasia may occur in Poland's syndrome. Underlying chest wall structures, including pectoralis muscles and ribs, are absent or diminished in size. The ipsilateral upper extremity

may also be affected. Reconstruction of the chest wall and placement of a mammary prosthesis or breast reconstruction by a variety of flap techniques is usually indicated.<sup>11,12</sup> Adolescents with small breasts and otherwise normal pubertal development are normal, and reassurance is the most appropriate intervention. Hypoplasia with any abnormality of pubertal development requires an endocrinologic evaluation for ovarian failure, including gonadal dysgenesis and androgen excess (congenital adrenal hyperplasia or intersex-associated enzyme deficiencies).<sup>13</sup> Breast augmentation is a therapeutic option for these patients.

An important iatrogenic cause of breast hypoplasia is an incision at or near the infant breast, at an exit site for an indwelling central venous catheter, a thoracotomy incision, or incision and drainage of a breast abscess. Extreme care must be taken when placing these incisions, particularly in prematurely born infants in whom the breast may be barely visible.

## Atrophy

Patients with atrophy of the breast who have undergone normal development should be evaluated for an underlying cause. Weight loss results in loss of fat from stroma and bilateral atrophy. Eating disorders also may be complicated by hypothalamic suppression and hypoestrogenism, further retarding breast growth.<sup>14</sup> In an otherwise well-nourished adolescent, endocrine disorders that result in low estrogen or increased androgens should be evaluated with appropriate hormone determinations.

Unilateral atrophy may occur in scleroderma.<sup>14</sup> Also, it has been reported as a complication of infectious mononucleosis.<sup>15</sup>

## Premature Thelarche

The differential diagnosis of breast enlargement in female patients is seen in [Table 77-2](#). Because of racial differences with thelarche, breast development is premature if it occurs before 8 years of age for white girls and 7 years for blacks and Hispanics. Premature thelarche is defined as isolated breast development without

sexual hair growth, vaginal mucosal estrogenization, linear growth spurt, adult body odor, and pubertal behavioral changes. It is unilateral in 50% of cases. It has a peak incidence between 6 months to 2 years and resolves in more than half of patients.<sup>16</sup>

Premature thelarche is distinguished from physiologic perinatal breast development and precocious puberty. Precocious puberty has a peak incidence between 5 to 8 years, later than true premature thelarche, and is associated with other features of puberty just listed. Gentle retraction of the labia is necessary to observe the vaginal mucosa. The prepubertal vaginal mucosa is reddish and delicate, whereas an estrogenized mucosa is pink and thicker. Two or more signs of precocious puberty establish this diagnosis.

Causes of premature thelarche may involve partial activation of the hypothalamic-pituitary-gonadal axis by follicle-stimulating hormone secretion, failure of ovarian follicular involution, and gonadotropin-independent estrogen production (McCune-Albright syndrome, rarely hepatocellular carcinoma, and ovarian and adrenal tumors). Exogenous estrogens in poultry, cosmetics, and hair products have been implicated in the early sexual development as well. Xenoestrogens are compounds that bind to the estrogen receptor and include a wide variety of environmental toxins used in pesticides, cosmetics, and packaging material. Patients with precocious puberty and those in whom the diagnosis of premature thelarche is uncertain should be referred to an endocrinologist, who likely will request a bone age radiograph; ultrasound evaluation of the liver, adrenals, and ovaries; and gonadotropin stimulation tests. Those with true central precocious puberty undergo suppression of the hypothalamic-pituitary-gonadal axis with long-acting gonadotropin-releasing hormone analogs.<sup>17</sup>

## Virginal Hypertrophy

The cause of virginal hypertrophy is probably an end-organ hypersensitivity to normal hormonal fluxes at the time of puberty.<sup>11,18</sup> Histologically, breasts show stromal and ductal hypertrophy with dilated ducts. Tissue necrosis and rupture of the skin may result from the sheer weight and justify reduction mammoplasty. Little experience is available with medical therapy, although some improvement has been reported with danazol therapy. Reduction mammoplasty is a safe and appropriate procedure for virginal hypertrophy. Repeated resections may be necessary as the breast may continue to grow.

## Unilateral Hypertrophy

Breast asymmetry may result from unilateral hypertrophy, a condition easily distinguished from hypoplasia and aplasia. Some degree of asymmetry is normal and is detectable in many patients. Breast growth may magnify differences and may hamper the child psychologically, even though both breasts are completely clinically normal. Once Tanner stage 5 breast maturity

is reached, breast reduction of the enlarged breast is reasonable.<sup>11,19</sup>

## Gynecomastia

Excellent reviews by Braunstein<sup>20</sup> and Diamantopoulos and Bao<sup>21</sup> discuss the various causes of gynecomastia and its diagnostic workup. Gynecomastia is the benign proliferation of glandular tissue of the male breast enough to be felt or seen as an enlarged breast. Male breast enlargement occurs physiologically in the neonate, adolescent, and elder. Infant gynecomastia, discussed previously, may persist for up to 12 months in boys and 24 months in girls. Prepubertal gynecomastia (enlargement in boys) and thelarche (the equivalent condition in girls) warrants careful investigation.

Thirty to 60 percent of boys exhibit physiologic or pubertal gynecomastia. A hypothesis is that a lag in maturation in testosterone synthesis with the onset of puberty allows a relatively greater estrogen effect, but studies have failed to detect hormonal differences in boys with pubertal gynecomastia. This disorder first appears between 10 and 12 years of age. Its highest prevalence is at 13 to 14 years, corresponding to Tanner stage 3 or 4. Involution is generally complete at 16 to 17 years but may persist longer in obese boys.

Pathologic gynecomastia results from imbalances between estrogen and androgen concentrations. Testicular (germ cell, Sertoli cell, and Leydig cell tumors) and adrenal neoplasms may overproduce estrogens. Feminizing adrenal tumors are generally malignant. Increased aromatase conversion of testicular precursors into active estrogen occurs in idiopathic gynecomastia and in infants with hepatocellular carcinoma. Decreased androgen levels or androgenic effects may result from primary defects in the testis, loss of tonic stimulation by pituitary gonadotropins, or increased binding of androgens to sex-hormone-binding globulin. Displacement of androgens from their receptors by the many drugs associated with gynecomastia (Table 77-3) may result in unopposed estrogen effects in sex-hormone-sensitive tissue, including the breast.

Histologic studies in the early stages of gynecomastia show marked duct epithelial cell proliferation, inflammatory cell infiltration, increased stromal fibroblasts, and enhanced vascularity. This proliferative stage, also known as the florid stage, may explain breast pain and tenderness that are typical of the clinical presentation. Epithelial proliferation and ductal dilation then both decrease, and the stroma begins to undergo fibrosis and hyalinization. Clinical resolution of breast enlargement and pain follow in 85% of cases, a fact that must be considered when contemplating treatment.

Painful, tender gynecomastia is often seen in adolescent boys. The patient often recalls trauma to the breast; however, the injury is more likely to have brought the lump to his attention than to have caused it. On palpation, true gynecomastia is a disc of rubbery tissue arising concentrically beneath and around the nipple and areola. This distinguishes it from pseudogynecomastia,

**Table 77-3** Drugs Associated with Gynecomastia

Hormones (growth hormone, human chorionic gonadotropin, estrogens, anabolic steroids)
Androgen synthesis/androgen receptor antagonists (ketoconazole, finasteride, cimetidine, cyproterone)
Antibiotics (isoniazid, ethionamide, metronidazole, highly active antiretroviral treatment)
Anti-ulcer (cimetidine, ranitidine, omeprazole)
Abuse (alcohol, heroin, amphetamines)
Chemotherapy (methotrexate, alkylating agents, <i>Vinca</i> alkaloids, cyclophosphamide)
Cardiovascular (furosemide, spironolactone, angiotensin-converting enzyme inhibitors, nifedipine, verapamil, reserpine)
Psychiatric/neurologic (phenytoin, tricyclic antidepressants, phenothiazines, risperidone, diazepam, clonidine, selective serotonin reuptake inhibitors)
Other (theophylline D-penicillamine, cyclosporine)

From Diamantopoulos S, Bao Y: Gynecomastia and premature thelarche: A guide for practitioners. *Pediatr Rev* 28:e57, 2007, reprinted with permission.

which is increased amounts of adipose tissue beneath the breast causing prominence of the area.

Because pubertal gynecomastia is so prevalent, a thorough history and physical examination, especially of the testes, is sufficient in adolescent boys. Reassurance and follow-up examinations at 6-month intervals is suggested. Pubertal gynecomastia generally resolves within 1 year. Suggestive aspects of the personal medical history (especially drugs and medications), abnormal physical findings (particularly of the testes and genitalia), onset of gynecomastia between early infancy (not persistent from birth) and the onset of puberty, rapid increase in breast size, macrogynecomastia greater than 4 cm in diameter, and pubertal gynecomastia that persists longer than 1 year should lead to a directed endocrinologic and oncologic workup. Drugs should be discontinued, if possible, and the patient re-examined in 1 month. Imaging studies of the testes and adrenal glands are necessary if a tumor is suspected.

Indications for therapy include severe pain, tenderness, or embarrassment sufficient to interfere with the patient's normal daily activities. Subcutaneous mastectomy through a periareolar incision is definitive treatment (Fig. 77-1). Liposuction is another surgical alternative.<sup>11,22</sup> Pharmacologic approaches include estrogen receptor modulators or antiestrogens (tamoxifen, raloxifene, and toremifene citrate) and aromatase inhibitors (testolactone, anastrozole, and letrozole). Tamoxifen and raloxifene improved the condition in 91% of boys in one study,<sup>23</sup> but anastrozole was no better than placebo.<sup>24</sup> It is difficult to assess the efficacy of these various medical regimens because gynecomastia undergoes spontaneous regression in a large number of cases. Side effects from these medications must be considered when employing drug therapy for pubertal gynecomastia.

**Figure 77-1.** A, This teenager has gynecomastia, which was causing him discomfort as well as having negative psychosocial ramifications. B, On the operating table, the enlarged breast tissue was removed and a nice cosmetic appearance achieved.

## INFLAMMATORY LESIONS

### Breast Trauma and Fat Necrosis

Soft tissue injury to the breast may result from blunt and penetrating trauma. Shoulder-harness restraints have been reported to cause subcutaneous rupture of the breast. Most breast trauma is mild and self-limiting. Specific therapy is rarely required.

Fat necrosis is a benign condition that can mimic breast carcinoma. It is thought to result from breast trauma.<sup>25</sup> A history of antecedent trauma is present in about 40% of cases. Areas of fat necrosis are seen as single or multiple firm, round, or irregular masses, often in the center of the breast near the areola. The masses may be painless, firm, and immobile and cause skin tethering and thickening, all features that suggest carcinoma. Spiculated calcifications may be present on mammography, further suggesting the presence of a neoplasm. Patients who are seen later with painless masses require biopsy to exclude malignancy.

### Mastitis and Abscess

Infections of the breast of a neonate, uncommon today, had a high mortality and caused substantial morbidity to the breast and chest wall before the antibiotic era. The disease primarily affects the neonatal breast before involution of the ductal anatomy. Eighty-four percent of these infections occur in the first 3 weeks of life. *Staphylococcus* is the causative organism in more than 90% of cases. *Streptococcus*, *Salmonella*, and *Escherichia coli* also may cause a breast infection.

Both genders are affected, with a female-to-male ratio of 1.8. The skin and nipple are red. Swelling and edema cause induration of the area. Fluctuance and deep discoloration to a fiery red or purple color indicate the presence of an abscess or extension of the infection beneath the fascia. Although in some infants, a small drop of pus may be expressed from the nipple, this is not sufficient drainage if an abscess is truly present. Most patients lack systemic reactions to infection, with only one fourth having a fever and fewer than 10% having other constitutional symptoms

(irritability or refusal to feed). One fourth have pustular skin lesions elsewhere, usually in the inguinal region.

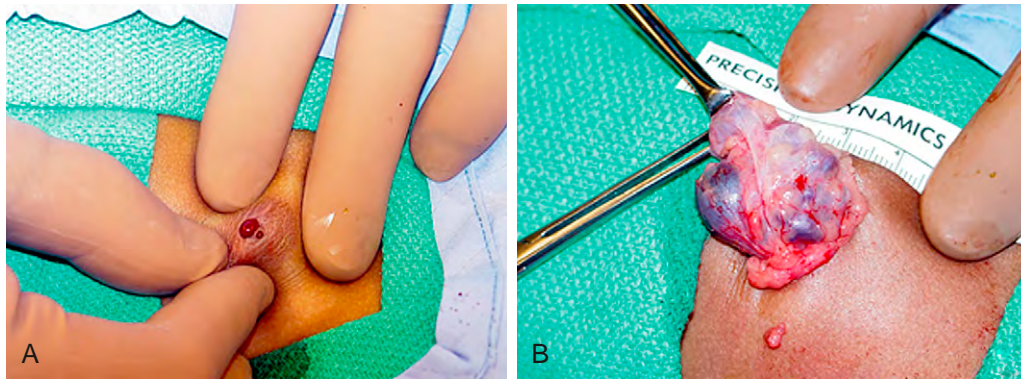

Mastitis and breast abscess require appropriate antibiotic therapy against *Staphylococcus*, *Streptococcus*, *Salmonella*, and *E. coli*. Areas of fluctuance or progression of inflammation while taking antibiotics suggest the presence of an abscess that requires drainage. Mastitis in neonates responds in nearly all cases to intravenous antibiotics and warm packs to the affected breast. The decision to explore the infant breast for an abscess must be made with great care to avoid unnecessary damage that may result in breast deformity later in adolescence. An initial needle aspiration of suggestive areas is a prudent first step. If no purulence is encountered, antibiotics are continued. Discovery of a true abscess requires incision and drainage. One study documented a significant decrease in breast size relative to the opposite breast in two of five patients who had undergone incision and drainage of a breast abscess as a neonate.<sup>26</sup>

Mastitis and abscess occur more commonly after thelarche. Causes include manipulation and breast feeding, although in many cases the cause cannot be identified. Nursing may continue in cases that develop while breast feeding. Adequate abscess drainage usually requires general anesthesia owing to loculations of pus and breast septations in the developing and mature breast.

## NIPPLE DISCHARGE

### Galactorrhea

Galactorrhea is inappropriate lactation that is not related to pregnancy or that continues post partum in the absence of breast feeding.<sup>13,27</sup> The five etiologic groups are neurogenic, hypothalamic, endocrine, drug-induced, and idiopathic. Neurogenic causes result from local breast and nipple irritation and stimulation. The most common hypothalamic cause of galactorrhea in adults is a prolactinoma, a rare tumor in childhood and adolescence. Failure of sexual maturation

**Figure 77-2.** A, Bloody and green discharge from a 5-month-old boy is seen. B, Multiple subareolar epithelial cysts, which were causing the drainage, were removed.

often accompanies galactorrhea in children with these tumors.<sup>28</sup> Visual symptoms and headaches are rare in children as compared with adults. Cessation of oral contraceptives, polycystic ovary, adrenal tumors, and gonadal tumors are rare causes of galactorrhea in adolescents.<sup>13</sup> Hypothyroidism in infants and children has been reported to be associated with galactorrhea and precocious puberty. Nipple discharge ceases with correction of the underlying thyroid condition.<sup>29,30</sup>

Nipple discharge in boys is always abnormal, and a cause must be sought. A prolactinoma is the most common cause in young boys.<sup>20</sup> If prolactin levels are high and evaluation of the sella turcica is unrevealing, annual imaging of the sella is necessary until the end of puberty, even if the galactorrhea resolves.

### Other Nipple Discharges

Nonmilky discharges include pus, cyst contents, and blood. Purulent discharges usually respond to antibiotics; chronic discharge may require drainage and duct excision. Serous drainage of brown to green fluid may indicate the presence of a communicating breast cyst and is usually self-limited. Bloody drainage, a sign of cancer in adults, is generally drainage from an intraductal papilloma or duct ectasia in children and adolescents.<sup>31</sup> Bloody nipple drainage may be culture positive for *Staphylococcus*, so drainage should be cultured and treated if positive. Excision of the abnormal duct is indicated if drainage persists or recurs (Fig. 77-2).<sup>32</sup>

### Mastalgia

Breast pain, or mastalgia, is a poorly characterized and underreported syndrome.<sup>33</sup> It accounts for about one fourth of visits to adult breast clinics and is the presenting symptom of breast cancer in 15% of cases. Its prevalence in young and adolescent girls is unknown.

Initial evaluation excludes localized lesions (benign and malignant) and inflammatory conditions. Pain is then characterized as cyclic or noncyclic. The distinction is important because the likelihood of response to drug treatment differs because cyclic pain is more likely to respond. Cyclic mastalgia usually occurs in the third decade of life. It is usually characterized as

bilateral, dull, burning, or aching. Pain starts 7 to 10 days before the onset of menses, building until menses, when the pain dissipates. Pain may persist throughout the menstrual cycle. Spontaneous resolution occurs in 22% of cases. Noncyclic mastalgia tends to occur a decade later and resolves in 50% of cases. Treatment includes removal of methylxanthines from the diet and reassurance. Evening primrose oil, danazol, and bromocriptine may be effective as adjunctive therapy.

## BREAST MASSES

### Evaluation of Breast Masses

The age of the patient affects the differential diagnosis for breast masses and hence the diagnostic approach (Tables 77-4 and 77-5). Patient age, history, and physical examination are sufficient to make the diagnosis in most cases. A retrospective review of 374 breast specimens from patients aged 20 years and younger over a 10-year period revealed only one papillary carcinoma.<sup>31</sup>

Cyst  
Fibrocystic disease  
Neurofibroma

## Malignant neoplasms

Primary breast cancer  
Metastatic (e.g., lymphoma)

The majority were fibroadenoma (44%), gynecomastia (22%), and juvenile hypertrophy (14%). Twenty-two lesions were a variety of soft tissue tumors, including phyllodes tumor, granular cell tumor, neurofibroma, low-grade angiosarcoma, high-grade stromal sarcoma, metastatic alveolar rhabdomyosarcoma, and giant cell fibroblastoma. Because primary breast cancer is so rare in the pediatric age group, observation has little risk and often is an appropriate step in determining the clinical diagnosis.<sup>32</sup> It is important, however, to observe all lesions to resolution and to obtain further studies when lesions continue to grow or have features that are worrisome to the experienced clinician (e.g., hard consistency, irregular margins, fixation to chest wall or skin, regional lymphadenopathy). A directed workup in such cases may include fine-needle aspiration for cytology, mammography, ultrasound examination, and, ultimately, biopsy.

The issue of breast self-examination among adolescents is controversial.<sup>13,34</sup> Given the rarity of breast cancer in this age group, some clinicians recommend that time could be better used educating them about greater risks to their health, such as drugs, alcohol, and smoking. However, four in five of adolescent breast masses were detected during self-examination. A consensus statement has recommended that individuals with an inherited predisposition to breast cancer begin monthly breast self-examination between 18 and 21 years, with annual clinical breast examinations and adjunctive mammography at age 25 to 35 years.<sup>35</sup>

### Prepubertal Breast Masses

Masses may occur in the prepubertal breast but are nearly always benign. The most important diagnosis to consider is asynchronous thelarche.<sup>13</sup> One breast bud may appear weeks to months ahead of the other. A breast bud is easily recognized as a disc of firm tissue

beneath the areola. In such cases, biopsy is never indicated because it may lead to unilateral iatrogenic amastia.

### Cysts and Fibrocystic Disease

Benign simple cysts occur throughout childhood, but they most commonly occur with the onset of breast development. They appear as soft, painless masses that are not fixed to surrounding breast tissue. Needle aspiration of the cyst results in complete disappearance. Fluid may be serous or brown. Persistence of the mass after cyst aspiration is an indication for biopsy. Fibrocystic disease is a disease of the mature breast, occurring most commonly in the fourth to fifth decades, and is generally not an issue in adolescents.<sup>36</sup> Masses that occur with fibrocystic disease may be asymptomatic or associated with mastalgia, often worse in the perimenstrual period.<sup>13</sup> Resolution of the mass may occur over the course of one or two cycles. A persisting or dominant mass should be aspirated for diagnostic and therapeutic reasons. A number of nonoperative interventions have been tried.<sup>13</sup> Dietary methylxanthines have been implicated as a contributing factor in fibrocystic disease, but elimination of sources of the compound (coffee, tea, cola drinks, and chocolate) may not be successful in resolving the condition. Oral contraceptives improve symptoms in 70% to 90% of individuals. Evening primrose oil has been found to be beneficial in 44%, given in a 1000-mg dose three times daily for 3 months.<sup>13</sup>

## FIBROEPITHELIAL TUMORS

### Fibroadenomas

Fibroadenomas are the most common breast mass in the pediatric age group.<sup>31</sup> Two variants, adult and juvenile, can affect children. Adult fibroadenomas affect older adolescents and young women (Fig. 77-3). They may be multiple in 10% to 15% of cases. The mass is usually painless and small, measuring 1 to 2 cm in diameter. It is well circumscribed, rubbery, and mobile. A true capsule is not present, but there is a well-demarcated stromal interface where the tumor comes in contact with normal tissue.<sup>31</sup> Areas of focal hemorrhage may be present, a feature associated with pain and rapid enlargement. Juvenile fibroadenomas affect younger adolescents around the time of puberty. In contrast to an adult fibroadenoma, the juvenile variant is much larger and may cause considerable breast asymmetry.<sup>11,18</sup> Fibroadenomas are considered to be benign, although adult fibroadenomas can rarely harbor a carcinoma.<sup>37</sup> Also, juvenile variants may be related to phyllodes tumors.<sup>31,37</sup> Clonal analysis shows that epithelial and stromal elements of the fibroadenoma are polyclonal, indicating a hyperplastic rather than a neoplastic process.<sup>38</sup> Adult fibroadenomas confer a small but definite increased risk for breast cancer development.<sup>39</sup> Clonal analysis in three patients in whom phyllodes tumor of the breast developed

**Figure 77-3.** This 16-year-old developed an enlarging, painful fibroadenoma in her left breast. The lesion measured  $7 \times 5 \times 4$  cm on ultrasound examination. She underwent excision of the medially placed lesion through a circumareolar incision and tolerated the operation well. The histologic examination returned a benign fibroadenoma. Her symptoms have resolved.

after excision of a fibroadenoma suggested that the former developed from the latter.<sup>40</sup> A phyllodes tumor tends to be larger ( $>4$  cm in diameter), occur in older patients (mean age, 28.5 years in fibroadenoma, 44 years in phyllodes tumor), has high density on mammography, and appears round or lobulated with posterior acoustic enhancement on breast ultrasonography compared with a fibroadenoma.<sup>41,42</sup> However, a considerable overlap exists between the two conditions with these criteria, and aspiration cytology or excisional biopsy is often necessary to confirm the diagnosis.<sup>31</sup>

Whether fibroadenomas can be safely followed without operation is debatable.<sup>43</sup> Some advocate nonoperative management if the lesion exhibits the expected characteristic features: 1 to 2 cm, solitary, firm, rubbery, nontender, and well circumscribed.<sup>44</sup> Fine-needle aspiration is useful in distinguishing fibroadenomas from carcinomas and phyllodes tumors, but differentiating fibroadenomas from other benign conditions is more difficult.<sup>43</sup> The probability of disappearance of the mass is 0.46 at 5 years and 0.69 at 9 years.<sup>44</sup> Although fibroadenoma is a long-term risk factor for breast cancer,<sup>45</sup> because of the rarity of breast cancer among adolescents it is reasonable to wait a period of years to see whether a small lesion will disappear. Enlarging fibroadenomas should be excised to avoid further enlargement of the mass and preserve the architecture of the remaining normal breast tissue. Rapid growth may cause impressively large lesions and require complex reconstructive surgery.<sup>18</sup> Excision of a fibroadenoma proceeds through an incision directly over the mass, following one of Langer's lines. The mass is held by a centrally placed suture or clamp and is removed with no more than a few millimeters of normal breast tissue. Further breast development is usually normal and symmetric because the tissue compressed by the tumor fills the defect over time.

## Phyllodes Tumors

Phyllodes tumors, formerly called cystosarcoma phyllodes, are rare fibroepithelial tumors that can be benign (with significant risk for local recurrence) or malignant (with rapidly growing metastases).<sup>46</sup> They range in size from 1 to 40 cm. Only about 10% of phyllodes tumors occur in women younger than the age of 20 years and never in children younger than the age of 12. The clinical presentation is a rapidly growing breast mass larger than 6 cm.<sup>34</sup> Closely resembling a fibroadenoma, a phyllodes tumor appears well circumscribed grossly but, like a fibroadenoma, lacks a true capsule. Complete surgical excision requires a 2-cm margin of normal breast parenchyma. Fibrous areas are interspersed with soft, fleshy areas, and cysts are filled with clear or semisolid bloody fluid, all features that distinguish it from a fibroadenoma. On microscopy, both epithelial and stromal elements show hyperplasia and may have areas of atypia, metaplasia, and malignancy. Characteristics of the stroma alone, particularly mitotic activity, determine whether a phyllodes tumor is malignant (Fig. 77-4).<sup>47</sup> The mean age of these patients is in the fourth decade, about a decade older than that for an adult fibroadenoma.

Distinguishing a phyllodes tumor from a fibroadenoma before operation is difficult, and a definitive diagnosis may require open excisional biopsy. Fine-needle aspiration depends on the detection of a dimorphic pattern of stromal elements and benign epithelial tissue, although the technique may not yield a definitive diagnosis in all cases.<sup>48</sup> The mammographic appearance of phyllodes tumors resembles that of fibroadenomas, with smooth polylobulated margins.<sup>46</sup> Ultrasonography is useful if cysts are found within an otherwise solid mass, a characteristic of phyllodes tumor.

When the preoperative diagnosis is known, wide local excision with a 2-cm margin of normal breast tissue is recommended.<sup>46,48</sup> Tumors that extend to the pectoralis fascia require removal of the muscle adjacent to the tumor. Owing to the similarity in appearance between a fibroadenoma and a phyllodes tumor, the latter may be enucleated without a margin when the diagnosis is not known before operation. Because 20% of phyllodes tumors will recur when resected without an adequate margin, most authorities recommend re-excision of normal breast tissue to ensure its removal with an adequate margin. Traditionally, malignant phyllodes tumors were treated with simple mastectomy. Recently, malignant tumors have been treated by using wide local excision with 2-cm margins with acceptable results.<sup>48,49</sup> Lymph node metastases are not present, so lymph node dissection is not indicated. Benign tumors more than 5 cm in diameter have a higher rate of recurrence (39%) than do smaller ones (10%).<sup>50</sup> Both benign and malignant phyllodes tumors recur. Among recurrences in previously resected benign tumors, about 20% show malignant histologic transformation with a worse overall prognosis. Local recurrence of a benign tumor should be re-excised, whereas most authorities recommend

**Figure 77-4.** A 16-year-old girl underwent resection of a malignant phyllodes tumor. **A**, Photomicrograph shows an area of necrosis typical of rapidly growing neoplasms ( $\times 10$ ). **B**, A higher-power view shows stromal and epithelial atypia and numerous mitotic figures ( $\times 20$ ). simple mastectomy for recurrence of a malignant tumor.

## Breast Cancer

Breast malignancy in children falls into three groups: primary malignancies, metastatic tumors that involve the breast, and second malignancies.<sup>51</sup> Primary breast cancer is extremely rare in childhood age groups. Although only 0.2% of primary breast cancers occur before age 25 years, they have been found in children younger than age 5 years and in male as well as female adolescents. More than 90% are first seen as a breast mass. On occasion, nipple discharge is a presenting sign, so a sample of fluid should be sent for cytologic examination.

Secretory carcinoma is a form that occurs relatively more frequently, but not exclusively, in children. It has a low-grade clinical behavior with a good prognosis for long-term survival after simple mastectomy.<sup>52</sup> Girls are affected five times greater than boys. The youngest patient reported is a 3-year-old boy.<sup>53</sup> Even though most tumors measure 3 cm or less, lesions of 12 cm have been described. Axillary lymph node involvement is present in about 20% of cases. Standard treatment is simple mastectomy, although some long-term survivors have been reported after excisional biopsy. Axillary node dissection is indicated if nodes are clinically involved. Recurrence after lumpectomy has been described in several reports. Long-term follow-up is imperative owing to the indolent nature of the disease and the risk for late recurrence.

Nonsecretory breast cancers are less common than secretory breast cancers in the pediatric age group. Some large children's hospitals report no primary breast cancers in their series of pediatric breast masses. A 40-year review of adolescent patients at the M. D. Anderson Cancer Center found 10 patients with primary adenocarcinoma of the breast, 4 with malignant phyllodes tumors, and 2 with metastatic tumors.<sup>54</sup> Ages ranged from 13 to 19 years, and 4 patients had a positive family history for breast disease. These adenocarcinomas were reported exclusively in female adolescents and young adults and probably represent the leading edge of the prevalence distribution for adult primary breast cancer. They include histologic types seen in primary breast cancers in mature women: invasive intraductal (most common), invasive lobular, and signet ring. A family history of breast cancer is a risk factor for early-onset breast cancer and was present in one fourth of these patients. The treatment regimen is the same as for adult primary breast cancer, dictated by histology, stage, presence of hormone receptors, and patient menstrual status.

The breast has been reported as the primary site for rhabdomyosarcoma, leukemia, and lymphoma, as well.<sup>31,51</sup> More commonly, it is the site of acute leukemic relapse. Metastatic carcinoma may involve the breast, with retinoblastoma, osteosarcoma, neuroblastoma, leukemia, lymphoma, and rhabdomyosarcoma having been reported.<sup>31,51</sup> Alveolar rhabdomyosarcoma appears to have a relative predilection for the breast, with 6% to 10% of cases metastasizing to the breast during its course.<sup>55</sup>

# ENDOCRINE DISORDERS AND TUMORS

Jae-O Bae, MD • Michael A. Skinner, MD

## THYROID GLAND

Diseases of the thyroid gland occur in 37 of 1000 school-aged children in the United States.<sup>1</sup> About half of these are diffuse gland hypertrophy or simple goiter. Thyroiditis is the second most common abnormality, followed by thyroid nodules and functional disorders. Malignant neoplasms are rare.

### Embryology and Physiology

The thyroid gland is the first endocrine organ to mature in fetal development, arising as an outpouching of the embryonic alimentary tract at about 24 days' gestation. The developing thyroid gland descends from the base of the tongue, ventral to the hyoid bone and the larynx, to its final location by about 7 weeks' gestation. In about half of the population, a persistence of the thyroglossal diverticulum results in a pyramidal thyroid lobe. Accessory thyroid tissue may appear in the tongue or anywhere along the course of the duct. Rarely, nondescent results in a lingual thyroid.

Histologically, by week 11 of gestation, colloid begins to form and thyroxine ( $T_4$ ) can be demonstrated in the embryo. Parafollicular cells, or C cells, arise from the ultimobranchial bodies and are found throughout the thyroid gland.

Thyroglobulin is recognized histologically as colloid. Thyroid hormone is synthesized at the interface between the follicular cell and the thyroglobulin. The first step in thyroid synthesis is the iodination of tyrosine molecules, which are then coupled to form the definitive thyroid hormones  $T_4$  and triiodothyronine ( $T_3$ ). When free  $T_4$  reaches the nucleus of the target cell, the  $T_3$  molecule interacts with the nuclear receptors. This receptor- $T_3$  conjugate then binds to DNA to regulate genetic transcription.<sup>2</sup>  $T_4$  increases cellular oxygen consumption and the basal metabolic rate, stimulates protein synthesis, and influences carbohydrate, lipid, and vitamin metabolism.

The production and secretion of  $T_3$  and  $T_4$  are stimulated by thyroid-stimulating hormone (TSH) secreted by the pituitary in response to thyrotropin-releasing

hormone, which is, in turn, secreted by the hypothalamus. Other peptides are present within the thyroid gland such as neuropeptide Y, substance P, cholecystokinin, and vasoactive intestinal peptide, which may assist in the production and secretion of thyroid hormones.<sup>3</sup>

TSH is nearly always decreased in the hyperthyroid state and elevated in hypothyroidism and is an extremely sensitive measure of this condition. The plasma free  $T_4$  level is a measure of biologically active thyroid hormone, unaffected by protein binding. Alternatively, when total plasma  $T_3$  and  $T_4$  are measured, it is necessary to consider the level of thyroid-binding globulin to estimate the level of unbound biologically active hormone.

Several imaging modalities are available to assist in evaluating the thyroid gland. Radionuclide scintigraphy is probably the most commonly used test. The radiolabeled iodines  $^{123}\text{I}$  and  $^{131}\text{I}$  are most effective in detecting ectopic thyroid tissue or metastatic thyroid carcinoma, whereas technetium-99m pertechnetate produces superior imaging of thyroid gland nodules or tumors. Ultrasonography is useful to delineate whether a neck mass actually arises from the thyroid and whether multiple nodules are present.

## Non-neoplastic Thyroid Conditions

### Goiter and Thyroiditis

The causes of thyromegaly in one study are listed in [Table 78-1](#).<sup>4</sup> Simple adolescent colloid goiter was the most common cause. Physiologically, diffuse thyroid enlargement may be due to a defect in hormone production, related to autoimmune diseases, or a response to an inflammatory condition. Goiters are classified as diffusely enlarged or nodular and either toxic or euthyroid. Most children with goiters are euthyroid, and surgical resection is rarely indicated.

The differential diagnosis for diffuse thyroid enlargement is seen in [Table 78-2](#). Laboratory evaluation should begin with plasma free  $T_4$  and TSH levels. With a simple colloid goiter, the patient is euthyroid. Ultrasonography or scintigraphy reveals uniform enlargement, and serum

<b>Table 78-1</b> Etiology of Thyroid Gland Enlargement in 152 Children	
<b>Diagnosis</b>	<b>Frequency (%)</b>
Simple goiter	83
Chronic lymphocytic thyroiditis	12.5
Graves' disease	2.5
Benign adenoma	1.5
Cyst	1

Adapted from Jaksic J, Dumic M, Filipovic B, et al: Thyroid disease in a school population with thyromegaly. *Arch Dis Child* 70:103-106, 1994.

thyroid antibody titers are normal. The etiology of this condition may be an autoimmune process.<sup>5</sup> The natural history of colloid goiter is not well known, but one study of adolescents found that 20 years after diagnosis nearly 60% of the glands were normal in size.<sup>1</sup> Exogenous thyroid hormone does not significantly enhance resolution of the goiter. In rare cases, resection may be indicated because of size or the suspicion of neoplasia.

Chronic lymphocytic (Hashimoto's) thyroiditis is another common cause of diffuse thyroid enlargement, occurring most frequently in female adolescents. This condition is part of the spectrum of autoimmune thyroid disorders. It is thought that CD4 T cells are activated against thyroid antigens and recruit cytotoxic CD8 T cells, which kill thyroid cells, leading to hypothyroidism.<sup>6</sup> Children are initially euthyroid and slowly progress to become hypothyroid. However, approximately 10% of children are hyperthyroid, a condition known as "hashitoxicosis." The thyroid gland is usually pebbly or granular and may be mildly tender.

Ninety-five percent of patients with Hashimoto's thyroiditis have elevated antithyroid microsomal antibodies or antithyroid peroxidase antibodies. Plasma thyroid hormone levels are normal or low, and TSH levels are elevated in 70% of patients. Thyroid imaging is usually not necessary if clinical and laboratory findings are strongly suggestive of the diagnosis. The radionuclide scan usually shows patchy uptake of the tracer and may

Subacute thyroiditis	

mimic the findings in Graves' disease or multinodular goiter. The principal ultrasound finding is nonspecific, diffuse thyroid hypoechogenicity. Rarely, autoantibodies cannot be detected and fine-needle aspiration is needed to confirm the diagnosis. In as many as one third of adolescent patients, the thyroiditis resolves spontaneously with the gland becoming normal and the antibodies disappearing. Thus, expectant management should be considered. Exogenous thyroid hormone should be administered in the hypothyroid patient. However, in euthyroid children, it is ineffective in reducing the size of the goiter.<sup>7</sup>

Subacute (de Quervain's) thyroiditis, a viral inflammation of the thyroid gland, is unusual in children. The thyroid is swollen, painful, and tender. Mild thyrotoxicosis results from injury to the thyroid follicles, with release of thyroid hormone into the circulation. Serum T<sub>3</sub> and T<sub>4</sub> levels are elevated, and TSH is decreased. Because of thyroid follicular cell dysfunction, decreased radioactive iodine uptake occurs, a finding that distinguishes subacute thyroiditis from Graves' disease. Histologically, granulomas and epithelioid cells may be seen. The treatment of subacute thyroiditis is symptomatic and generally consists of nonsteroidal anti-inflammatory agents or corticosteroids. The condition typically lasts 2 to 9 months, and complete recovery can be expected.

Acute suppurative thyroiditis is a bacterial infection of the gland. The gland is acutely inflamed, and the patient is septic. Patients are usually euthyroid. Staphylococci or mixed aerobic and anaerobic flora are common causal agents. A congenital pharyngeal sinus tract may predispose the patient to infection. Management consists of intravenous antibiotics. Abscess drainage may be necessary. The thyroid gland should be expected to recover completely.

### Graves' Disease

Graves' disease, or diffuse toxic goiter, is the most common cause of hyperthyroidism in childhood. The condition is an autoimmune disease caused by the presence of immunoglobulins of the IgG class directed against components of the thyroid plasma membrane, possibly including the TSH receptor. These autoantibodies have several effects. They stimulate the thyroid follicles to increase iodide uptake and cyclic adenosine monophosphate production and induce the production and secretion of increased thyroid hormone.

TSH receptor antibodies are present in more than 95% of patients with active Graves' disease. The inciting event eliciting the antibody response against the TSH receptor is unknown. Reports have demonstrated that TSH-binding sites are present in a number of gram-positive and gram-negative bacteria. It is possible that infection may elicit the production of antibodies that react with the TSH receptor.<sup>8</sup> An infectious etiology for Graves' disease is further supported by scattered epidemiologic reports of disease clustering.<sup>9</sup> Graves' disease is seen in girls about five times more often than in boys, and the incidence steadily increases throughout childhood, peaking in the adolescent years. Congenital

Graves' disease, resulting from the transplacental passage of maternal antibodies, occurs in about 1% of infants born to women with active Graves' disease. The onset may be delayed until 2 to 3 weeks after birth.

In most children, the onset of Graves' disease develops over several months. Initial symptoms include nervousness, emotional lability, and declining school performance. Later, weight loss becomes evident, as does sweating, palpitations, heat intolerance, and general malaise. A smooth, firm, nontender goiter is present in more than 95% of cases. A bruit may be heard on auscultation. Exophthalmos is unusual in children, but a conspicuous stare may be evident. Laboratory evaluation generally reveals elevated free  $T_4$  and decreased TSH levels. Ten to 20 percent of patients will have elevation of  $T_3$  only, a condition known as  $T_3$  toxicosis. The diagnosis of Graves' disease is definitively established by the presence of these TSH receptor antibodies.

Although the basic pathogenesis of Graves' disease is understood, no generally successful methods are available to correct the immunologic defect. The treatment of Graves' disease is palliative and is designed to decrease the production and secretion of thyroid hormone. The natural course of untreated Graves' disease is unpredictable. In some patients, the thyrotoxicosis may be persistent but variable in severity. In others, it may be cyclic, with exacerbations of varying degree and duration.

Current treatment includes antithyroid medications, ablation with radioactive  $^{131}\text{I}$ , and surgical resection.<sup>10</sup> In the United States, most pediatric endocrinologists initiate therapy with methimazole or propylthiouracil, which reduces thyroid hormone production by inhibiting follicle cell organification of iodide and the coupling of iodotyrosines. Propylthiouracil also inhibits peripheral conversion of  $T_4$  to  $T_3$  and may be the agent of choice if rapid alleviation of thyrotoxicosis is desired. Both agents may possess some immunosuppressive activity because usually a reduction in antithyroid antibodies occurs. In most cases, methimazole is preferred because of its increased potency, longer half-life, and associated improved compliance. The initial adolescent dose is 30 mg once daily, which is reduced if the patient is younger. When the patient becomes euthyroid, as determined by normal  $T_3$  and  $T_4$  levels, the daily dose of methimazole should be reduced to 10 mg.  $T_3$  and  $T_4$

levels must be monitored. The thyroid gland decreases in size in about one half of patients. Thyroid enlargement with therapy signals either an intensification of the disease or hypothyroidism from overtreatment.

Side effects of methimazole include nausea, minor skin reactions, urticaria, arthralgias, arthritis, and fevers. The most serious reaction is an idiosyncratic agranulocytosis, occurring in less than 1% of patients. This may occur at any time during the course of treatment or even during a second course of the drug. The most common symptom of agranulocytosis is pharyngitis with fever, for which the patient should be warned to seek medical attention. In most cases, the granulocyte count increases 2 to 3 weeks after stopping the drug, but rare fatal opportunistic infections have been reported. Treatment with parenteral antibiotics during the recovery period has been recommended.

When treating Graves' disease, the goal is to allow natural resolution of the underlying autoimmune process. In general, the disease remission rate is approximately 25% after 2 years of treatment, with a further 25% remission every 2 years.<sup>11</sup> The resolution rate is decreased if TSH-receptor antibodies persist during and after treatment. The addition of  $T_4$  to methimazole has had variable results in reducing disease recurrence. However, the use of  $T_4$  cannot be recommended in pediatric patients receiving antithyroid medications.

The thyroid gland must be ablated if resistance or severe reactions to the antithyroid medications occur. Both surgical resection and ablation with radioactive  $^{131}\text{I}$  have complications. The advantages of  $^{131}\text{I}$  therapy include its effectiveness, safety, ease of administration, and relatively low cost.<sup>12</sup> Even though the disease recurrence rate is low after  $^{131}\text{I}$  treatment, patients have a 50% to 80% incidence of long-term hypothyroidism.<sup>13</sup> Despite studies demonstrating no increased risk of cancer relative to the general population, concerns remain over the possibility of teratogenic or carcinogenic effects of  $^{131}\text{I}$  in children and adolescents.<sup>12,14</sup>

Either a subtotal or total thyroidectomy is indicated for patients who refuse radioiodine treatment, for those children whose thyroid gland is so large that airway symptoms develop, or for those in whom medical management fails (Fig. 78-1). Antithyroid medication should be administered to decrease  $T_3$  and  $T_4$  levels

**Figure 78-1.** This teenage girl developed Graves' disease and her parents declined radioiodine treatment. **A**, The diffusely enlarged, hyperemic thyroid gland is visualized. **B**, The thyroid bed is seen after subtotal thyroidectomy. Each upper pole (asterisk, arrow) was left intact.

into the normal range before operation. Alternatively,  $\beta$ -blocking agents, such as propranolol, may be used to ameliorate the adrenergic symptoms of hyperthyroidism. In addition, Lugol's solution, 5 to 10 drops per day, should be administered for 4 to 7 days before thyroidectomy to reduce the vascularity of the gland.

The incidence of hypothyroidism after subtotal thyroidectomy is 12% to 54%, and the hypothyroidism may be subclinical in up to 45% of children.<sup>12</sup> When abnormal TSH levels are considered, the incidence of hyperthyroidism or hypothyroidism is even higher. The rate of recurrent hyperthyroidism is approximately 13%. It is likely that the relapse rate increases with time after operation because approximately 30% of adult patients exhibit recurrent hyperthyroidism 25 years after their subtotal thyroidectomy.<sup>10</sup>

### Hypothyroidism

Hypothyroidism may result from a defect anywhere in the hypothalamic-pituitary-thyroid axis and is rarely treated surgically. Approximately 90% of pediatric hypothyroidism is congenital, detected by neonatal screening programs, and results from dysgenesis of the thyroid gland. Two thirds of these infants have a rudimentary gland, and complete absence of thyroid tissue is noted in the rest of the patients. The rudimentary gland may be ectopic (e.g., the base of the tongue). Maternal thyroid hormone may prevent symptoms even in children with complete thyroid agenesis. Ectopic thyroid tissue may supply a sufficient amount of  $T_4$  for years or may prove to be insufficient later in childhood.

## Neoplastic Thyroid Conditions

### Thyroid Nodules

Thyroid nodules are uncommon in children but have a relatively high likelihood of associated cancer. In children, the incidence of malignancy in thyroid nodules is about 20%.<sup>15-17</sup> This cancer rate is lower than has been reported in previous decades because fewer children today have been exposed to neck irradiation. Appropriate and prompt evaluation and management are important because the malignancy may be at an early curable stage. A summary of pathologic results from several large series of children who underwent operation for thyroid nodules is seen in Table 78-3. Other diagnostic possibilities for thyroid nodules include cystic hygroma, thyroglossal duct remnant, and germ cell tumor.

Girls have twice the incidence of thyroid nodules as boys.<sup>18</sup> Most patients are initially seen with an asymptomatic mass in the low anterior neck. It is impossible to differentiate benign from malignant lesions on clinical grounds, but a careful neck examination should be performed, especially to determine whether enlarged cervical lymph nodes are present. Thyroid imaging studies are unreliable in distinguishing benign from malignant nodules. However, if ultrasonography reveals multiple nodules, the diagnosis of thyroiditis becomes more likely. Because malignant nodules may be either solid or cystic, ultrasonography is not helpful

Data from Desjardins JG, Khan AH, Montupet P, et al: Management of thyroid nodules in children: A 20-year experience. *J Pediatr Surg* 22:736-739, 1987; Hung W, Anderson KD, Chandra RS, et al: Solitary thyroid nodules in 71 children and adolescents. *J Pediatr Surg* 27:1407-1409, 1992; and Yip FWK, Reeve TS, Poole AG, et al: Thyroid nodules in childhood and adolescence. *Aust N Z J Surg* 64:676-678, 1994.

in this regard. Similarly, thyroid scintiscan is not a reliable diagnostic modality because malignant nodules may be either functioning or nonfunctioning. A therapeutic trial of exogenous thyroid hormone to induce nodule regression is not recommended for children.

The usefulness of fine-needle aspiration cytology in children has not been well defined. Pediatric surgeons have historically recommended the removal of thyroid nodules. Few large studies have defined the natural history of cytologically benign nodules in children. In one study of 57 children with thyroid nodules evaluated with aspiration, the incidence of malignancy was 18%.<sup>19</sup> If these benign nodules could be accurately diagnosed without surgical removal, significant potential savings may occur in operative morbidity and cost.

Because the adolescent spectrum of thyroid disease is similar to that of adults, fine-needle aspiration may be acceptable in evaluating thyroid nodules in this population. The incidence of malignancy in thyroid nodules in patients age 13 to 18 years is approximately 11%.<sup>18</sup> Benign nodules in adolescent patients can be followed up with serial physical examinations and ultrasound studies. Exogenous thyroid hormone to suppress benign thyroid nodules has not been shown to alter their natural history.

Surgical resection should be performed if the nodule is malignant or has indeterminate cytology or if the size of a benign nodule increases. If a cystic thyroid lesion disappears after aspiration, surgical treatment may be deferred. If the lesion recurs, it should be removed. Even though cyst fluid can be sent for cytologic analysis, the sensitivity of this test for determining the presence of cancer in children is unknown.<sup>20</sup>

Thyroid nodules in prepubertal children have a higher risk of malignancy. The natural history of benign lesions in younger children is unknown, and the safety of nonoperative treatment has not been demonstrated. Based on these data, the current recommendation for management of all thyroid nodules in children younger than age 13 is surgical resection. Preoperative ultrasonography and thyroid scintigraphy aid in determining the anatomy.<sup>16,21</sup>

### Thyroid Carcinoma

Thyroid carcinoma represents about 3% of all pediatric malignancies in the United States. The peak incidence is between ages 10 and 18 years, and it occurs more often in girls in a ratio of 2:1. Approximately 10% of all malignant thyroid tumors occur in children. In comparison to adults, pediatric patients with thyroid carcinoma present with more advanced-stage disease and with a higher incidence of lymph node and pulmonary metastases but with lower mortality.<sup>22</sup>

The incidence of childhood thyroid malignancy has decreased in most parts of the world since the mid 1970s owing to the reduced use of radiation to treat benign diseases. A marked increase of thyroid tumors was noted in the Republics of Belarus and Ukraine after the 1986 Chernobyl nuclear power plant catastrophe.<sup>23</sup> The latency period for developing thyroid cancer after radiation exposure is 4 to 6 years. In Belarus, a 62-fold increase in thyroid tumors was noted after the Chernobyl accident.

Treatment of a previous malignancy is another significant risk factor for thyroid carcinoma. Thyroid cancers constitute about 9% of second malignancies.<sup>24</sup> Hodgkin's lymphoma is the most common malignancy associated with a subsequent thyroid cancer. Whereas most thyroid second neoplasms follow previous radiation exposure to the neck, alkylating agents alone also predispose to thyroid cancer. The mean age at diagnosis of thyroid second neoplasms is 20 years, demonstrating the importance of careful surveillance for second tumors in children who have been successfully treated for cancer.

The diagnosis of thyroid carcinoma is impossible to determine based on clinical grounds alone. In adults, fine-needle aspiration cytology has been used as the initial evaluation of a thyroid nodule. Its use in children has not been thoroughly explored because most surgeons recommend surgical resection of all thyroid lesions because of the concern for false-negative interpretations.

Various molecular biologic events may account for the disparity in behavior of the different histologic subtypes of thyroid cancer. *RAS* proto-oncogene mutations are found in about 20% of papillary tumors and 80% of follicular tumors.<sup>25</sup> Other studies have reported that *RAS* is frequently activated in benign follicular adenomas, suggesting that this genetic event occurs early in the transformation process.<sup>26</sup> An activating mutation of the *RET* proto-oncogene is found in about 35% of papillary thyroid cancers.<sup>27</sup> The *RET* protein is a receptor tyrosine-kinase molecule, which

probably functions within the cell to regulate proliferation or differentiation. This protein has been shown to be responsible for the development of medullary thyroid carcinoma (MTC). Specific point mutations are associated with the multiple endocrine neoplasia type 2 (MEN 2A, MEN 2B) syndromes and familial MTC (FMTC). In addition, as many as 40% of patients with sporadic nonfamilial MTCs possess *RET* mutations.<sup>28</sup>

Thyroid carcinoma usually presents clinically as a thyroid mass, sometimes with enlarged cervical lymph nodes. Regional lymph node metastases are present in three of four children when the disease is first detected (Table 78-4). The pathologic diagnosis can be established by using either fine-needle aspiration cytology or frozen section biopsy at operation. The functional status of the mass can be determined by preoperative scintiscan. Ultrasonography may be helpful in planning the operation.<sup>21</sup> Because pulmonary metastases are frequent, a preoperative chest radiograph should be obtained.

No clinical trial has established whether total thyroidectomy, with lymph node dissection if the regional nodes are involved, is better than subtotal thyroidectomy.<sup>29-31</sup> Radioiodine ablative therapy is more effective after removal of the entire gland because less functioning thyroid tissue takes up the radionuclide. Surgeons preferring a lesser resection believe that differentiated thyroid carcinoma in children is an indolent disease and that survival is not clearly related to the extent of gland removal.<sup>32,33</sup> Although these complications occur less commonly in recent reports, the historical incidence of recurrent laryngeal nerve injury ranges from zero to 24%, whereas permanent hypocalcemia occurs in 6% to 27% of patients undergoing total thyroidectomy.<sup>32,34</sup>

In one retrospective review, multivariate analysis revealed that younger age at diagnosis and the histologic type of tumor were the only factors predictive of early disease recurrence.<sup>32</sup> Children with follicular histology and older than 12 years at diagnosis were more likely to be cured at the initial procedure. Thus, tumor factors may be more important than treatment factors in determining the outcome.

Lobectomy with isthmus resection may be sufficient for tumors clearly isolated to one lobe. However, thyroid cancer is bilateral in up to 66% of cases. Also, about 80% of tumors exhibit multifocality. Therefore, most pediatric surgeons believe that more aggressive thyroid gland resections are indicated and recommend that either a total or near-total thyroidectomy be performed for the management of differentiated thyroid cancer.<sup>35,36</sup>

The recurrent laryngeal nerve should be identified and protected. When tumor invades the recurrent laryngeal nerve, the nerve can be safely preserved without compromising survival through adjuvant therapy with <sup>131</sup>I irradiation to successfully eradicate residual tumor.<sup>37</sup> The most reliable way to preserve parathyroid gland function is to identify and preserve the glands at the time of thyroidectomy (Fig. 78-2). If there is apparent devascularization, then one should autotransplant one or two of the glands into the sternocleidomastoid

muscle or into the nondominant forearm.<sup>38,39</sup> If there is regional nodal metastasis, a node dissection is recommended. In patients with locally advanced disease, it is imperative to remove as much of the thyroid gland as possible to allow subsequent radioiodine scanning and treatment if the tumor recurs. Finally, after surgical resection, most investigators recommend that all patients be treated with exogenous thyroid hormone to suppress TSH-mediated stimulation of the gland.

**Figure 78-2.** The relationship of the parathyroid glands to the recurrent laryngeal nerve during prophylactic thyroidectomy for multiple endocrine neoplasia type 2 is seen. The left recurrent laryngeal nerve is marked by an asterisk. The superior parathyroid gland (arrowhead) is typically located posterior to the nerve. The inferior parathyroid gland (arrow) is usually found anterior to the nerve.

The incidence of pulmonary metastases at diagnosis in childhood is about 6%, but they rarely occur in the absence of significant cervical lymph node metastases.<sup>33,40</sup> Pulmonary metastases require treatment with radioiodine. Plain chest films demonstrate the pulmonary disease in only 60% of cases, making scanning with radioiodine necessary. The pulmonary scintiscan may be falsely negative if significant residual thyroid gland remains in the neck.<sup>40</sup>

Overall survival in nonmedullary thyroid carcinoma is 98%.<sup>22</sup> A higher rate of recurrence has been seen in children who did not receive postoperative <sup>131</sup>I than in those who did.<sup>22</sup> The time to first recurrence has ranged from 8 months to 14.8 years (mean, 5.3 years), thereby emphasizing the importance of long-term follow-up for these children. Prognostic factors associated with recurrence include capsular or soft tissue invasion, positive margins, and tumor location at diagnosis (thyroid, lymph nodes, lung).<sup>22</sup> A whole-body <sup>131</sup>I scan should be performed approximately 6 weeks after the initial thyroid resection and followed by therapeutic doses of the radionuclide administered as necessary to ablate residual tissue and treat residual metastatic disease. Radioactive ablation has been shown to decrease the risk of local recurrence, increase the sensitivity of subsequent diagnostic whole-body scans, and improve the utility of serum thyroglobulin as a marker for recurrent or residual disease during long-term follow-up.<sup>35</sup>

Thyroglobulin has been shown to be a useful marker of residual or metastatic thyroid cancer. The plasma level of this protein should be measured yearly, and an elevated value should raise the suspicion of recurrent disease.<sup>41</sup> The diagnostic accuracy of this test is significantly decreased in children who have residual

thyroid tissue or in those who are taking thyroid hormone supplementation.

MTC accounts for approximately 5% of thyroid neoplasms in children. Arising from the parafollicular C cells, MTC may occur either sporadically or in association with MEN 2A, MEN 2B, or the FMTC syndrome. MTC is usually the first tumor to develop in MEN patients and is the most common cause of death in this group. The neoplasm is particularly virulent in patients with MEN 2B and may occur in infancy.<sup>42</sup>

As with other pediatric thyroid neoplasms, the clinical diagnosis of MTC not associated with a known familial or MEN syndrome is usually made only after metastatic spread of the tumor has occurred to the adjacent cervical lymph nodes or to distant sites.<sup>43</sup> Surgical resection is the only effective treatment for MTC, underscoring the importance of early diagnosis and therapy before metastasis occurs. For this reason, current management of MTC in children from MEN 2 and FMTC kindreds relies on the presymptomatic detection of the *RET* proto-oncogene mutation responsible for the disease. Prophylactic thyroidectomy in young asymptomatic children carrying a mutated allele of the *RET* proto-oncogene in MEN 2A kindreds has been demonstrated to prevent or cure MTC. In a study of 50 children and teenagers with the *RET* proto-oncogene mutation who underwent prophylactic thyroidectomy, 66% already had foci of MTC within the thyroid gland.<sup>44</sup> However, no child younger than 8 years of age was found to have metastatic disease at time of surgery. Moreover, when followed for 5 to 8 years, none had evidence of persistent or recurrent disease when screened by physical examination and plasma calcitonin levels obtained after calcium and pentagastrin stimulation. Based on this information, affected children with MEN 2A should undergo total thyroidectomy at approximately age 5 years.<sup>45-47</sup> Because of the increased virulence of MTC in children with MEN 2B, prophylactic thyroidectomy should be performed at approximately age 1 year. Complete removal of the thyroid gland is the recommended surgical management of MTC in children because of the high incidence of bilateral disease.<sup>48</sup> Central lymph node dissection (i.e., removal of lymph nodes medial to the carotid sheaths and between the hyoid bone and the sternum) is likely not necessary except in older children or when gross lymphadenopathy is discovered at the time of prophylactic thyroidectomy. Early detection by DNA mutation analysis and early operative intervention result in a normal life expectancy in these children.<sup>49</sup>

## PARATHYROID GLANDS

### Embryology and Physiology

Parathyroid gland development begins about week 5 of gestation when the epithelium in the dorsal portions of the third and fourth pharyngeal pouches begins to proliferate. During week 6 of development, the inferior parathyroid glands, associated with the third pair of pharyngeal pouches, migrate caudad

with the thymic primordium and come to rest on the dorsal surface of the thyroid gland low in the neck. The superior parathyroid glands arise from the fourth pharyngeal pouches and come to rest cephalad to the other glands. Mobilization of calcium from the bones is directly stimulated by parathormone (PTH), a process that also requires vitamin D.

### Hyperparathyroidism

PTH is secreted as an 84-amino acid protein, which is rapidly cleaved in the liver and kidney into the carboxyl-terminal, amino-terminal, and mid-region fragments. The biologic activity of PTH resides in the amino-terminal segment, but the plasma level of this moiety is low, owing to its very short half-life in the circulation. The carboxyl-terminal fragment levels are 50- to 500-fold those of the amino-terminal fragment. Most clinical assays of PTH measure the carboxyl-terminal levels of the hormone. These assays are usually effective for the evaluation of hyperparathyroidism, but plasma levels of the carboxyl-terminal fragment may be selectively elevated if there is a component of renal failure. The laboratory hallmark of hyperparathyroidism is the finding of an inappropriately elevated plasma PTH level with hypercalcemia.

The differential diagnosis of hypercalcemia in childhood is shown in Table 78-5. Unlike hypercalcemia in adults, hypercalcemia in children is rarely related to a neoplasm. However, in rare cases, pediatric tumors may secrete a parathyroid-related polypeptide that elevates the calcium level. Reported neoplasms include malignant rhabdoid tumor, mesoblastic nephroma, rhabdomyosarcoma, neuroblastoma, and lymphoma. In these patients, the PTH level is generally normal or decreased.

### Primary Hyperparathyroidism

Primary hyperparathyroidism in childhood usually results from a solitary hyperfunctioning adenoma and more rarely from diffuse hyperplasia of all four glands.<sup>50</sup> Hyperparathyroidism resulting from hyperplasia in all

**Table 78-5** Differential Diagnosis of Hypercalcemia in Childhood

four glands is a feature of MEN 1. Hyperparathyroidism develops in approximately 30% of patients having MEN 2A in their second or third decade of life.<sup>51</sup> At the time of prophylactic thyroidectomy for MEN 2, the parathyroid glands can be identified and autotransplanted into the nondominant forearm.<sup>38</sup> If hyperparathyroidism develops, a portion of the heterotopic tissue may easily be removed from the forearm.

Surgical options for parathyroid gland hyperplasia involving all of the glands include either  $3\frac{1}{2}$  gland parathyroidectomy or total parathyroidectomy with heterotopic autotransplantation of some parathyroid tissue back into the nondominant forearm.<sup>52</sup> The latter approach has been shown to be safe in infants and children and has the advantage of avoiding repeated neck exploration if hyperparathyroidism should recur.<sup>38,47</sup> Moreover, total parathyroidectomy with heterotopic autotransplantation results in improved survival rate in infants with severe hypercalcemia.<sup>52</sup> Patients with total parathyroidectomy and autotransplantation require a short period of vitamin D and calcium supplementation until the heterotopic tissue begins to function.<sup>38</sup>

Primary hyperparathyroidism of infancy is a rare, often fatal, condition that usually develops within the first 3 months of life.<sup>52,53</sup> Signs include hypotonicity, respiratory distress, failure to thrive, lethargy, and polyuria. The serum PTH level always is elevated, and histologic diffuse parathyroid gland hyperplasia occurs. In about half of the cases, a familial component to the disease is found. Early recognition and treatment are essential to allow normal growth and development of the infant.

The management of primary hyperparathyroidism in children is surgical. Neck exploration with evaluation of all four parathyroid glands is the standard parathyroidectomy operation and should be employed when parathyroid gland hyperplasia or MEN is suspected. However, because a solitary hyperfunctioning adenoma accounts for the majority of primary

hyperparathyroidism, less invasive parathyroidectomy procedures have gained popularity. These operations are safe and effective alternatives to traditional bilateral neck exploration when preoperative studies demonstrate a single abnormal gland.<sup>54</sup> Unilateral neck exploration with focused evaluation and excision relies on accurate preoperative localization studies and rapid intraoperative PTH (IO-PTH) assays to confirm that the offending gland or glands have been excised.  $^{99m}\text{Tc}$ -sestamibi is avidly taken up by parathyroid tissue, especially adenomas (Fig. 78-3).<sup>55</sup> The sensitivity of detecting abnormal parathyroid glands by sestamibi scan alone is 87%; however, when in conjunction with ultrasonography sensitivity reaches 96% in detecting a parathyroid adenoma.<sup>56,57</sup> Unilateral neck exploration is guided by the localizing studies (Fig. 78-4). A baseline serum PTH level is obtained, followed by PTH levels drawn at 5 and 10 minutes after the presumptive abnormal parathyroid gland has been

**Figure 78-4.** This intraoperative photograph demonstrates an enlarged right superior parathyroid adenoma (arrow) during unilateral neck exploration that was directed by preoperative localizing studies.

**Figure 78-5.** A rapid intraoperative parathyroid hormone (IO-PTH) assay during unilateral focused parathyroidectomy is depicted. Baseline plasma PTH levels have been drawn. Time 0 represents the moment of resection of the hypersecreting parathyroid gland. PTH levels are drawn at 5 and 10 minutes. A 50% decline in PTH level from baseline at 10 minutes indicates that the offending parathyroid gland or glands have been removed.

excised. Because intact PTH half-life is only a few minutes, a greater than 50% drop in IO-PTH level within 10 minutes signifies successful removal of the hyperfunctioning parathyroid tissue (Fig. 78-5).<sup>58</sup>

### Familial Hypocalciuric Hypercalcemia

Familial hypocalciuric hypercalcemia differs from primary hypoparathyroidism in that the PTH value is normal but urinary excretion of calcium is low. Patients are usually asymptomatic with an elevated serum calcium level. The serum magnesium level also may be elevated.

The disease is inherited as an autosomal dominant disorder caused by a heterozygous mutation in the  $\text{Ca}^{2+}$ -sensing receptor gene.<sup>59</sup> The parathyroid glands are normal, and usually there is no benefit to parathyroidectomy. If both parents are carriers, the neonate may have severe hypercalcemia. These infants have inherited mutations in both copies of the  $\text{Ca}^{2+}$ -sensing receptor gene and often have hyperplasia of all of their parathyroid glands. These infants do benefit from parathyroidectomy with transplantation of one gland.

### Secondary Hyperparathyroidism

Secondary hyperparathyroidism occurs in children with renal insufficiency or malabsorption. PTH production is increased in response to decreased calcium levels. Affected patients typically respond to medical treatment designed to decrease intestinal phosphorus absorption. In rare cases, severe renal osteodystrophy develops, manifested by skeletal fractures and metastatic calcifications. Especially severe cases of secondary hyperparathyroidism may be candidates for total parathyroidectomy with autotransplantation.<sup>50</sup>

### Tertiary Hyperparathyroidism

Tertiary hyperparathyroidism occurs when persistent hyperfunction of the parathyroid glands occurs, even

after the inciting stimulus has been removed. This is often seen in patients with chronic renal failure and secondary hyperparathyroidism who undergo renal transplantation. Tertiary hyperparathyroidism is commonly due to hyperplasia of all four glands. Children with this condition are candidates for total parathyroidectomy with autotransplantation.

## ADRENAL GLANDS

### Anatomy and Embryology

The primordial adrenal cortex arises from the coelomic mesoderm and becomes visible between weeks 4 and 6 of development. During development, the fetal adrenal gland contains the permanent cortex, fetal cortex, and medulla. The fetal cortex, whose function is unknown, is responsible for the large size of the fetal adrenal gland, with the fetal adrenal gland being four times the size of the fetal kidney at the fourth month of gestation. The fetal cortex begins to decrease in size within a few hours of birth and disappears by the first year of life. The cells of the permanent cortex are arranged into three separate zones: the zona glomerulosa, zona fasciculata, and zona reticularis. The zona glomerulosa gives rise to the narrowed zona fasciculata and reticularis of the adult cortex. The zona reticularis does not reach adult form until late childhood.<sup>60</sup>

The adrenal glands weigh 1 g at birth and grow to 4 to 5 g by late childhood. The mature adrenal gland measures 3 to 5 cm in length and 4 to 6 mm in thickness. The adrenal glands have a profuse arterial supply. One or more middle adrenal arteries arise from the aorta, six to eight superior adrenal arteries from the inferior phrenic artery, and one or more inferior adrenal arteries from the renal artery. The adrenal gland is drained by a single large adrenal vein. The right adrenal vein drains into the inferior vena cava and the left adrenal vein drains into the left renal vein.

The adrenal gland can be found in several anomalous locations. In adrenal heterotopia, the adrenal gland is situated in the normal location but lies under the capsule of the kidney (adrenal-renal heterotopia) or capsule of the liver (adrenal-hepatic heterotopia). Extra-adrenal tissue may be found anywhere in the abdominal cavity but usually is found along the anatomic derivatives of the urogenital ridge for the adrenal cortex and along the dorsal root ganglia for the medullary tissue. Accessory adrenal glands usually occur without a medullary subcomponent and have been found in 16% of 100 consecutive autopsies.<sup>61</sup> Another 16% had complete accessory glands.

### Physiology

The adrenal cortex produces three major hormones: aldosterone, cortisol, and androgens. The zona glomerulosa is exclusively responsible for the production of aldosterone because it lacks the enzyme  $17\alpha$ -hydroxylase, which is necessary to produce the

precursors to cortisol and androgens. The zona fasciculata and zona reticularis together produce cortisol, androgens, and small amounts of estrogens. These areas lack the enzymes necessary to produce the precursors to aldosterone.

### Aldosterone

Aldosterone regulates extracellular fluid volume as well as sodium and potassium balance. Aldosterone concentrations are regulated by the renin-angiotensin system. Renin is secreted by the juxtaglomerular cells in response to decreased pressure in the renal afferent arterioles and by decreased plasma concentration that is detected by the macula densa. Renin converts angiotensinogen into angiotensin I, which is then converted to angiotensin II by the angiotensin converting enzyme in the lung. Angiotensin II is a potent vasoconstrictor and also directly stimulates the zona glomerulosa to release aldosterone. Aldosterone stimulates renal tubular reabsorption of sodium in exchange for potassium and hydrogen, thereby increasing renal fluid resorption and expanding intravascular volume.

### Cortisol

The regulation of cortisol is controlled through the cortisol-releasing factor (CRF) from the hypothalamus and subsequent stimulation of pituitary adrenocorticotropic hormone (ACTH). The neuroendocrine control of cortisol results in a peak in cortisol level in the early morning and a nadir in the late evening. The metabolic effects of cortisol include stimulation of hepatic gluconeogenesis, inhibition of protein synthesis, increased protein catabolism, and lipolysis of adipose tissue. Cortisol also causes a loss of collagen, inhibition of wound healing through decreased fibroblast activity, and induction of a negative calcium balance, leading to osteoporosis.

### Androgens

The adrenal androgens include dehydroepiandrosterone (DHEA) and DHEA sulfate (DHEA-S). These hormones undergo peripheral conversion to the biologically active forms testosterone and dihydrotestosterone. In the normal male, adrenal androgens account for less than 5% of the circulating testosterone. The adrenal androgens become most clinically relevant with congenital adrenal hyperplasia (CAH), a group of autosomal recessive enzyme deficiencies resulting in an accumulation of steroid precursors shuttled away from the synthesis of cortisol and/or aldosterone and into the pathway of androgens. Deficiency in the enzyme 21-hydroxylase accounts for over 90% of CAH.

### Adrenal Masses

The differential diagnosis of adrenal masses is listed in [Table 78-6](#). Neuroblastoma accounts for more than 90% of adrenal masses. Adrenal masses are being detected at a greater rate than previously described for children

**Table 78-6** Differential Diagnosis of an Adrenal Mass

Neonatal child abuse

because of the increased use of diagnostic testing for other clinical conditions that are unrelated to adrenal disease. The significance of such adrenal masses seen by computed tomography (CT) is unknown in children. At autopsy, adrenal masses are detected in less than 1% of patients younger than age 30 years.<sup>62</sup> This incidence increases to 7% in patients older than 70 years. Follow-up of patients with nonfunctioning adrenal masses demonstrates that 5% to 25% increase in size by at least 1 cm, and the risk of malignancy is 1 in 1000. Patients who have an incidentally discovered adrenal mass should undergo hormone evaluation, including a 1-mg dexamethasone suppression test, aldosterone levels, and measurement of plasma free metanephrines.<sup>62</sup> Surgical treatment is indicated for all functional adrenal cortical tumors and pheochromocytoma. In children, most surgeons will resect these tumors regardless of size ([Fig. 78-6](#)). However, no clear evidence supports this management over conservative therapy, especially in lesions smaller than 3 cm.

## Adrenal Cortex

### Hypercortisolism (Cushing's Syndrome)

Hypercortisolism, or Cushing's syndrome, describes any form of glucocorticoid excess that can be caused by pituitary adenomas secreting ACTH, adrenal tumors including carcinoma and adenoma, ectopic ACTH syndrome, nodular adrenal hyperplasia, and ACTH-producing tumors ([Table 78-7](#)). Additionally, the administration of supraphysiologic quantities of ACTH or glucocorticoids can lead to iatrogenic Cushing's syndrome, the most common cause of hypercortisolism in adults and children. Cushing's disease is caused by a pituitary microadenoma or, more rarely, by a macroadenoma. It is the

**Figure 78-6.** This teenager was found to have a right adrenal mass measuring 4.5 cm in greatest dimension. Preoperative evaluation did not reveal evidence of a functioning tumor. **A**, She was placed in the left lateral decubitus position for the laparoscopic right adrenalectomy. The incisions utilized for the operation are seen. **B**, The harmonic scalpel is being used to free the tumor (*asterisk*) from the lateral surrounding tissue. **C**, The tumor (*asterisk*) has been almost completely mobilized and the cephalad attachments are being lysed with the harmonic scalpel. **D**, The tumor (*asterisk*) is being retracted laterally, and the right adrenal vein is being clipped with endoscopic clips. This tumor was excised uneventfully and was found to be a nonfunctioning adrenal adenoma. The patient was discharged on her first postoperative day.

second most common cause of Cushing's syndrome in pediatric patients. Ectopic ACTH syndrome is rare in children but has been reported in infants younger than 1 year. Tumors that can produce ACTH include pulmonary neoplasms, neuroblastomas, pancreatic islet cell carcinomas, thymomas, carcinoids, MTCs, and pheochromocytomas. In children, the most frequent cause of ectopic ACTH is a bronchial carcinoid. ACTH levels are usually 10 to 100 times higher than those seen in Cushing's disease. These markedly elevated levels of ACTH lead to hypokalemic alkalosis. Additionally, ACTH-independent multinodular adrenal hyperplasia is characterized by hypersecretion of both cortisol and adrenal androgens.

Hypercortisolism is more common in children than previously recognized. In Harvey Cushing's original description,<sup>63</sup> the patient was a 23-year-old woman whose clinical features indicated long-standing disease. In infants and children younger than 7 years, the most common cause of Cushing's syndrome is an adrenal tumor. Among 60 infants younger than 1 year, 48 had adrenal tumors, with a 4:1 ratio between girls and boys (Fig. 78-7).<sup>64</sup> In adults and children older than 7 years, adrenal hyperplasia secondary to hypersecretion of pituitary ACTH predominates.

Clinical features of Cushing's syndrome can take 5 years or longer to develop. Thus, the classic

cushingoid appearance may not be seen in children. The most frequent and reliable findings in children with Cushing's syndrome are weight gain and growth failure.<sup>65</sup> Specifically, any obese child who stops growing should be evaluated for Cushing's syndrome.

**Figure 78-7.** This 8-month-old was seen in the emergency department for progressive facial swelling. **A**, Examination reveals cushingoid features with moon facies. In addition, she had generalized obesity. Her plasma cortisol level was elevated and her ACTH level was suppressed. **B**, CT scan revealed a 4.3 × 4.8 × 4.8-cm left adrenal mass that was homogeneous and showed no evidence of invasion of adjacent structures. The infant subsequently underwent laparoscopic left adrenalectomy and was discharged on postoperative day 2. **C**, At 2-month follow-up, there is marked improvement in the physical manifestations of her Cushing's syndrome. (From Kim E, Aguayo P, St. Peter SD, et al: Adrenocortical adenoma expressing glucocorticoid in an 8-month-old female. *Eur J Pediatr Surg* 18:1-2, 2008. Reprinted with permission.)

The initial phase in the diagnosis of Cushing's syndrome is to screen for the syndrome. Next, it is necessary to determine its etiology. Screening for Cushing's syndrome can be accomplished by measuring the plasma cortisol at 8:00 AM (normal levels, <14 mg/dL) and 6:00 PM (normal levels, <8 mg/dL) to coincide with the diurnal variation in plasma cortisol. The loss of diurnal rhythm is usually the earliest reliable laboratory index of Cushing's disease. A single measurement at midnight should be less than 2 mg/dL in normal patients and more than 2 mg/dL in Cushing's disease.<sup>66</sup> The most sensitive screening test is the 24-hour urinary 17-hydroxycorticosteroid or free cortisol value, which is more than 150 mg/day in patients with Cushing's syndrome. The overnight dexamethasone suppression test is performed by administering 1 mg of dexamethasone at 11:00 PM and measuring the plasma cortisol level the following morning at 8:00 AM. In normal individuals, ACTH is suppressed and the cortisol level is decreased by 50% or more of baseline (<5 mg/dL). This dose of dexamethasone is insufficient to cause suppression in patients with Cushing's syndrome.

Once Cushing's syndrome is established, further tests are used to determine the specific cause. The high-dose dexamethasone suppression test is used to distinguish pituitary causes from nonpituitary causes. An oral dose of 2 mg of dexamethasone is given every 6 hours for 48 hours (or 40 mg/kg/dose for infants). Urine is then collected for 24 hours to measure free cortisol and 17-hydroxysteroids. In patients with a pituitary neoplasm, the steroid excretion levels are suppressed to 50% of baseline. In patients with an adrenal adenoma or adrenocortical carcinoma and most patients with tumors that produce ACTH, the levels are not suppressed. Plasma ACTH levels are generally low or normal with adrenal causes of hypercortisolism, modestly elevated with pituitary neoplasms, and extremely elevated with tumors producing ectopic ACTH.

Among children, 80% to 85% of those with Cushing's disease have a surgically identifiable

microadenoma<sup>67</sup> and transsphenoidal hypophysectomy offers the best chance for cure. Twenty percent of patients experience relapse after complete resection and manifest Cushing's disease within 5 years. Alternate therapies include pituitary irradiation, adrenalectomy, and drugs that inhibit adrenal function. Of these alternate therapies, adrenalectomy is the preferred treatment when two transsphenoidal procedures fail. Mitotane, an adrenolytic agent that causes a chemical adrenalectomy, has severe side effects, including nausea, anorexia, and vomiting.

### Primary Hyperaldosteronism

Primary hyperaldosteronism is defined as excess production of aldosterone from the adrenal glands with consequent suppression of renin. Most commonly, this is caused by either adrenocortical hyperplasia or an adrenal adenoma. Adrenal adenoma, or Conn's syndrome, is the most common cause of primary hyperaldosteronism in adults, whereas adrenocortical hyperplasia is the most common cause in children.<sup>68</sup> Rarely, adrenal carcinoma can present as primary hyperaldosteronism.

Signs and symptoms of primary hyperaldosteronism are nonspecific. Patients have hypertension, muscle weakness, polydipsia, and polyuria. Hyperaldosteronism increases the total body sodium level and consequently increases the total body fluid volume. It is characterized by hypertension and hypokalemic alkalosis. The elevated aldosterone levels suppress renin and angiotensin.

The diagnosis should be entertained in any child with hypertension and hypokalemia. Initial screening in children with hypertension involves checking a potassium level. Hypokalemia (<3.5 mEq/L) is consistent with primary hyperaldosteronism. The aldosterone level is elevated, the renin level is suppressed, and patients frequently have a metabolic alkalosis. If necessary, the diagnosis may be confirmed by performing

a saline load challenge. A large volume of intravenous normal saline is infused over 4 hours. In normal subjects, the saline bolus should decrease plasma aldosterone levels below 6 to 8 ng/dL. Alternatively, an outpatient saline load test consists of administering a high-sodium diet for 3 to 5 days that fails to suppress aldosterone in patients with hyperaldosteronism. The serum aldosterone level must be determined in the morning before the patient has assumed an upright position.

After hyperaldosteronism is diagnosed, it is important to distinguish between an aldosterone-secreting adenoma and bilateral adrenal hyperplasia. A solitary adrenal mass greater than 1 cm with a normal-appearing contralateral gland on CT or magnetic resonance imaging (MRI) supports the diagnosis of an adenoma.<sup>69</sup> When imaging does not clearly demonstrate a solitary adrenal mass, selective adrenal vein sampling can differentiate unilateral versus bilateral aldosterone hypersecretion. Alternatively, some institutions utilize scintigraphy with <sup>131</sup>I-iodomethylnorcholesterol (NP-59), a cholesterol analog that is taken up as cholesterol in the steroidogenic pathway. Dexamethasone suppression of ACTH-dependent adrenocortical tissue is followed by NP-59 administration. An adenoma is suggested if asymmetric adrenal uptake occurs. Bilateral hyperplasia is suggested if the uptake is symmetric.

The treatment of a functional adrenal adenoma is excision. The mortality rate from operative removal is generally less than 1%, with a cure rate of 75%. Treatment of patients with bilateral adrenal hyperplasia is with spironolactone.

### Adrenocortical Carcinoma

Adrenocortical carcinoma is rare. National Cancer Institute's Surveillance, Epidemiology and End Results (SEER) data report that adrenocortical carcinoma represents 1.3% of all carcinomas in children and adolescents younger than 20 years of age in the United States, accounting for only 0.1% of all childhood malignancies.<sup>70</sup> There is a female-to-male predominance of about 2:1. The tumors occur equally on the right and left sides and are hormonally functional in 80% to 100% of patients. In the SEER database, half of the adrenocortical carcinomas occur in children younger than 5 years of age. Around the world, there is geographic variability, with southern Brazil having a 15-fold greater incidence of adrenocortical carcinoma compared with other populations. This increased incidence has been attributed to a unique germline mis-sense mutation.<sup>71</sup>

The etiology of adrenocortical carcinoma is unknown, but its association with several hereditary tumor syndromes gives insight into the molecular pathogenesis of this malignancy. Li-Fraumeni syndrome is an autosomal dominant familial disease and is characterized by the early onset of tumors, including sarcomas, osteosarcomas, breast and brain cancers, leukemia, and adrenocortical carcinoma. Germline mutations in the *TP53* tumor suppressor gene on chromosome 17p13.1 are found in 70% of affected families, and

these mutations have been found in 20% to 27% of sporadic cases of adrenocortical carcinomas.<sup>72</sup> Beckwith-Wiedemann syndrome is a congenital overgrowth disorder in which patients are predisposed to certain embryonal tumors such as Wilms' tumor, hepatoblastoma, neuroblastoma, rhabdomyosarcoma, and adrenocortical carcinoma. Overexpression of insulin-like growth factor (IGF)-2 is believed to contribute to the tumorigenesis in Beckwith-Wiedemann syndrome.<sup>73</sup> Several genetic alterations such as loss of imprinting or loss of heterozygosity of the 11 p15 gene locus causing a strong IGF-2 overexpression have been demonstrated in the majority of adrenocortical carcinomas.<sup>71,74,75</sup> Other hereditary syndromes associated with adrenocortical tumor formation include Carney complex, MEN 1, and congenital adrenal hyperplasia. However, these adrenal tumors are mostly adenomas and rarely carcinoma.

The clinical presentation of adrenocortical carcinoma in children is usually associated with steroid overproduction. In contrast to adult tumors, most adrenocortical tumors are hormonally active. Virilization is the most frequent presenting feature (66%), whereas the remainder of children will usually first be seen with Cushing's symptoms.<sup>76,77</sup> Virilization is secondary to secretion of the adrenal androgens. Features include axillary and pubic hair, deepening of the voice, acne, a rapid acceleration of height, hirsutism, enlargement of the penis or clitoromegaly, and development of body odor. Feminization may occur in 2% to 25% of patients and results from an overproduction of estrogens, particularly estradiol.<sup>78</sup> Nonfunctional tumors in children are infrequent. Only about 5% of pediatric adrenocortical tumors produce no clinical evidence of hormone excess. Accordingly, these patients usually are first seen late in disease with abdominal pain or fullness.

Because most tumors present with virilization symptoms, evaluation should be directed toward detection of elevated androgens. Screening should include measurement of plasma testosterone, urinary and plasma DHEA, and DHEA-S. Urinary 17-ketosteroids are also important because usually two thirds of 17-ketosteroids are derived from adrenal androgens. Although the most specific assessment of adrenal androgen production is DHEA-S, 17-ketosteroids are more frequently elevated in malignant disease.<sup>79</sup> The clinical presentation of Cushing's syndrome is confirmed by hypercortisolism and the loss of diurnal variation. Cortisol excess is determined by elevated plasma cortisol, urinary 17-hydroxycorticosteroids, and urinary free cortisol. Adrenal malignant disease generally causes markedly greater elevations of 17-hydroxycorticosteroids and plasma cortisol than is usually seen with functioning adenomas.

Radiographic evaluation should proceed concurrently with endocrine evaluation so that surgical intervention can proceed in an expeditious manner. Plain abdominal radiographs reveal a soft tissue mass in 47% of patients, and adrenal calcification can be noted in up to 30% of patients.<sup>80</sup> Ultrasonography, which can detect tumors as small as 3 cm,

should be used for screening the adrenal region and for postoperative assessment of recurrence. Smaller lesions are smooth and homogeneous with no pattern of hyperechogenicity or hypoechogenicity. Larger lesions usually demonstrate a “scar sign,” radiating linear echoes that represent an interphase between separate areas of necrosis, hemorrhage, and neoplasm.<sup>81</sup> CT can detect tumors as small as 0.5 cm and also can identify malignancy in the presence of regional invasion or distant metastases in the liver, lung, or brain. MRI has an accuracy similar to that of CT with lesions larger than 1 to 2 cm.<sup>82</sup> MRI has the advantage of producing coronal sections that can identify 1-cm images not identified on CT scan.<sup>83</sup> Finally, adrenal scintigraphy using iodocholesterol-labeled analogs has shown promise in identifying and differentiating functional adrenal lesions.<sup>84</sup> Differentiation between hyperplasia, adenoma, and carcinoma is made possible by the inability of carcinoma to concentrate radionuclide. Bilateral symmetric images indicate hyperplasia. Unilateral uptake suggests adenoma, and nonvisualization is suggestive of carcinoma.<sup>85</sup>

Surgical resection offers the only chance for cure. If extensive disease is found during operation, wide en-bloc resection of the tumor, lymph nodes, and involved organs is indicated.<sup>86</sup> For less extensive disease, minimally invasive techniques for adrenalectomy have been advocated, although most authors cite invasive disease as a contraindication to laparoscopic resection.

Adjuvant therapy has marginal results. Survival in patients who have undergone adjuvant therapy with localized disease has been reported to be 5 years versus 2.3 years for patients who have tumor spread beyond the adrenal gland.<sup>86</sup> For patients who underwent further surgical procedures for recurrent disease, survival is extended 3.5 years. Pediatric series report the incidence of metastases at diagnosis as being between 5% and 64%.<sup>72</sup> Mitotane is an adrenolytic agent that selectively causes adrenal gland necrosis and has been the most widely used chemotherapeutic agent. It is used for metastatic disease, for incompletely excised tumors, and for the hormonal effects of the tumors. In adults, response rates of tumors to mitotane are reported to be between 10% and 60%,<sup>72</sup> with a mean duration of response of only 10.2 months.<sup>87</sup> In the pediatric literature, tumor responses have been reported between 30% and 40%.<sup>88,89</sup> Additional regimens that have shown some promise include the combination of cisplatin, etoposide, and taxol. The role of radiation therapy in children has not been well established. In adults, adrenocortical carcinoma is thought to be radioresistant. However, some response has been noted in small series of children with metastatic disease.<sup>78</sup> In one report, radiation was used to shrink an “unresectable” tumor that was subsequently completely excised.<sup>72</sup>

Patients who are untreated for adrenocortical carcinomas have a mean survival of 2.9 months.<sup>90</sup> These tumors are highly lethal, with nonfunctional tumors demonstrating a worse prognosis. A delay in diagnosis leads to a worse prognosis as well. The range of time

from symptoms to diagnosis has been reported to be between 6 and 36 months.<sup>72</sup> The prognosis depends on the child’s age and the resectability of the tumor. In one review of 55 children with adrenocortical carcinoma, the 2-year survival rates were 82% for children younger than 2 years and 29% for children older than 2 years. Survival rates were more than 67% if the tumors were completely excised, but no survivors were found after partial resection.<sup>91</sup>

## Adrenal Medulla

Pheochromocytoma is a neuroendocrine tumor that arises from neural crest–derived chromaffin cells in the adrenal medulla. During embryologic development, chromaffin cells migrate to the adrenal medulla as well as around the paraganglia of the carotid arteries, aortic arch, abdominal aorta, and thoracic sympathetic ganglia. Any of these nests of chromaffin cells has the potential to become a tumor and they are the cause of extra-adrenal pheochromocytoma, also termed *paraganglioma*. The adrenal gland is the most common site for these tumors and accounts for 85% of adrenal and extra-adrenal pheochromocytoma in adults. Children are reported to have a higher incidence of extra-adrenal pheochromocytoma, approximately 30%,<sup>92</sup> and multifocal and familial disease<sup>93</sup> but a lower incidence of malignancy compared with adults.<sup>94</sup> As in adults, children with pheochromocytoma present with signs and symptoms of catecholamine excess, including hypertension, headaches, sweating, visual complaints, nausea, vomiting, weight loss, polydipsia, and polyuria. Pheochromocytoma should be considered in any child with hypertension.<sup>95</sup>

The evaluation of pheochromocytoma includes biochemical studies to establish the diagnosis and radiologic imaging to localize the disease. Traditionally, the biochemical diagnosis of pheochromocytoma was based on measuring urinary catecholamine levels. More recently, measurements of plasma catecholamines as well as their plasma or urinary metabolites have been widely utilized. Catecholamines are metabolized within chromaffin cells to metanephrines. This intratumoral process occurs independent of variations in catecholamine release. Therefore, measuring plasma or urinary metanephrines provides a more reliable method for diagnosing pheochromocytoma than measuring the parent amines.<sup>96</sup> The current guidelines, based on the First International Symposium on Pheochromocytoma, recommends that the initial testing for pheochromocytoma should include measurements of fractionated metanephrines (i.e., normetanephrine and metanephrine) in plasma, urine, or both.<sup>97</sup> Radiologic imaging options include MRI, CT, and <sup>123</sup>I- or <sup>131</sup>I-metaiodobenzylguanidine (MIBG) scanning. MRI has the highest sensitivity and is preferred over CT in children because of decreased radiation exposure.<sup>93,98</sup> Although not as sensitive, <sup>131</sup>I-MIBG scanning is the most specific imaging technique and is favored when recurrent or metastatic disease is suspected. Almost all paragangliomas are found in the abdomen and pelvis. When pheochromocytoma is suspected biochemically

but not found by imaging, an intrathoracic or intracranial tumor should be suspected.

The perioperative management of patients with pheochromocytoma is critical to successful surgical outcome. These patients are in a hyperadrenergic state with vascular contraction and relatively low intravascular volume. Catecholamine blockade and intravascular volume expansion are standard preoperative strategy. An  $\alpha$ -adrenergic antagonist (e.g., phenoxybenzamine, prazosin, doxazosin, or terazosin) is started a minimum of 2 weeks before surgery.  $\beta$ -adrenergic blockers may be used to treat tachycardia but must never be used until the patient has had adequate  $\alpha$  blockade owing to the risks of unopposed  $\alpha$ -adrenergic stimulation with  $\beta$  blockade alone. Alternatively, calcium channel blockers have been successfully utilized in the perioperative management of pheochromocytoma and may provide fewer fluctuations in blood pressure and may have cardioprotective effects.<sup>94</sup>

Pheochromocytoma resection has traditionally been performed via an open transabdominal adrenalectomy. Even with appropriate preoperative preparation, intraoperative hypertensive and hypotensive episodes are common and must be anticipated by the anesthesia and surgical team. Surgically, it is important to ligate the adrenal vein early and to minimize handling the gland itself to limit catecholamine surges during the procedure. Laparoscopic transabdominal adrenalectomy has gained significant popularity and has been validated for pheochromocytoma resections in adults.<sup>99</sup> Although the data in children are currently limited to small patient series, laparoscopic adrenalectomy appears equally safe and effective for select patients in experienced hands (Fig. 78-8).<sup>100-102</sup>

Up to 25% of pheochromocytomas are familial, and germline mutations in the following genes have been associated with pheochromocytoma: *VHL* (von Hippel-Lindau syndrome); *NFI* (von Recklinghausen's neurofibromatosis type 1); *RET* (MEN 2A or 2B); *SDHD* and *SDHB* (familial paragangliomas associated with gene mutations of the mitochondrial succinate dehydrogenase family).<sup>93</sup> Pheochromocytomas are more frequently associated with MEN 2 syndromes in children

than those in adults. Also, pheochromocytomas associated with the MEN 2 syndrome are more likely to be bilateral and benign.

In children with familial pheochromocytoma such as in MEN 2 or von Hippel-Lindau syndrome, bilateral tumors inevitably occur. Controversy exists over management of these patients. Bilateral adrenalectomy has been suggested by some but predisposes these patients to significant morbidity secondary to corticosteroid replacement as well as complications of medication noncompliance, such as Addisonian crises.<sup>103</sup> Cortical-sparing adrenalectomies have been proposed for patients with bilateral tumors and those that are at high risk for developing a metachronous contralateral lesion.<sup>104</sup>

For patients with metastatic disease, <sup>131</sup>I-MIBG scanning and chemotherapy should be considered. Current evidence supports high initial doses of <sup>131</sup>I-MIBG for all patients with metastatic lesions who have positive diagnostic <sup>131</sup>I-MIBG scans. With tumors that respond symptomatically or hormonally to treatment, survival has been reported to be 4.7 years after treatment.<sup>105</sup> Chemotherapy also seems to have an additive effect with <sup>131</sup>I-MIBG scanning to increase survival of these patients.<sup>106</sup>

## PRECOCIOUS PUBERTY

In boys, precocious puberty is defined as the development of secondary sexual characteristics before age 9 years. In girls, the development of breasts (thelarche) before age 7.5 years, the development of pubic hair (pubarche) before age 8.5 years, or the onset of menses (menarche) before age 9.5 years is considered precocious. Precocious puberty can be complete or incomplete.

True, or complete, precocious puberty is due to the premature maturation of the hypothalamic-pituitary axis and results in gonadal enlargement and premature development of secondary sexual characteristics. The secondary sexual characteristics that develop in true precocious puberty are appropriate for the sex

**Figure 78-8.** A teenage boy was found to have marked hypertension and a pheochromocytoma after a metabolic evaluation. He underwent laparoscopic left adrenalectomy and tolerated the procedure nicely. **A**, The pheochromocytoma (asterisk) is seen lying on the cephalad portion of the left kidney. The tumor was removed uneventfully. **B**, On the cut section of the adrenal gland, the tumor can be seen to be nicely demarcated from the normal adrenal gland.

of the child and merely occur at a younger-than-appropriate age. In incomplete or pseudoprecocious puberty, only one secondary sexual characteristic develops prematurely. Moreover, it may or may not be appropriate for the patient's gender. Pseudoprecocious puberty is not due to pituitary gonadotropin secretion. Rather, it is due to production of human chorionic gonadotropin (hCG), luteinizing hormone (LH), follicle-stimulating hormone (FSH), androgens, or estrogens, or it is due to stimulation of their receptors by the tumors.

### Precocious Puberty in Girls

True precocious puberty, resulting from premature activation of the hypothalamic-pituitary axis, is idiopathic in 75% to 95% of girls. The condition may be a normal variant that is simply at the younger age of a normal distribution curve. Neurogenic disturbances can cause true precocious puberty by interfering with inhibitory signals from the central nervous system (CNS) to the hypothalamus or by producing excitatory signals. Neurogenic disorders may include hydrocephalus, cerebral palsy, trauma, irradiation, chronic inflammatory disorder, or tumors, such as hypothalamic hamartomas or pineal tumors.

McCune-Albright syndrome is an interesting disorder that can cause either true precocious puberty or pseudoprecocious puberty. Patients have a classic triad of precocious puberty, café-au-lait nevi with irregular "coast of Maine" borders, and polyostotic fibrous dysplasia. In these patients, autonomously functioning ovarian follicular cysts may develop, causing precocious puberty. Excess production of LH, FSH, or prolactin by pituitary adenomas also has been described. Other endocrine abnormalities including acromegaly, Cushing's syndrome, and hyperthyroidism have been associated with this syndrome.<sup>107</sup>

Generally, incomplete precocious puberty is first seen as isolated premature breast development (thelarche) or premature growth of pubic hair (pubarche). Premature pubarche is frequently caused by androgen excess. Isolated prepubertal menses is rare, and prepubertal vaginal bleeding is usually caused by a foreign body, sexual abuse, or tumors of the genital tract. Incomplete precocious puberty can be a normal variant or can be due to the production of hormones from neuroendocrine, adrenal, ovarian, or exogenous sources. In the Van Wyk-Grumbach syndrome, premature breast development is associated with hypothyroidism. Unlike most other causes of precocious puberty, growth is inhibited rather than stimulated. This syndrome may be due to the shared  $\alpha$ -subunit of LH, FSH, and TSH. Tumors that produce excess quantities of LH or hCG can cause virilization.

### Precocious Puberty in Boys

As with girls, true precocious puberty in boys may be neurogenic, constitutional, or idiopathic. However, in boys, true precocious puberty is more often neurogenic than idiopathic.

The most common CNS tumor that causes male precocious puberty is a hamartoma of the tuber cinereum. These hamartomas are ectopic hypothalamic tissue connected to the posterior hypothalamus. Because they are nonprogressive tumors and are in a surgically precarious location, they are generally treated with gonadotropin-releasing hormone (GnRH) agonists. Other disorders that can cause precocious puberty in boys are gliomas of the optic nerve or hypothalamus, astrocytomas, choriocarcinomas, meningiomas, rhabdomyosarcomas, neurofibrosarcomas, nonlymphocytic leukemia, ependymomas, neurofibromatosis type 1, and germinomas. Other space-occupying lesions or causes of increased intracranial pressure such as head trauma, suprasellar cysts, granulomas, brain irradiation, and hydrocephalus also can cause true precocious puberty. Some of these tumors or CNS conditions can cause both precocious puberty and growth hormone deficiency. In these patients, the growth rate may appear normal because the testosterone stimulates growth and compensates for the deficiency of growth hormone. However, the degree of growth is inadequate for the degree of pubertal development.

Incomplete precocious puberty can be caused by autonomous production of androgens or hCG. With many types of incomplete precocious puberty, the testes are not enlarged as they are with true precocious puberty. As with girls, the McCune-Albright syndrome can cause either true or pseudoprecocious puberty. Tumors producing hCG such as teratomas, chorioepitheliomas, hepatomas, hepatoblastomas, or germinomas of the pineal gland may lead to Leydig cell stimulation. Testotoxicosis is an autosomal recessive disorder in which premature Leydig cell maturation causes incomplete precocious puberty. The etiology in some families is due to the constitutive stimulation of the LH receptor and can cause the onset of precocious puberty at age 1 to 4 years. Ketoconazole, spironolactone, and testolactone can be used to treat testotoxicosis.

Excess androgen production causing virilization can be caused by congenital adrenal hyperplasia, specifically the 21-hydroxylase or the 11-hydroxylase enzymatic defects. During embryonic development, adrenal rests may be left in the testes. In untreated adrenal hyperplasia, ACTH stimulation may cause enlargement of these adrenal rests and the secretion of androgens. These testes have an irregular appearance. Excess testosterone production also can be caused by interstitial cell tumors of the testes. Finally, exogenous administration of androgens or hCG (for undescended testes) can cause precocious puberty.

### Evaluation

For both boys and girls, evaluation of precocious puberty begins with a thorough history and physical examination. The patient's height and weight should be measured, and the growth curve should be examined. The bone age also should be determined. If the bone age and the height age correlate closely, it is likely that the presenting symptom is an extreme variant

of normal. This simply requires close follow-up in 6 months to verify the diagnosis. However, if the bone age is abnormally accelerated relative to the height age, further investigation is warranted. The Tanner stage should be carefully documented. In boys, the size and shape of the testes are of utmost importance. In true precocious puberty, the testes generally enlarge symmetrically, whereas asymmetric or nodular enlargement is noted with Leydig cell tumors or adrenal rests. Feminization in boys may appear as gynecomastia.

Serum estradiol, testosterone, and DHEA levels should be obtained. In girls, a vaginal smear for estrogen effect may be more sensitive than a serum estradiol level. Significantly elevated DHEA levels are typically seen in adrenal tumors. Evidence of association with other syndromes may warrant measuring other hormone levels, including prolactin, thyroid hormone, or cortisol. A GnRH test can be useful in determining whether the patient has complete or incomplete precocious puberty. Patients with true precocious puberty respond to GnRH with a typical pubertal pattern, whereas those with pseudoprecocious puberty have a minimal response to gonadotropin. Alternatively, a sleep-related increase in plasma LH levels can be diagnostic but is more cumbersome to obtain. In patients with feminizing or masculinizing features, ultrasonography is useful to locate abdominal or pelvic masses. MRI should be used in patients with true precocious puberty to locate potential intracranial lesions.

## Treatment

In general, tumors causing precocious puberty should be removed if they are surgically accessible. A number of agents have been used in the medical treatment of precocious puberty. True (gonadotropin-dependent) precocious puberty can be treated with GnRH agonists. Although initially these agents stimulate gonadotropin secretion, ultimately, GnRH receptors are down-regulated, and LH and FSH secretion is subsequently decreased. Examples of GnRH agonists include deslorelin, busarelin, nafarelin, leuprolide, and triptorelin.

Other medications have been used in the medical treatment of incomplete precocious puberty. Medroxyprogesterone acetate, a progestational agent, can halt the progression of secondary sexual characteristic development and can prevent menstruation. Ketoconazole is an antifungal agent that also inhibits the synthesis of testosterone by blocking the conversion of 17-hydroxyprogesterone to androstenedione. Testolactone competitively inhibits the aromatase enzyme that converts androgens to estrogens. Androgen antagonists include cyproterone acetate and spironolactone.

## CARCINOID TUMORS

Carcinoid tumors comprise less than 0.1% of tumors identified at one large pediatric cancer center.<sup>108</sup> These tumors arise from amine uptake and decarboxylation cells and are usually classified according to their site of origin as foregut, midgut, or hindgut carcinoids.<sup>109</sup> Foregut tumors account for approximately 5% of carcinoid tumors and can arise in the bronchus, stomach, or duodenum. Midgut tumors account for about 80% to 85% of carcinoid tumors. The majority of carcinoids arise from the appendix (46%), followed by the jejunum and ileum (28%), and the rectum (17%). Carcinoid tumors also have been found to arise from ovarian teratomas.

Most patients present with vague symptoms. Only 10% of patients have symptoms of carcinoid syndrome (flushing, diarrhea, abdominal pain, asthma, and right-sided cardiac valvular problems).<sup>110</sup> Carcinoids are detected incidentally in up to 60% of patients, usually when associated with appendiceal carcinoids.

Most pediatric patients are first seen with appendiceal carcinoids smaller than 2 cm (Fig. 78-9). These can be treated with simple appendectomy.<sup>108</sup> Right hemicolectomy is indicated for tumors larger than 2 cm, those close to the cecum, and those with mucin production. Metastases are extremely rare in children, but regular follow-ups with measurement of serotonin and chromogranin A should be performed.<sup>111</sup> Treatment of

**Figure 78-9.** These two histologic photomicrographs depict a carcinoid tumor of the appendix. **A**, Lower-power view shows the nests of neuroendocrine cells (*arrow*) that are seen invading the muscularis mucosa. **B**, Higher-power view shows the solid islands or nests (*arrow*) of uniform oval to polygonal cells with minimal pleomorphism. There are indistinct cellular borders and round uniform nuclei with finely granular diffuse chromatin and inconspicuous nucleoli. Mitotic figures are rare.

metastatic disease includes hepatic chemoembolization and surgical resection for isolated hepatic metastases. Long-acting octreotide or  $^{131}\text{I}$ -MIBG is used for widely metastatic disease.<sup>112</sup>

Carcinoids are fairly indolent tumors. In one retrospective series of 40 children with appendiceal carcinoids, no recurrences or metastases were reported.<sup>113</sup> The site of origin has universally been shown to predict survival, with the appendix having the best survival and midgut or hindgut having the worst.

Of significance, the most common pulmonary tumor is the bronchial carcinoid. These most frequently appear with recurrent or persistent pneumonia secondary to obstruction of the bronchus by the tumor. Usually these tumors excrete low levels of serotonin. Children

commonly present with wheezing, atelectasis, and weight loss. Also, they can have cough, pneumonitis, and hemoptysis, which are frequently seen in adults.

Bronchial carcinoids can be diagnosed by bronchoscopy. They have a characteristic pink, friable, mulberry appearance. Biopsy should not be attempted because the carcinoids have a propensity to hemorrhage and because of their classic gross appearance. If no evidence of lymph node involvement is found, segmental bronchial resection can be performed. However, lobectomy or pneumonectomy is often required for treatment. These tumors are radiosensitive and radiation therapy can be considered for unresectable disease. The prognosis after complete resection is excellent, with a 10-year survival rate of approximately 90%.<sup>114,115</sup>

# BARIATRIC SURGICAL PROCEDURES IN ADOLESCENCE

Go Miyano, MD • Victor F. Garcia, MD • Thomas H. Inge, MD, PhD

Childhood obesity is an increasingly prevalent and progressive disease with few successful treatment options. Not only have increasing numbers of children and adolescents been affected over the years, but the average weight of obese individuals has soared as well. Pediatric specialists are increasingly considering alternative measures to combat the serious immediate and long-term health complications of this disease. Evidence from clinical trials show that behavioral weight management may have longer-lasting effects in younger children compared with adults, but good long-term results are rare. These conventional treatment approaches are not effective for most who suffer with severe obesity,<sup>1-3</sup> leading some to consider weight loss surgical options for select adolescents. A number of important factors must be considered when contemplating bariatric surgical procedures for severe obesity in adolescents. Surgical weight loss results in significant improvement, if not resolution, of most obesity-related co-morbidity in adults.<sup>4</sup> Preliminary results suggest that this also is true for adolescents,<sup>5,6</sup> but little information is available about long-term efficacy and potential adverse consequences to an adolescent with lifelong restriction of calories and certain micronutrients. The issue of recidivism and the potential multigenerational consequences of bariatric surgical treatment in children and adolescents necessitate that considerable care and deliberation be applied to decision-making concerning surgical weight management.

## DEFINITIONS

*Obesity* specifically refers to the condition of having excess body fat. Measurement of body mass index (BMI) is a reasonably accurate method for predicting adiposity, is reproducible in the clinical setting, and can be easily used as a screening tool.<sup>7-10</sup> In children and adolescents, physiologic increases in adiposity, height, and weight during growth are expected. Childhood obesity is a global problem. In that context, it should

be noted that there are ethnic and racial variations in onset, prevalence, and severity of the metabolic consequences of childhood obesity. Growth charts that are typically used to define obesity are age and gender specific.<sup>11,12</sup>

The terms *overweight* (BMI for age and gender > 85th percentile), *obese* (BMI for age and gender > 95th percentile), and *extreme obesity* (BMI for age and gender > 99th percentile) have been used to refer to the increasing weight problem in children.<sup>13,14</sup> The 85th and 95th percentiles of BMI for age were chosen mainly because these percentile boundaries approximate the BMI in young adults of 25 kg/m<sup>2</sup> (overweight) and 30 kg/m<sup>2</sup> (obese), respectively. Whereas more than 32% of adults in the United States are obese, about 18% of children and adolescents are obese, a prevalence that has more than tripled in the past 2 decades.<sup>15</sup> Regarding extreme obesity, adolescent boys and most adolescent girls younger than age 18 with a BMI of 35 kg/m<sup>2</sup> are above the 99th BMI percentile.<sup>16</sup> Increasing metabolic risks associated with higher BMI for age, especially greater than or equal to the 99th BMI percentile, have been found when compared with lower levels of obesity.<sup>16</sup> In addition, because all children with a BMI above the 99th percentile become obese adults (BMI ≥ 30 kg/m<sup>2</sup>) and because obese adults who were obese as children have more health complications and a higher mortality,<sup>16-18</sup> bariatric surgical procedures in the mature adolescent may be a reasonable option for weight reduction that may well reduce the risk of obesity-related morbidity and early mortality.<sup>19</sup>

## ANTECEDENTS AND CONSEQUENCES OF ADOLESCENT OBESITY

Adolescent obesity is a multifaceted disease with serious immediate, intermediate, and long-term consequences.<sup>20</sup> Critical periods exist between preconception and adolescence during which the risk of development of obesity is increased.<sup>21</sup> Important risk factors for

childhood and adolescent obesity are (1) low birth weight,<sup>22-25</sup> (2) bottle feeding,<sup>26,27</sup> (3) early adiposity rebound,<sup>28-32</sup> (4) having a diabetic mother,<sup>33,34</sup> (5) puberty,<sup>35-37</sup> and (6) parental obesity.<sup>38-40</sup> Knowledge of these risk factors for adolescent obesity gives insight into the genetic and environmental factors that result in obesity. With few exceptions, little understanding exists of which risk factors portend the development of extreme obesity.<sup>41-43</sup> This lack of understanding adds to the complexity in decision-making regarding the application and timing of surgical treatment of obesity.

Associated with the remarkable increase in the prevalence of pediatric obesity is a parallel increase in the severity of obesity and in obesity-related chronic diseases. These diseases have an onset at a younger age and carry an increased risk for adult morbidity and mortality.<sup>44,45</sup> Childhood obesity has adverse social and economic consequences.<sup>46-48</sup> The most important co-morbid conditions for childhood obesity, which are used to justify the use of weight loss operations, are cited in Table 79-1.

## GUIDELINES FOR PERFORMING BARIATRIC SURGICAL PROCEDURES IN ADOLESCENCE

### Patient Selection Criteria

National Institutes of Health (NIH) guidelines suggest that it is reasonable to consider weight loss surgery for adults with a BMI of 35 kg/m<sup>2</sup> or greater in the presence of severe obesity-related co-morbidities (e.g., sleep apnea, diabetes, joint disease severe enough to require joint replacement) or a BMI of 40 kg/m<sup>2</sup> in the presence or absence of co-morbidities.<sup>49</sup> Although these criteria have remained unchanged since 1991, investigators at several institutions have used lower BMI guidelines for studying the effect of weight loss surgery on adults without adverse consequences. Data would support the use of lowered BMI guidelines for patients with severe co-morbidities, such as type 2 diabetes, which are responsive to weight loss.<sup>50</sup>

Because less is known about the long-term risks and durability of the surgery, most pediatric specialists have supported more restrictive guidelines for operations in adolescents. Currently, we consider BMI greater than or equal to 35 kg/m<sup>2</sup> with significant co-morbidities or BMI of 40 kg/m<sup>2</sup> with other co-morbidities as factors to be used in the selection of adolescents who are most likely to benefit from bariatric surgical procedures.

Specifically, when a teenager has achieved a BMI greater than or equal to 35 kg/m<sup>2</sup> with serious obesity-related co-morbidity, and surgical therapy will be predictably successful in reversing the obesity and co-morbidity, it is reasonable to consider a surgical treatment before adulthood. This is the case for adolescents with type 2 diabetes mellitus, pseudotumor cerebri, sleep apnea (apnea-hypopnea index > 15), and severe steatohepatitis. For adolescents with less severe co-morbidities or risk factors for long-term diseases, for which there is no disadvantage of waiting until adult-

hood, we recommend a BMI of 40 kg/m<sup>2</sup> as a threshold for operative intervention. These co-morbidities include, among others, mild obstructive sleep apnea syndrome (OSAS), hypertension, milder forms of obstructive sleep apnea (OSA), impaired quality of life, insulin resistance, glucose intolerance, or dyslipidemia. Figure 79-1 outlines a suggested algorithm for management.

### Bariatric Programs for Adolescents

For highly motivated adolescents with co-morbid conditions (Table 79-2) who have been unsuccessful with prior dedicated attempts at weight loss, bariatric surgery

**Figure 79-1.** Algorithm of management strategies for the severely obese adolescent.

should be considered as a therapeutic option. Young patients being considered for bariatric surgical procedures should be referred to a specialized center with a multidisciplinary bariatric team with pediatric expertise. Such a team is equipped for the sometimes difficult patient selection decisions and can provide long-term follow-up and management of the unique challenges posed by the severely obese adolescent. Guidelines have been established by the American Society for Bariatric Surgery (ASBS) ([www.asbs.org](http://www.asbs.org)), and the American College of Surgeons (ACS) that define such multidisciplinary bariatric teams to include specialists with expertise in obesity evaluation and management, psychology, nutrition, physical activity, and bariatric surgical treatment.<sup>51</sup> Depending on the individual needs of the adolescent patient, additional expertise in general pediatrics, adolescent medicine, endocrinology, pulmonology, gastro-

enterology, cardiology, orthopedics, and ethics should be readily available. At Cincinnati Children’s Hospital, the patient review process is similar to that used in our multidisciplinary oncology and transplant programs.<sup>52</sup> This review by a panel of experts from various disciplines results in specific treatment recommendations for individual patients, including appropriateness and timing of possible operative intervention.

## Factors Influencing Timing of Surgery

### Physical Maturation

The timing for surgical treatment of extremely obese adolescents remains controversial and depends, in most cases, on the compelling health needs of the patient. However, certain physiologic factors must be considered in treatment planning. There is a theoretical concern about the impact of significant caloric restriction on attainment of a genetically predetermined adult stature. Physiologic maturation is generally complete by sexual maturation (Tanner) stage 4.<sup>53</sup> Skeletal maturation (adult stature) is normally attained by the age of 13 to 14 years in girls and 15 to 16 years in boys.<sup>54</sup> Overweight children generally experience accelerated onset of puberty. As a result, they are likely to be taller and have advanced bone age compared with age-matched non-obese children.

If uncertainty exists about whether adult stature has been attained, skeletal maturation (bone age) can be objectively assessed with a radiograph of the hand and wrist.<sup>55</sup> If an individual has attained more than 95% of adult stature, it is unlikely that a bariatric procedure would significantly impair completion of linear growth.<sup>56</sup> For those who have not yet reached or nearly reached their predicted adult stature, one must balance the risks of growth delay due to caloric restriction against the potentially more significant risks of progression of obesity-related co-morbid conditions if surgery is delayed.

**Table 79-2** Obesity-Related Conditions That May Be Improved with Bariatric Surgical Procedures

**Serious Conditions**

- Type 2 diabetes mellitus
- Obstructive sleep apnea
- Pseudotumor cerebri

**Less Serious Conditions**

- Hypertension
- Dyslipidemias
- Nonalcoholic steatohepatitis
- Venous stasis disease
- Significant impairment in activities of daily living
- Intertriginous soft tissue infections
- Stress urinary incontinence
- Gastroesophageal reflux disease
- Weight-related arthropathies that impair physical activity
- Obesity-related psychosocial distress

## Psychological Maturation

Adolescent psychological development also impacts the ability to participate in surgical decision-making and postoperative dietary compliance. Cognitive development refers to the development of the ability to think and reason. At any given age, adolescents are at varying stages of cognitive, psychosocial, and biologic maturity. The more mature adolescent who can reason and think abstractly is better able to consider the consequences of taking or not taking nutritional supplements or of following and adhering to the prescribed medical and nutritional regimens that are necessary for lifelong success (e.g., maintenance of weight loss and prevention of avoidable nutritional complications) after bariatric procedures.<sup>57</sup>

Before any decision for surgical treatment is made, all candidates should undergo a comprehensive psychological evaluation. Goals of this evaluation include:

- To determine the level of cognitive and psychosocial development, primarily to judge the extent to which the adolescent is capable of participating in the decision to proceed with the intervention
- To identify past and present psychiatric, emotional, behavioral, or eating disorders
- To define potential support for, or barriers to, regimen compliance, the family readiness for surgical treatment, and the required lifestyle changes (particularly if one or both parents are obese)
- To assess reasoning and problem-solving ability
- To assess whether reasonable outcome expectations exist
- To assess family unit stability and identify psychological stressors or conflicts within the family
- To determine whether the adolescent is autonomously motivated to consider bariatric surgical treatment or whether any element of coercion is present
- To assess weight-related quality-of-life status.

Unfortunately, no “relative value scale” exists that would enable one to assign appropriate significance to the wealth of information (subjective and objective) obtained in the psychological evaluation. However, during a comprehensive assessment, we have found that a complete psychological assessment is very helpful for team decision-making and that generally good team agreement is reached about whether a particular patient has a majority (or conversely a minority) of the attributes of a good candidate for bariatric surgery (Table 79-3).

## SURGICAL OPTIONS

In 1991, the NIH Bariatric Consensus Development Conference established parameters that led to a more uniform application of bariatric surgical procedures for adults. After that conference, an increase in the use of these procedures was seen. This conference concluded that, at that time, insufficient data existed to make recommendations about bariatric surgical treatment

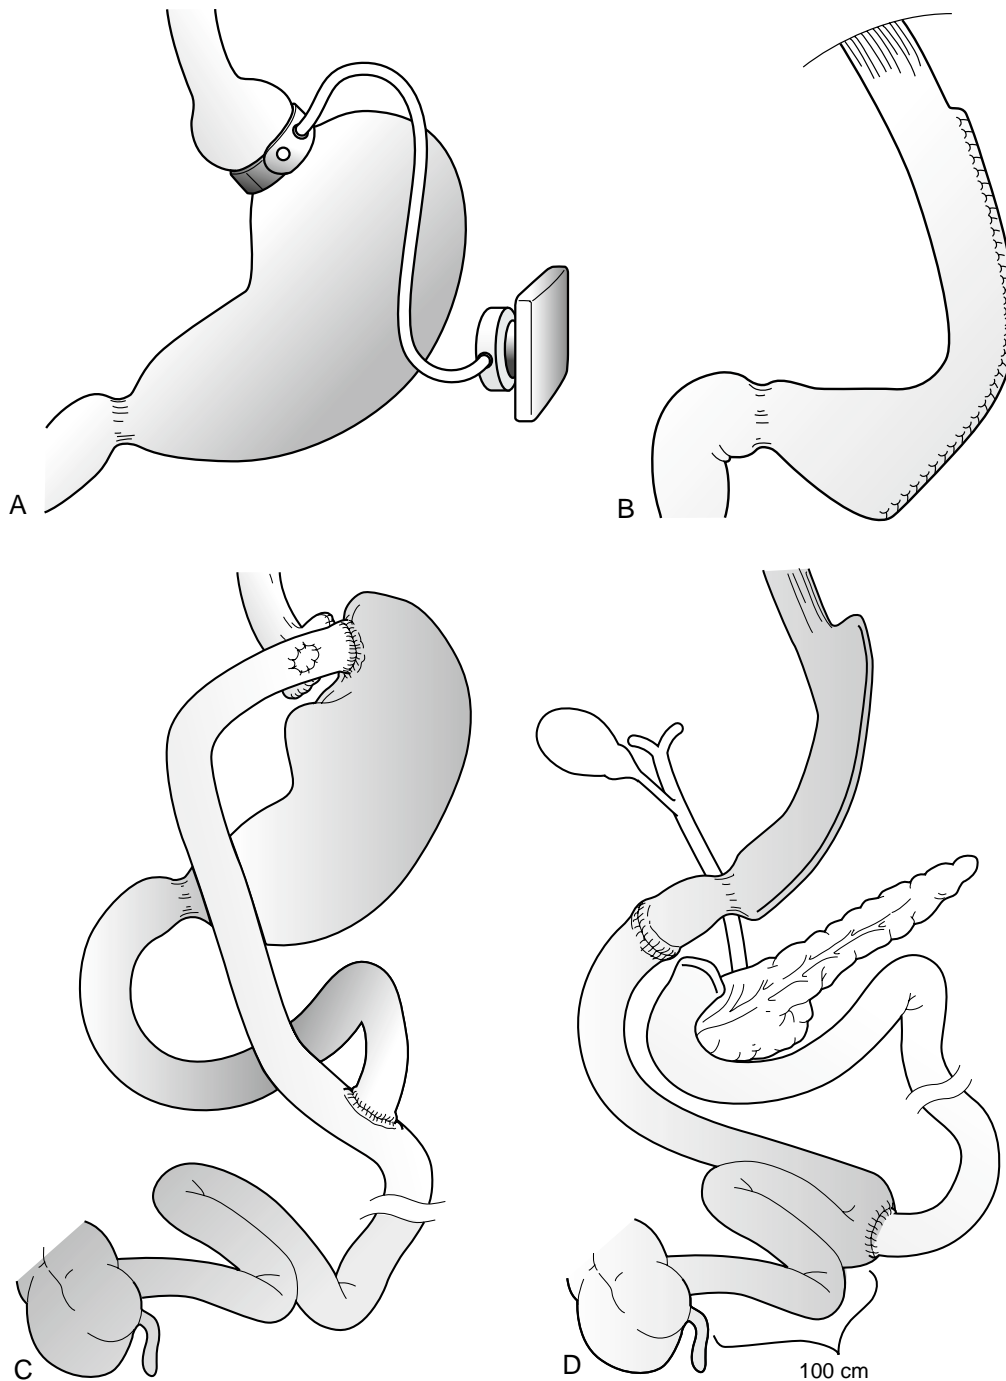

**Table 79-3** Suggested Attributes of A “Good” Adolescent Bariatric Candidate

- Patient is motivated and has good insight.
- Patient has realistic expectations.
- Family support and commitment are present.
- Patient is compliant with health care commitments.
- Family and patient understand that long-term lifestyle changes are needed.
- Patient agrees to long-term follow-up.
- Decisional capacity is present.
- Weight loss attempts are well documented and at least temporarily successful.
- No major psychiatric disorders are evident that may complicate postoperative regimen adherence.
- No major conduct/behavioral problems are noted.
- No substance abuse has occurred in the preceding year.
- No plans for pregnancy are present in the upcoming 2 years.

for patients younger than 18 years. Fortunately, outcome data are emerging for the adolescent age group, and adolescent bariatric research is now receiving some attention at the NIH. Indeed, six studies with an adolescent bariatric focus have now been funded by the National Institute of Diabetes and Digestive and Kidney Diseases to examine various outcomes of adolescent weight loss surgery. Five of these have been based at Cincinnati Children’s Hospital and one at the University of Pennsylvania. In addition, a multi-center research consortium called Teen-Longitudinal Assessment of Bariatric Surgery has also emerged that includes investigators at Cincinnati Children’s Hospital, Texas Children’s Hospital, Children’s Hospital of Alabama, Nationwide Children’s Hospital, and the University of Pittsburgh. More information about this research consortium can be obtained on the website [www.cchmc.org/teen-LABS](http://www.cchmc.org/teen-LABS).

Of the many procedures that have been advocated for weight loss, the operations that have been used primarily can be classified as either purely restrictive or restrictive and malabsorptive (Fig. 79-2). The laparoscopic adjustable gastric band (AGB) and laparoscopic vertical sleeve gastrectomy (LSG) are purely restrictive procedures, and the degree of weight loss with these operations in adults has generally been satisfactory. The LSG is a new operation that produces significant initial weight loss with low operative risk in adult studies.<sup>58,59</sup> Because it likely does not affect micronutrient absorption, it may be a safe alternative with fewer nutritional risks than Roux-en-Y gastric bypass (RYGB) and also may avoid device-related long-term risks inherent in the AGB procedure.

There are good reasons to think that adolescents may be better served by purely restrictive options such as the AGB (Figs. 79-3 and 79-4) or LSG.<sup>60</sup> Although nutritional deficiencies are not as likely to develop from the purely restrictive operations as compared with diversionary operations (gastric bypass, duodenal switch), these operations still impair overall energy intake significantly. This may lead to impaired intake of important vitamins and minerals if not adequately

**Figure 79-2.** Operative procedures for weight loss that are performed laparoscopically. **A**, Adjustable gastric band (AGB). **B**, Vertical sleeve gastrectomy (VSG). **C**, Roux-en-Y gastric bypass (RYGB). **D**, Duodenal switch operation.

supplemented. With surgical procedures that do not transect the gastrointestinal tract, there is less operative risk and a reportedly lower mortality risk compared with gastric bypass.<sup>61</sup> A specific patient group for which one might suspect that a purely restrictive operation would be well suited is the younger adolescent, or even preadolescent, with a significant, progressive co-morbid condition (e.g., type 2 diabetes, OSAS, or pseudotumor cerebri). However, these patients have

the greatest potential for noncompliance with postoperative nutritional recommendations.

The adjustable gastric band is not currently approved by the Food and Drug Administration for adolescents younger than 18 years of age. The theoretical benefits of nontransectional surgical revision are lost when considering LSG owing to the long staple line. Both the AGB and the LSG must be seen as procedures with less than adequate long-term outcome data. Any patient

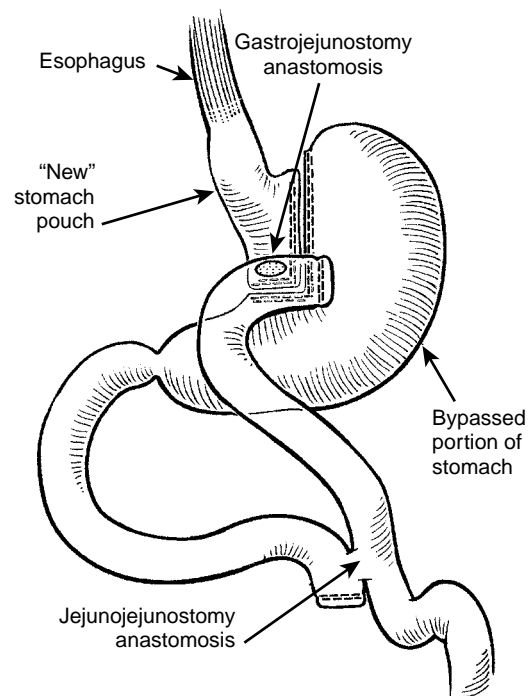

**Figure 79-3.** A, The tubing and the adjustable gastric band are being pulled behind the stomach with the grasper. The tubing is then exteriorized through one of the ports to allow manual traction on the gastric band as it dilates the narrow retrogastric tunnel. Once the thick portion of the gastric band emerges from behind the stomach, the tubing is then re-introduced into the abdomen and threaded through the hole in the buckle of the gastric band. B, The buckle is being locked in place.

**Figure 79-4.** Plication of the anterior wall of the stomach over the gastric band is accomplished with three or four sutures using 2-0 permanent suture. These sutures should be deep and full thickness. It is important to remove the orogastric tube before placement of these sutures so that the tube is not incorporated in these plication sutures.

undergoing these operations must be carefully counseled about the unknown long-term efficacy. Clinical outcome data should be collected prospectively to enable objective assessment of efficacy and safety.

The RYGB (Figs. 79-5 to 79-8) consists of both a restrictive pouch size and a mildly malabsorptive component (the bypass of the stomach and duodenum). Moreover, it also offers an additional negative reinforcement of “dumping syndrome” in some patients, providing excellent weight loss in adolescents and adults. The partial biliopancreatic bypass with duodenal switch is primarily a malabsorptive procedure that results in good weight loss for adults with the highest classes of obesity (generally  $> 60 \text{ kg/m}^2$  BMI), but at

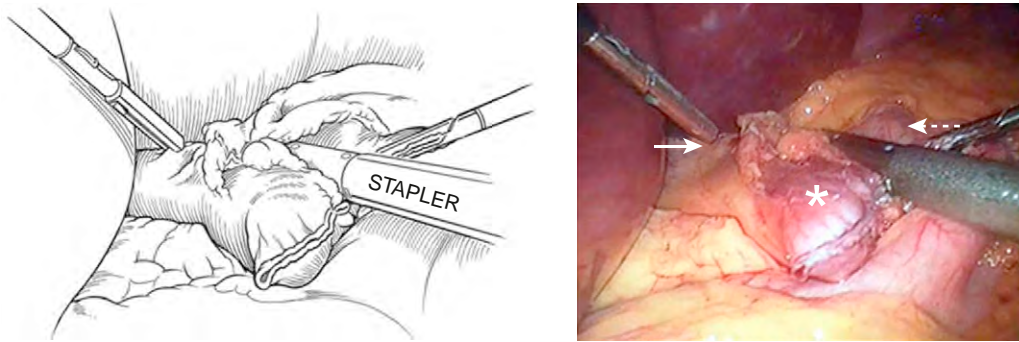

**Figure 79-5.** The Roux-en-Y gastric bypass consists of both a restrictive pouch size and a mildly malabsorptive component (the bypass of the stomach and duodenum). The gastric pouch is based on the lesser curve and is created using a 34-French orogastric tube as a guide. A 75- to 150-cm Roux limb is used in most patients.

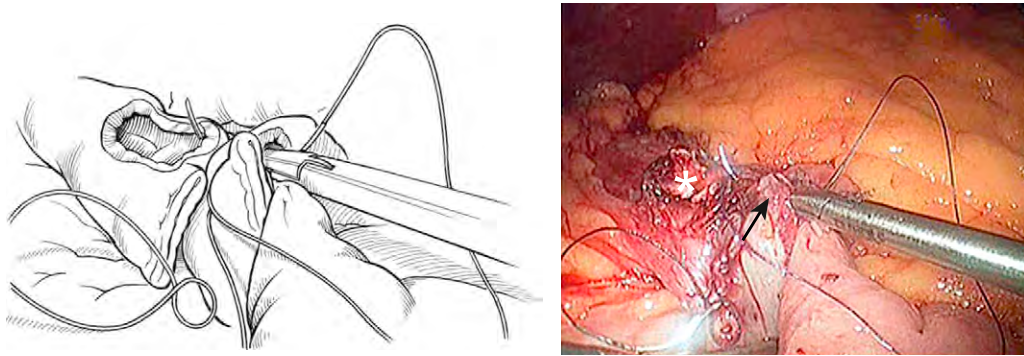

the expense of higher risks of operative complications and postoperative nutritional risks. Thus, the duodenal switch is not widely recommended for adolescents.

Regardless of the procedure used, surgeons and allied health personnel new to the field should, at a minimum, undergo a basic training course offered by one of the professional surgical organizations (ASBS, ACS, or the Society of American Gastrointestinal Endoscopic Surgeons). Before performing laparoscopic

**Figure 79-6.** A 30-mL gastric pouch (*asterisk*) is created along the lesser curve of the stomach just beyond the gastroesophageal junction using a linear cutting stapler. The esophagogastric junction is labeled (*solid arrow*) demonstrating that the distal most portion of the pouch is typically located within several centimeters of the gastroesophageal junction. The first vertical application of the stapler that creates the distal most portion of the vertically oriented, tubular gastric pouch is being shown. Also shown is the remnant stomach (*dotted arrow*), which will be left in situ beside the gastric pouch. The Roux limb will be brought anterior to this remnant stomach.

**Figure 79-7.** The inner posterior running layer of the gastrojejunostomy is being performed. This full-thickness suture line unites small bowel and gastric pouch tissue, resulting in a mucosa-to-mucosa approximation. The lumen of the gastric pouch is marked by an *asterisk* and the jejunal wall is indicated by the *arrow*.

**Figure 79-8.** The two-layer hand-sewn gastrojejunal anastomosis has been completed. The gastric pouch is marked with an *asterisk*. An under-saline leak test is then performed using air insufflated through an orogastric tube (not shown).

bariatric operations, surgeons must meet all local credentialing requirements for the performance of bariatric procedures and advanced laparoscopic operations. Credentialing guidelines for both open and laparoscopic bariatric procedures have been outlined previously.<sup>62-66</sup>

## PERIOPERATIVE AND SURGICAL MANAGEMENT

### Preoperative Education and Management

The multidisciplinary preoperative evaluation that leads to the decision to offer surgical treatment is followed by considerable patient and family preoperative education. It is important that this process is organized and not rushed because patients must comprehend a great deal of information about the anatomic and physiologic changes that occur after surgery that impact success and the risks for the short- and long-term complications. Detailed information about the options for various surgical procedure(s), nursing care, dietary strategies, physical activity, and behavioral approaches to support adherence to the postoperative regimen is provided. Patients may also benefit from discussion with others who have undergone surgical treatment. In the weeks before the operation, a final outpatient visit for anesthesiology consultation, final informed permission (consent) discussion, and final review of the postoperative regimen is scheduled. At the conclusion of this visit, some programs require the patient to take a written test, which is scored and reviewed with the patient, as further documentation of his or her level of understanding of the procedure and known and potential adverse and beneficial consequences.

During the evaluation of a potential surgical patient, studies include serum chemistry and liver profiles, lipid profile, complete blood cell count, hemoglobin A<sub>1C</sub> level, fasting blood glucose value, thyroid-stimulating hormone level, and *Helicobacter pylori* titers. If these titers are positive, a breath test is done to confirm or exclude active *H. pylori* infection. An electrocardiogram is obtained to screen for cardiac problems and dysrhythmias. For instance, prolonged QT syndrome does exist in morbidly obese adolescent patients and may be previously unrecognized. Because unrecognized sleep disorders are relatively prevalent in the severely obese, a complete sleep history is sought, including a history of snoring, irregular breathing, and increased daytime somnolence. A history suggestive of sleep apnea should prompt formal polysomnography. If the fasting glucose concentration is elevated, or if other symptoms of diabetes exist, patients should undergo a 2-hour glucose tolerance test to determine if more significant abnormalities of carbohydrate metabolism exist, including impaired glucose tolerance and type 2 diabetes.

On the day before the operation, the patients are limited to clear liquids. Preoperative medications

include low-molecular-weight heparin (40 mg injected subcutaneously and continued twice daily postoperatively). A second-generation cephalosporin antibiotic is administered within 1 hour of surgery. Sequential compression boots also are used intraoperatively and postoperatively. Most patients are candidates for laparoscopic procedures, although some of the heavier and centrally obese patients may present challenges, particularly in the early portion of a surgeon's learning curve.

### General Aspects of Surgical Techniques for the Morbidly Obese

In general, an open laparotomy should be avoided in morbidly obese individuals due to difficulty with adequate visualization and the higher risk of wound complications. For initial abdominal access, we have found that a laparoscopically guided technique using a transparent, bladeless, 12-mm cannula is safe and efficient. Alternatively, some surgeons prefer a blind puncture using the Veress needle in the left upper quadrant. To access the gastroesophageal junction for bariatric procedures, a wide variety of surgical instruments have been developed with the morbidly obese patient in mind. However, it should be noted that the majority of laparoscopic procedures in morbidly obese individuals can be efficiently and safely accomplished using standard adult 5-mm instrumentation. The left lobe of the liver is retracted with the Nathanson retractor (Cook Surgical, Bloomington, IN) to expose the stomach for bariatric operations. The details and nuances of the procedures used for adolescents can be obtained from a variety of excellent bariatric texts.<sup>67</sup>

## POSTOPERATIVE MANAGEMENT

Postoperatively, the patients are placed in a monitored, non-intensive care unit setting, and maintenance fluids are administered based on lean body weight (typically 40% to 50% of actual weight). Early warning signs of complications include fever, tachycardia, tachypnea, increasing oxygen requirement, oliguria, hiccoughs, regurgitation, left shoulder pain, worsening abdominal pain, a feeling of anxiety, or acute alteration in mental status. These signs warrant aggressive attention and appropriate investigation because they may signal a gastrointestinal leak, pulmonary embolus, bowel obstruction, or acute dilation and impending rupture of the bypassed gastric remnant. Routinely, a water-soluble upper gastrointestinal contrast study is obtained on postoperative day 1 for patients who have undergone procedures that transect the gastrointestinal tract. After satisfactory passage of contrast is documented, patients are begun on clear liquids and subsequently advanced to a high protein liquid diet for the first month after operation.

Bariatric surgical treatment reduces the intake and decreases the absorption of food items rich in essential

fatty acids, vitamins, and other specific nutrients, the long-term results of which are not well understood and are of legitimate concern. Poor nutrition during fetal development can result in a variety of adverse health outcomes, including future obesity, as suggested by the Dutch famine cohort.<sup>22</sup> Therefore, success in adolescent bariatric surgical treatment requires an expanded definition—not only sustained weight loss but also subsequent normal progression through the remainder of adolescence, adulthood, and eventually uncomplicated reproduction with normal offspring.

Nutritional and metabolic consequences of bariatric surgical procedures have been well delineated in adults.<sup>68-79</sup> To avoid nutritional complications, patients must adhere to procedure-specific guidelines for diet and vitamin/mineral supplementation. Restrictive operations (including gastric bypass) essentially result in a surgically enforced very low-calorie intake, thus requiring attention to an adequate (0.5 g/kg) daily protein intake to minimize lean mass loss during the rapid weight loss phase. Impaired absorption of iron, folate, calcium, and vitamin B<sub>12</sub> may occur after gastric bypass.<sup>71,80</sup> Some obese adolescents may have vitamin deficiency even before operative intervention.<sup>81</sup> Even with postoperative supplementation, severe deficiencies may occur. Adolescence also may be a particular risk for thiamine deficiency.<sup>82</sup> In addition, poor postoperative compliance among adolescents who have undergone bariatric operations has been reported.<sup>83</sup> Because certain micronutrient deficiencies, such as folate and calcium, have established ramifications for the patient and potential offspring, both warrant special consideration.

Folate is a water-soluble B vitamin that is essential for growth, cell differentiation and embryonic morphogenesis, gene regulation, repair, and host defense.<sup>84</sup> Adequate maternal periconceptional folic acid consumption during critical periods of organ formation early in the first trimester may reduce the likelihood of fetal malformations, including neural tube defects and perinatal complications such as low birth weight, prematurity, and placental abruption and infarction. This information is particularly relevant because the majority of adolescents seeking bariatric surgical treatment are girls, many of whom will want to be mothers in the future. Thus, physicians caring for adolescents who undergo bariatric surgical procedures must stress the importance of daily folate and other B-complex vitamin intake. Moreover, patients should be monitored annually (and before planned conception) for serum vitamin levels, particularly when uncertainty about compliance exists.<sup>84</sup>

There are no studies examining outcomes of pregnancy after bariatric surgical procedures in the adolescent population. However, unplanned adolescent pregnancy is a legitimate concern after massive weight loss.<sup>85</sup> We strongly recommend that all girls and caregivers are informed about increased fertility (a physiologic change due to increased insulin sensitivity) and the likelihood for increased risk-taking

**Table 79-4** Strategies to Improve Postoperative Compliance

- Rehearse the dietary regimen to enable preoperative problem identification and solving before the surgical intervention.
- Use actual measuring cups, a food scale, and photographs of specific recommended food items to enhance the adolescent's ability to follow through with plans.
- Provide the adolescent with a diet diary and exercise diary with form pages to fill out, and practice this preoperatively.
- Provide a list of acceptable food items for every phase of the postoperative recovery (first week, second through fourth weeks, second through third months) including the caloric density and protein, carbohydrate, and fat content of the items to encourage label reading.
- Provide a detailed listing of micronutritional supplements needed postoperatively, including why the supplement is needed and the potential consequences of not taking it.

after surgical weight loss. These patients should be counseled to avoid pregnancy during the 2-year period after operation and should be offered reliable contraception. The modern intrauterine devices are effective and safe and may be placed at the time of the bariatric operation.

Adolescence is a period of rapid skeletal mineral accretion and is, therefore, a window of opportunity to influence life-long bone health, both positively and negatively. While obese adolescents have higher than average bone mineral density/content, they may well have less than normal bone mineral density and content for their weight. This may translate into greater risk for fractures.<sup>86</sup> Furthermore, impaired accretion of bone mineral content in adolescence increases the risk for osteoporosis and results in a two-fold greater risk of fracture in later life.<sup>87</sup> Given the impaired absorption of both vitamin D and calcium after bariatric surgical procedures and the large individual variation in bone accretion, it is essential to monitor closely the bone mineral density of adolescents undergoing bariatric surgical treatment. Behavioral strategies can and should be used to encourage compliance with postoperative vitamin and mineral intake, which should positively influence nutritional outcomes after adolescent bariatric surgical procedures.<sup>87</sup>

Adolescent compliance may be enhanced by (1) visual aids, (2) focus on immediate benefit from treatment, (3) participation in self-management, (4) self-monitoring, and (5) reinforcement (Table 79-4).<sup>88</sup> With the alterations in eating patterns required after bariatric surgical procedures, repetitive reinforcement is needed to facilitate the formation of lifelong health-promoting habits. The adolescent bariatric surgical program should build on the best practices of other adolescent disease-management programs. Success will be based on the premise that sustained weight control for the adolescent requires ongoing behavioral intervention, structured family involvement, and continued support.<sup>87,89,90</sup>

## LONG-TERM MANAGEMENT

Postoperative follow-up visits after bariatric surgical procedures in adolescence are intensive but depend in part on the type of surgical procedure performed. For example, we see gastric bypass patients every 2 weeks for 1 month, then monthly for 3 months, and then approximately every third month for the next 18 months. Dietary advancement after the first month is a methodical process of introducing new items of gradually increasing complexity toward the goal of a well-balanced, small portion (~1 cup per meal) diet, which includes the daily intake of 0.5 to 1 g of protein per kg of ideal weight. Nonsteroidal anti-inflammatory medications should be avoided to reduce the risk of intestinal ulceration and bleeding after gastric bypass. Ursodiol and ranitidine are often prescribed for 6 months. Postoperative vitamin and mineral supplementation typically consists of two pediatric chewable multivitamins, a calcium/vitamin D supplement, and an iron supplement for menstruating females. Because of the severity of thiamine deficiency, additional B-complex vitamins beyond what is contained in multivitamin preparations should be given.<sup>91</sup> We routinely re-emphasize five basic "rules" with each patient encounter: (1) eat protein first, (2) drink 64 to 96 ounces of water or sugar-free liquids daily, (3) do not snack between meals, (4) exercise 30 to 60 minutes per day, and (5) always remember vitamins and minerals.

Serum chemistries, complete blood cell count, and representative B-complex vitamin levels (e.g., B<sub>1</sub>, B<sub>12</sub>, folate) are obtained at 6 months and 12 months postoperatively, and then yearly. Body composition is assessed preoperatively with either bioelectrical impedance or dual-energy x-ray absorptiometry (DEXA), and then on an annual basis after operation. DEXA not only allows for the measurement of the rate

and relative amounts of fat and lean body mass loss but also provides a quantitative assessment of bone mineral density changes.

## OUTCOMES IN ADOLESCENTS

Results of RYGB have been retrospectively reviewed in small series of adolescents with generally satisfactory results.<sup>92-100</sup> However, a 14-year follow-up of a small cohort of nine patients demonstrating considerable late weight re-gain suggests that adolescents may require different selection criteria or postoperative management than adults to achieve optimal long-term weight loss outcomes.<sup>5</sup> In a 2007 report, data from 17 studies that enrolled a total of 553 pediatric patients were reviewed. Eight studies reported outcomes after laparoscopic AGB, six after RYGB, two after vertical banded gastroplasty (VBG), and one after banded bypass. One study reported data separately for RYGB and VBG. A detail technology report from this review is available at <http://www.hta.hca.wa.gov>.

At Cincinnati Children's Hospital Medical Center, 86 adolescents have undergone laparoscopic gastric bypass between 2001 and 2007. The mean age of this group is 17 years and with a mean BMI of 59 kg/m<sup>2</sup>. Seventy-five of these patients have been observed for more than 12 months after operation. On average, BMI in this follow-up cohort changed from 59 to 36 kg/m<sup>2</sup>, representing a 39% (range, 16%-49%) reduction over 1 year. Despite this dramatic weight loss, precise body-composition analysis with DEXA at 1 year after surgery has suggested that lean body mass is preserved relative to fat mass loss. Satisfactory preservation of visceral protein despite extremely hypocaloric intake (typically 400 to 600 kcal per day) also is suggested by serial monitoring of serum albumin and total lymphocyte counts.

# EVIDENCE-BASED MEDICINE

Shawn D. St. Peter, MD

“In God we trust; all others must bring data.”

—W. Edwards Deming, physicist  
and quality improvement pioneer

**E**vidence-based medicine (EBM) is defined as the conscientious, explicit, and judicious use of the current best evidence in making decisions about the care of individual patients.<sup>1</sup> A simpler concept would be treating patients based on data rather than the surgeon’s thoughts or beliefs. EBM represents the concept that medical practice can be largely dictated by *evidence* gained from the *scientific method*. Given that the practice of medicine has historically been based on knowledge handed down from mentor to apprentice, the concepts of EBM embody a new paradigm, replacing the traditional paradigm that was based on authority. In a global sense, it describes a methodology for evaluating the validity of clinical research and applying those results to the care of patients.

## HISTORY

The initial groundwork forming the framework for EBM can be considered the earliest scientists who pursued explanatory truth instead of accepting beliefs. The process of discovering truth became replicable for aspiring scientists when the scientific method was outlined. No one individual can be credited for developing the scientific method because it is the result of the progressive recognition for a natural process of acquiring facts. However, the earliest publication alluding to the steps of current scientific methodology may be found in *Book of Optics* published in 1021 by Ibn al-Haytham (Alhazen).<sup>2</sup> His investigations were based on experimental evidence. Furthermore, his experiments were systematic and repeatable as he demonstrated that rays of light are emitted from objects rather than from the eyes. In Western literature, Roger Bacon wrote about a repeating cycle of observation, hypothesis, and experimentation in the 1200s. Influenced by the contributions of many scientists and philosophers, Francis Bacon delineated a recognizable form of the scientific

method in the 1620 publication of *Novum Organum Scientificum*.<sup>3</sup> He suggested that mastery of the world in which man lives is dependent on careful understanding. Moreover, this understanding is based entirely on the facts of this world and not, as the ancients portrayed it, in philosophy. Nearly 400 years later, we find ourselves coming to the same conclusions in the practice of medicine and surgery. We now understand that facts and truths transcend experience and that facts about optimal care can be gained through experimentation more reliably than from beliefs generated through experience.

The establishment of the scientific method in the pursuit of proven truths was fundamental to the development of EBM as an entity. The current scientific method consists of several steps that are outlined in [Table 80-1](#). However, the concepts of EBM are not simply encompassed by the application of these steps to attain facts but also address the ability to understand the value of the results generated from experimentation. Under the auspices of EBM, investigators are burdened with the first five steps, from inquiry to experimentation, while all caregivers must develop a deep understanding of experimental methodology, analysis of data, and how conclusions are drawn to be able to place appropriate value on published studies to influence their practice.

The movement urging physicians to utilize proven facts in the development of decision-making algorithms began in 1972 with the publication of the revolutionary book *Effectiveness and Efficiency: Random Reflections on Health Services*.<sup>4</sup> The author, Archie Cochrane, a Scottish epidemiologist working in the United Kingdom’s National Health System, has likely had the greatest influence in the development of an organized means of guiding care through data and results. The book demonstrates disdain for the scientific establishment, devalues expert opinion, and shows that physicians should systematically question **what is the best care for the patient**. Most impressively, Cochrane calls for an international registry of randomized controlled trials and for explicit quality criteria for appraising published research. At the time of his passing in 1988, these aspirations had not fully materialized. However,

**Table 80-1** Fundamentals of the Scientific Method

1. Establish an inquiry.
2. Develop background knowledge.
3. Develop a hypothesis.
4. Design a logical experiment to prove or disprove the hypothesis.
5. Conduct and/or repeat the experiment.
6. Analyze data.
7. Draw conclusions.
8. Communicate results.

the field of medicine is fortunate that Cochrane's prophetic ideas have precipitated the maturation of centers of evidence-based medical research that make up the global not-for-profit organization called the Cochrane Collaboration. The product of the Collaboration is *The Cochrane Library*, which is a collection of seven databases that contain high-quality, independent evidence to inform health care decision-making.<sup>5</sup> The most clinically utilized database is the Cochrane Database of Systematic Reviews containing reviews on the highest level of evidence on which to base clinical treatment decisions. There are now over 550,000 entries.

After Cochrane and other proponents of care guided by evidence popularized the importance of comparative data, it took over a decade for the amorphous clouds of these concepts to solidify into tangible terms and usable methods. The methodology of specifically qualifying data and judging the relative merit of available studies did not begin to appear in the literature until the early 1990s. In a paper published in 1990 by David Eddy on the role of guidelines in medical decision-making, the term *evidence-based* first appeared in the literature.<sup>6</sup> Much of the framework currently used to determine best available evidence was established by David Sackett and Gordon Guyatt at the McMaster University-based research group called the Evidence-Based Medicine Working Group. In 1992, *JAMA* published the group's landmark paper titled, "Evidence-Based Medicine: A New Approach to Teaching the Practice of Medicine," and the term *evidence-based medicine* was born.<sup>7</sup> A cementing moment in the paradigm shift occurred when the Centre for Evidence-Based Medicine was established in Oxford, England, in 1995 as the first of several centers. Over the past decade, centers or departments focusing on clinical research and EBM have been developed at universities and hospitals around the world, including our own ([www.centerforprospectiveclinicaltrials.com](http://www.centerforprospectiveclinicaltrials.com)). EBM principles are now represented in a module of the core curriculum that is integral to three of the six general competencies outlined by the Accreditation Council for Graduate Medical Education that oversees the accredited residency training programs in the United States. The concept of EBM is no longer a movement of progressive physicians but rather a basic guiding principle of medical training and practice.

## LEVELS OF EVIDENCE

Utilization of evidence in guiding health care decision-making requires an understanding of the merit of the evidence and the ability to decipher whether a given course of treatment has been proven superior. The quality of evidence specifically indicates the extent to which one can be confident that an estimate of effect is correct. Systems to stratify evidence by quality have been developed by several sources. Although there are specific differences in published rankings, the generally accepted levels in a broad sense are defined as follows:

Level 1 evidence is supported by prospective, randomized trials.

Level 2 evidence is supported by cohort studies, outcomes data, or low-quality prospective trials.

Level 3 evidence comprises case-control studies.

Level 4 evidence is based on case series.

Level 5 evidence is expert opinion or beliefs based on rational principles.

The general levels are outlined in [Table 80-2](#). However, the quality of data that is conveyed within each level and study type is clearly a wide spectrum. The complete delineation in the levels of evidence as defined by the Oxford Centre for Evidence-Based Medicine is outlined in [Table 80-3](#).

As can be seen by the levels listed in [Tables 80-2 and 80-3](#), the strength of evidence improves significantly by the application of prospective data collection. In clinical medicine, and particularly in the practice of surgery, there are many aspects of trial design that are not feasible such as blinding, placebo treatments, independent follow-up evaluation, and others. However, if one accepts these limitations and conducts a trial with prospective evaluation, the results remain markedly more meaningful than a retrospective case-control comparative series that compares surgeons and/or timeframes against one another.

The review of several studies can gain strength over an individual study, which is valid in many models and fields of medicine. However, one should be cautioned about the real strengths of such a meta-analysis before considering it to have a high level of evidence. The strength of these combined reviews is derived from the strength of the individual trials providing the numbers for the analysis. In the best scenario, such a combined review is composed of multiple prospective trials with similar design that each compare the effect

**Table 80-2** General Levels of Evidence

Level	Type of Evidence
1	Prospective, randomized trials
2	Review of case-control or cohort studies with agreement or poor-quality randomized trials
3	Case-control studies
4	Case-series or poor-quality case-control and cohort studies
5	Expert opinion, or applied principles from physiology, basic science, or other conditions

Table 80-3 Levels of Evidence as Defined by the Oxford Centre for Evidence-Based Medicine	
Level	Type of Evidence
1a	Systematic review of randomized trials displaying homogeneity
1a–	Systematic review of randomized trials displaying worrisome heterogeneity
1b	Individual randomized controlled trials (with narrow confidence interval)
1b–	Individual randomized controlled trials (with a wide confidence interval)
1c	All or none randomized controlled trials
2a	Systematic reviews (with homogeneity) of cohort studies
2a–	Systematic reviews of cohort studies displaying worrisome heterogeneity
2b	Individual cohort study or low quality randomized controlled trials (<80% follow-up)
2b–	Individual cohort study or low quality randomized controlled trials (<80% follow-up/wide confidence interval)
2c	“Outcomes” research; ecological studies
3a	Systematic review (with homogeneity) of case-control studies
3a–	Systematic review of case-control studies with worrisome heterogeneity
3b	Individual case-control study
4	Case series (and poor quality cohort and case-control studies)
5	Expert opinion without explicit critical appraisal, or based on physiology, bench research or “first principles”

of two treatments on a specific outcome. However, in the field of pediatric surgery, multiple prospective trials with similar designs that address the same disease with the same interventions are nonexistent. Therefore, such combined reviews do not currently exist in pediatric surgery that can be considered level 1 evidence. Also, surgeons should not overvalue the influence of combined reviews derived from retrospective studies. Such reviews should be interpreted as a mosaic of the individual studies. Any attempt by authors to combine a number of retrospective studies to harness statistical power is fraught with hazard.

## GRADES OF RECOMMENDATION

The quality of the evidence as defined in Tables 80-2 and 80-3 applies a score of strength for each individual contribution in the literature. However, on many topics, particularly common clinical scenarios, there is an abundance of published studies such that the appropriate care cannot be guided by a single study. The total body of available information places caregivers in the difficult position of evaluating the published principles from the multiple sources that makes up practice guidelines. The caregiver applying these clinical practice guidelines and other recommendations needs to know how much confidence can be placed in the

recommendations from a conglomerate of citations. Strength of recommendation scales were born from this need.<sup>8-12</sup> Given that the level of evidence indicates the extent to which one can be confident that an estimate of effect is correct, the strength or grade of recommendation indicates the extent to which one can be confident that adherence to the recommendation will do more good than harm.<sup>13</sup> As with the levels of evidence, there are multiple published grading scales. The grading format used by the Oxford Centre for Evidence-Based Medicine is outlined in Table 80-4.

The levels of evidence are more easily assessed because each contribution falls into a given level based on study design. However, establishing the grade of recommendation can be more complex given the fact that multiple levels of evidence from different timeframes invariably exist on any given clinical topic. This is further confusing because many disease processes have multiple outcome measures. Also, each treatment option can affect different outcomes in independent ways that must be balanced against the risk or toxicity of each treatment. A working group has outlined a process for establishing grade based on the following sequential steps<sup>14</sup>:

1. Assess the quality of evidence across studies for each important outcome.
2. Decide which outcomes are critical to a decision.
3. Judge the overall quality of evidence across these critical outcomes.
4. Evaluate balance between benefits and harms.
5. Levy the strength of recommendation.

Currently, an accepted standard of respecting the level of evidence and assessing grades of recommendation is lacking in the pediatric surgery field.

## LANDSCAPE OF PEDIATRIC SURGERY

Progress in the field of pediatric surgery regarding EBM has been hindered by its relatively young age and the size of its membership. As opposed to our adult general surgery colleagues who operate on a foundation built through centuries of work, the first American textbook in pediatric surgery, *Abdominal Surgery of Infancy and Childhood* by Robert Gross and William Ladd, was published in 1941. These men trained the initial cohort of pediatric surgeons who then developed

Table 80-4 Grades of Recommendation as Defined by the Oxford Centre for Evidence-Based Medicine	
Grade	Level of Evidence
A	Consistent level 1 studies
B	Consistent level 2 or 3 studies or extrapolations from level 1 studies
C	Level 4 studies or extrapolations from level 2 or 3 studies
D	Level 5 evidence or troublingly inconsistent or inconclusive studies of any level

other training centers around the country. The total number of training sites has remained relatively small. As a result, the philosophies of only a few people have been taught to the entire practicing population of pediatric surgeons. The practice of pediatric surgery has generally progressed without extensive critical analysis. This phenomenon is pronounced in the pediatric surgery literature, which has been replete with retrospective case-control studies and case series (levels 3 and 4). There are few publications in the pediatric surgery literature that entail comparative analysis, and the majority that do are retrospective studies.

## RETROSPECTIVE STUDIES

Because our field is overly represented with retrospective comparisons, it is important to recognize the natural flaws introduced by retrospective analysis. At least one of two confounding factors is present when an institution reviews and compares different therapies retrospectively. When an institution is concurrently using different treatment plans, usually the comparison between treatment plans also compares caregivers. The other possibility is that the center has changed treatment plans and then retrospectively investigates the effect of this change. Although this sounds attractive, it becomes a comparison between timeframes. Historical comparison groups are difficult to use with scientific confidence owing to the rapid ongoing changes in hospital systems. Many institutions have quality assurance programs that intend to make all patient care more consistent and efficient. Such change will impact outcomes regardless of the surgical treatment. A universal concern with retrospective studies is the assurance of reviewing the entire population and the entire dataset. It can be very difficult to accurately identify all the data desired when retrospectively collecting information. As a result, datasets are often incomplete, which decreases scientific confidence. Another issue, rarely acknowledged in retrospective studies, is the difficulty with capturing the entire population intended for study. There are many coding nuances within an institution that may exclude patients from lists when the database is searched by ICD-9 code. A specific type of patient, such as a treatment failure, can go undetected, because of being hidden under a different diagnosis code. This can create tremendous error in the published data.

## CONSIDERATIONS FOR PROSPECTIVE TRIALS IN PEDIATRIC SURGERY

Although it is clear that prospective trials offer the highest scientific integrity and the best vehicle for determining superior efficacy among options, they have been underutilized in the field of pediatric surgery. Critics have postulated that consented prospective trials would have a limited role in pediatric surgery care because parents would be unwilling to enroll their children into such studies. Studies should not

be conducted in any human population when there is substantial risk of harm balanced against questionable benefit. A well-designed study should offer patients the potential for a better outcome than the standard means of treatment outside the study. However, there is no example in the published literature to support the speculation that studies should not be attempted in children. Moreover, there are several prospective, randomized trials being conducted and emerging in the pediatric surgery literature now that would suggest otherwise.<sup>15-18</sup>

The specific details of trial development are beyond the scope of this chapter, but there are general considerations that can allow pediatric surgeons to identify situations for which a trial can be employed. Specifically, these include an understanding of equipoise or stepwise progression, the need for patient volume, an understanding of population characteristics, and the possibility of influencing practice habits.

## Equipoise

There is usually a role for a trial when equipoise exists for the currently available therapeutic options. Equipoise is the assumption that two treatment plans are equal. Thus, the trial simply pits the two options head to head to identify which is superior. Each caregiver participating in a study does not need to possess true inherent equipoise without bias. Naturally, each practitioner will have biases and suppositions about which management strategy is superior, but there remains a role for a trial when each caregiver can honestly acknowledge that there is not enough evidence to prove his or her own thoughts are correct. The most obvious examples for where a role exists for a trial are circumstances in which more than one management strategy is utilized in a given institution. This usually occurs due to caregiver bias. An example would be the open operation versus the laparoscopic approach for pyloromyotomy.<sup>15</sup> Another would be tube thoracostomy and fibrinolysis versus thoracoscopic decortication for empyema.<sup>17-19</sup> If a given patient condition is treated by pathway A or B based simply on the caregivers who were on call that day when no evidence exists to support either pathway, then not only is there a role for a trial, but, in reality, there is an ethical need to conduct such a study to prevent the potential tragedy wherein half of the patients are receiving inferior care simply due to bias without evidence.

The other natural situation for prospective evaluation is when caregivers can follow the next step in the progression to simplify care but that step may be at the expense of increasing a negative outcome. As an example, if a group would like to attempt to shorten the length of any therapy, then this is clearly advantageous to the patient unless there is a greater investment that subsequently results from treatment failures. As caregivers we owe it to the patients to pursue courses of treatment that ease their investment, but we cannot compromise outcome. Parents would enjoy a shorter course of anal dilation after anoplasty for imperforate anus but not to the point that it results

in a detectable increase in anal stricture. Also, caregivers contemplating fewer doses of antibiotics, shorter periods of observation for various injuries, or less invasive therapeutic options should introduce them under prospective evaluation to be sure the attenuation in care is not offset by higher negative event rates. Under this paradigm, once each study is complete, then a treatment protocol can exist that becomes simple to compare to the next advancement. Our colleagues in oncology understand this concept well. In the cooperative oncology groups, each treatment plan follows a protocol with known outcomes and is compared to a potentially better regimen. Under this plan, once survival for a given cancer becomes high enough, then stepwise progression focuses on minimizing toxicity or surgical morbidity. The surgical fields have been less effective in advancing care using this model, largely due to the individual surgeon unwilling to relinquish his or her independent plans of care.

### Patient Volume

The conduction of a study requires adequate patient volume. This is easily completed for common conditions. However, acquisition of good evidence has long been difficult in pediatric surgery owing to the large number of rare conditions. When considering less common conditions, physicians often suggest to simply expand the number of institutions to overcome volume limitations. This would appear to be a reasonable suggestion, but is extremely difficult to implement because each additional institution will need to take on a tremendous workload. Moreover, not all surgeons at each institution will buy in to the study design. Also, depending on the nature of the study, not all surgeons may be able to offer treatment in both arms. For instance, one of the reasons that a prospective randomized trial failed in comparing open and minimally invasive surgical approaches for cancer in the mid 1990s was because very few of the surgeons could perform the required minimally invasive surgical procedures.<sup>19</sup> It remains a fact that the integrity of the study will decrease with the addition of more institutions and more caregivers because it is less likely the protocols will be followed completely.

The lack of large volumes with certain conditions can be interpreted in a different and more pragmatic way for the practicing surgeon. Instead of focusing on the attainment of a large number of patients to try to detect a difference with strong statistical power, perhaps we should investigate more reasonable sample sizes to see if a larger difference can be detected. Why would we intentionally seek a larger difference when a smaller one might be detected in a larger study? For example, if a busy group of six surgeons were to conduct a study that enrolls over 5 years, and the study fails to detect a difference in any outcome parameter, even though the calculated power may be statistically small and unconvincing by traditional trial design, the number of patients treated by the group is the equivalent volume that an individual surgeon would treat over a 30-year career. Therefore, if the difference is small

enough not to be evident over an individual surgeon's career, the surgeon should not be too concerned about the relevance of the variable studied and should focus on a different treatment variable to improve patient outcome.

### Population Characteristics

The most important consideration of the study population is the homogeneity of the disease. A study on two types of stomal takedown techniques would be difficult due to the large variations in reasons for stoma placement, the intestinal level of the stoma, the degree of expected adhesions, the integrity of the remaining bowel, the function of the anus, and so on. The population should provide enough patient-to-patient similarity that the outcome from one patient can be related to another.

### Generalizability

A study is less useful when there are just a few surgeons who can use the results. This applies not only to technologies or techniques that very few centers can provide but also to the development of the protocol. The protocol should attempt to assimilate real-world, typical practice problems without compromising structural integrity. If the protocol is overly strict, although it provides superior ability for detection of any differences, the results may not be applicable to the typical practice. Therefore, the subsequent value of the study diminishes.

### Relevance

Before developing a project that will provide an answer, the question needs to be asked as to whether a problem exists in the first place. The important parameters for relevance are event rate and burden. While a very powerful study could be done on two methods of closing the skin after an inguinal hernia, the event rate of infection or wound breakdown is so small that surgeons do not concern themselves with this aspect of their practice. The time required for skin closure is a minute or less regardless of technique. Moreover, when infection does occur, the wound is not large enough to create a clinically important problem. Therefore, the practicing surgeon is unlikely to alter his or her technical habits of hernia repair based on the results of such a study.

---

## RESOURCES

The application of EBM practices requires a functional knowledge of how to identify, interpret, and implement the information available into care plans and practice guidelines. Although many institutions have entire departments focusing on the utilization of EBM, not all physicians have ready access to the available information. In the field of surgery, there are many examples of heterogeneous care plans within institutions and group practices despite convincing, high-level evidence. Also, there are many reasons for these often

conflicting care plans. One is that personal bias for some providers is stronger than their ability to interpret data. Thus, they continue working in their comfort zone and are skeptical of sound data. Some of these surgeons completed training in the apprentice era, and they have continued to follow what their chief

told them. Also, some physicians who understand the principles of EBM simply do not have wide access to the evolving body of EBM. To overcome some of these hurdles, several web-based support sites have been developed for both EBM tutorial and review of available studies. A few examples are listed in [Table 80-5](#).
