### Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment, and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

# CONTRIBUTORS

**Stephanie P. Acierno, MD, MPH**

Senior Pediatric Surgical Fellow  
Seattle Children's Hospital  
University of Washington School of Medicine  
Seattle, Washington  
*75: Head and Neck Sinuses and Masses*

**Pablo Aguayo, MD**

Instructor  
Senior Resident  
Department of Surgery  
Kansas University Medical Center  
Kansas City, Kansas  
*31: Duodenal and Intestinal Atresia and Stenosis*

**Craig T. Albanese, MD, MBA**

Professor of Surgery and Pediatrics  
Chief, Division of Pediatric Surgery  
Stanford University School of Medicine  
John A. and Cynthia Fry Gunn Director of Surgical  
Services  
Lucile Packard Children's Hospital  
Stanford, California  
*22: Congenital Bronchopulmonary Malformations*

**D. Adam Algren, MD**

Assistant Professor  
Departments of Emergency Medicine and Pediatrics  
University of Missouri–Kansas City School  
of Medicine  
Emergency Medicine Physician and Medical  
Toxicologist  
Children's Mercy Hospital  
Kansas City, Missouri  
*12: Bites*

**Uri S. Alon, MD**

Professor of Pediatrics  
University of Missouri–Kansas City School  
of Medicine  
Pediatric Nephrologist  
Children's Mercy Hospital  
Kansas City, Missouri  
*4: Renal Impairment*

**Maria H. Alonso, MD**

Assistant Professor of Surgery and Pediatrics  
University of Cincinnati College of Medicine  
Surgical Assistant Director, Liver Transplantation  
Cincinnati Children's Hospital Medical Center  
Cincinnati, Ohio  
*45: Solid Organ and Intestinal Transplantation*

**Richard J. Andrassy, MD**

Professor and Chairman  
Department of Surgery  
University of Texas Medical School at Houston  
Chief, Section of Pediatric Surgery  
University of Texas M.D. Anderson Cancer Center  
Surgeon-in-Chief  
Memorial Hermann Hospital  
Houston, Texas  
*72: Rhabdomyosarcoma*

**Walter S. Andrews, MD**

Professor of Surgery  
University of Missouri–Kansas City  
School of Medicine  
Chief, Transplant Surgery  
Children's Mercy Hospital  
Kansas City, Missouri  
*69: Lesions of the Liver*

**Mara B. Antonoff, MD**

Senior Resident  
Department of Surgery  
University of Minnesota Medical School  
Minneapolis, Minnesota  
*1: Physiology of the Newborn*

**Jae-O Bae, MD**

Pediatric Surgery Fellow  
University of Texas Southwestern Medical Center  
Dallas, Texas  
*78: Endocrine Disorders and Tumors*

**Klaas M. A. Bax, MD, PhD, FRCS(Ed)**

Professor of Pediatric Surgery  
Erasmus Medical School  
University of Rotterdam  
Head, Department of Pediatric Surgery  
Sophia Children's Hospital  
Rotterdam, The Netherlands  
*27: Esophageal Atresia and Tracheoesophageal Malformations*

**Robert E. Binda, Jr., MD**

Associate Professor of Pediatric Anesthesiology  
University of Missouri–Kansas City School  
of Medicine  
Director, Pain Management  
Children's Mercy Hospital  
Kansas City, Missouri  
*3: Anesthetic Considerations*

**Casey M. Calkins, MD**

Assistant Professor of Surgery  
Medical College of Wisconsin  
Pediatric General and Thoracic Surgery  
Children's Hospital of Wisconsin  
Milwaukee, Wisconsin  
*38: Acquired Anorectal Disorders*

**Patrick C. Cartwright, MD**

Professor of Surgery  
University of Utah School of Medicine  
Chief, Division of Urology  
Primary Children's Medical Center  
Salt Lake City, Utah  
*57: Bladder and Urethra*

**Michael G. Caty, MD**

Professor of Surgery and Pediatrics  
Chief, Division of Pediatric Surgery  
State University of New York at Buffalo  
Surgeon-in-Chief  
Department of Pediatric Surgical Services  
Women and Children's Hospital of Buffalo  
Buffalo, New York  
*33: Meconium Disease*

**Nicole M. Chandler, MD**

Staff Surgeon  
Pediatric General and Thoracic Surgery  
All Children's Specialty Physicians  
St. Petersburg, Florida  
*26: The Esophagus*

**Tyler L. Christensen, MD**

Chief Resident in Urology  
Department of Surgery  
Washington University School of Medicine  
Barnes Jewish Hospital  
St. Louis Children's Hospital  
St. Louis, Missouri  
*55: Ureteral Obstruction and Malformations*

**Dai H. Chung, MD**

Professor and Vice-Chair  
Department of Pediatric Surgery  
Vanderbilt University School of Medicine  
Nashville, Tennessee  
*13: Burns*

**Paul M. Colombani, MD, MBA**

Professor of Surgery  
Johns Hopkins University  
Chief, Division of Pediatric Surgery  
Johns Hopkins Hospital  
Baltimore, Maryland  
*26: The Esophagus*

**Arthur Cooper, MD, MS**

Professor of Surgery  
Columbia University College of Physicians  
and Surgeons  
Director of Trauma and Pediatric Surgical Services  
Harlem Hospital Center  
New York, New York  
*14: Early Assessment and Management of Trauma*

**Douglas E. Coplen, MD**

Associate Professor of Surgery  
Washington University School of Medicine  
Director of Pediatric Urology  
St. Louis Children's Hospital  
St. Louis, Missouri  
*55: Ureteral Obstruction and Malformations*

**Hillary L. Copp, MD**

Assistant Professor  
Department of Urology  
University of California, San Francisco  
San Francisco, California  
*52: Undescended Testes and Testicular Tumors*

**Andrew M. Davidoff, MD**

Associate Professor  
Department of Surgery and Pediatrics  
University of Tennessee School of Medicine  
Chairman, Department of Surgery  
St. Jude Children's Research Hospital  
Memphis, Tennessee  
*68: Neuroblastoma*

**Romano T. DeMarco, MD**

Associate Professor of Urology  
University of Missouri-Kansas City School  
of Medicine  
Director, Urology Research  
Department of Surgery  
Children's Mercy Hospital  
Kansas City, Missouri  
*62: Prune-Belly Syndrome*

**Jack S. Elder, MD**

Clinical Professor of Urology  
Case Western Reserve University School of Medicine  
Cleveland, Ohio  
Chief, Department of Urology  
Henry Ford Health System  
Associate Director  
Vattikuti Urology Institute  
Department of Urology  
Children's Hospital of Michigan  
Detroit, Michigan  
*58: Posterior Urethral Valves*

**Mauricio A. Escobar, Jr., MD**

Attending Surgeon  
Mary Bridge Children's Hospital and Health Center  
Tacoma, Washington  
*33: Meconium Disease*

**Mary E. Fallat, MD**

Professor of Surgery  
 Director, Division of Pediatric Surgery  
 University of Louisville  
 Chief of Surgery  
 Kosair Children's Hospital  
 Louisville, Kentucky  
*39: Intussusception*

**Steven J. Fishman, MD**

Associate Professor of Surgery  
 Harvard Medical School  
 Senior Associate in Surgery  
 Co-Director, Vascular Anomalies Center  
 Children's Hospital Boston  
 Boston, Massachusetts  
*74: Vascular Anomalies*

**Jason S. Frischer, MD**

Assistant Professor  
 Department of Surgery  
 University of Cincinnati School of Medicine  
 Division of Pediatric General and Thoracic Surgery  
 Cincinnati Children's Hospital Medical Center  
 Cincinnati, Ohio  
*6: Extracorporeal Membrane Oxygenation*

**Samir Gadepalli, MD**

Clinical Lecturer  
 Department of Pediatric Surgery  
 University of Michigan  
 C.S. Mott Children's Hospital  
 Ann Arbor, Michigan  
*7: Mechanical Ventilation in Pediatric Surgical Disease*

**Alan S. Gamis, MD**

Professor of Pediatrics  
 University of Missouri–Kansas City School  
 of Medicine  
 Section Chief, Oncology  
 Children's Mercy Hospital  
 Kansas City, Missouri  
*71: Lymphomas*

**Victor F. Garcia, MD**

Professor of Surgery  
 University of Cincinnati College of Medicine  
 Director, Trauma Services  
 Associate Surgical Director  
 Comprehensive Weight Management Center  
 Cincinnati Children's Hospital Medical Center  
 Cincinnati, Ohio  
*79: Bariatric Surgical Procedures in Adolescence*

**Carissa L. Garey, MD**

Surgical Scholars Resident  
 Department of Surgery  
 Children's Mercy Hospital  
 Kansas City, Missouri  
*41: Meckel's Diverticulum*

**John M. Gatti, MD**

Associate Professor of Surgery and Urology  
 University of Missouri–Kansas City School of Medicine  
 Director of Minimally Invasive Urology  
 Children's Mercy Hospital  
 Kansas City, Missouri  
*53: The Acute Scrotum*  
*63: Disorders of Sexual Differentiation*

**Keith E. Georgeson, MD**

Joseph M. Farley Professor of Surgery and Vice  
 Chairman  
 Department of Surgery, Division of Pediatrics  
 Program Director, Pediatric Surgery Fellowship  
 University of Alabama School of Medicine  
 at Birmingham  
 Director, Pediatric Surgical Sciences and Division  
 of Pediatric Surgery  
 Children's Hospital of Alabama  
 Birmingham, Alabama  
*35: Hirschprung's Disease*

**Saif A. Ghole, MD**

Department of Surgery  
 Stanford University School of Medicine  
 Stanford University Hospital and Clinics  
 Stanford, California  
*22: Congenital Bronchopulmonary Malformations*

**George K. Gittes, MD**

Professor of Surgery  
 Chief, Division of Pediatric Surgery  
 University of Pittsburgh School of Medicine  
 Benjamin R. Fisher Chair of Pediatric Surgery  
 and Surgeon-in-Chief  
 Children's Hospital of Pittsburgh  
 Pittsburgh, Pennsylvania  
*46: Lesions of the Pancreas*

**Richard W. Grady, MD**

Associate Professor of Urology  
 University of Washington School of Medicine  
 Attending and Fellowship Program Director  
 Seattle Children's Hospital  
 Seattle, Washington  
*59: Bladder and Cloacal Exstrophy*

**Neil E. Green, MD**

Professor of Orthopaedic Surgery  
 Vanderbilt School of Medicine  
 Department of Orthopaedics and Rehabilitation  
 Monroe Carell Jr. Children's Hospital at Vanderbilt  
 Nashville, Tennessee  
*18: Pediatric Orthopedic Trauma*

**Clarence S. Greene, Jr., MD**

Associate Professor of Neurosurgery  
 University of Missouri–Kansas City School of Medicine  
 Attending Neurosurgeon  
 Children's Mercy Hospital  
 Kansas City, Missouri  
*19: Neurosurgical Conditions*

**Michael R. Harrison, MD**

Director, Fetal Treatment Center  
University of California, San Francisco  
Children's Hospital  
San Francisco, California  
*10: Fetal Therapy*

**André Hebra, MD**

Professor of Surgery and Pediatrics  
Chief, Division of Pediatric Surgery  
Medical University of South Carolina  
Surgeon-in-Chief  
The Children's Hospital  
Charleston, South Carolina  
*21: Tracheal Obstruction and Repair*

**Marion C. W. Henry, MD, MPH**

Attending Pediatric Surgeon  
Section of Pediatric Surgery  
Yale University School of Medicine  
New Haven, Connecticut  
*34: Necrotizing Enterocolitis*

**David N. Herndon, MD**

Professor and Jesse H. Jones Distinguished Chair  
in Surgery  
Departments of Surgery and Pediatrics  
University of Texas Medical Branch  
Chief of Staff, Department of Surgery  
Shriners Hospital for Children at Galveston  
Galveston, Texas  
*13: Burns*

**Barry A. Hicks, MD**

Professor of Surgery and Pediatrics  
Division of Pediatric Surgery  
University of Texas Southwestern Medical Center at  
Dallas  
Children's Medical Center–Dallas  
Dallas, Texas  
*16: Abdominal and Renal Trauma*

**Shinjiro Hirose, MD**

Pediatric Surgeon  
Fetal Treatment Center  
University of California, San Francisco  
Children's Hospital  
San Francisco, California  
*10: Fetal Therapy*

**Ronald B. Hirschl, MD**

Arnold G. Coran Professor  
Department of Pediatric Surgery  
University of Michigan Health System  
Section Head and Surgeon-in-Chief  
C.S. Mott Children's Hospital  
Ann Arbor, Michigan  
*7: Mechanical Ventilation in Pediatric Surgical Disease*

**George W. Holcomb III, MD, MBA**

The Katharine B. Richardson Endowed Professor  
of Pediatric Surgery  
University of Missouri–Kansas City School  
of Medicine  
Surgeon-in-Chief  
Director, Center for Minimally Invasive Surgery  
Children's Mercy Hospital  
Kansas City, Missouri  
*29: Gastroesophageal Reflux*  
*40: Alimentary Tract Duplications*  
*50: Laparoscopy*

**Gregory W. Hornig, MD**

Clinical Assistant Professor of Neurosurgery  
University of Missouri–Kansas City School  
of Medicine  
Chief, Section of Neurosurgery  
Children's Mercy Hospital  
Kansas City, Missouri  
*19: Neurosurgical Conditions*

**Romeo C. Ignacio, Jr., MD**

Pediatric Surgery Fellow  
Division of Pediatric Surgery  
University of Louisville  
Kosair Children's Hospital  
Louisville, Kentucky  
*39: Intussusception*

**Thomas H. Inge, MD, PhD**

Associate Professor  
Department of Pediatrics and Surgery  
University of Cincinnati College of Medicine  
Director, Surgical Weight Loss Program  
for Teens  
Cincinnati Children's Hospital Medical Center  
Cincinnati, Ohio  
*79: Bariatric Surgical Procedures in Adolescence*

**Tom Jaksic, MD, PhD**

W. Hardy Hendren Professor of Surgery  
Harvard Medical School  
Vice Chairman of Pediatric Surgery  
Children's Hospital Boston  
Boston, Massachusetts  
*2: Nutritional Support of the Pediatric Patient*

**Yoshifumi Kato, MD, PhD**

Associate Professor  
Pediatric General and Urogenital Surgery  
Juntendo University School of Medicine  
Tokyo, Japan  
*44: Biliary Tract Disorders and Portal Hypertension*

**Scott J. Keckler, MD**

Surgical Scholars Resident  
Department of Surgery  
Children's Mercy Hospital  
Kansas City, Missouri  
*40: Alimentary Tract Duplications*

**Cassandra Kelleher, MD**

Pediatric Surgery Fellow  
Hospital for Sick Children  
Toronto, Ontario, Canada  
*48: Congenital Abdominal Wall Defects*

**Robert E. Kelly, Jr., MD**

Professor of Clinical Surgery and Pediatrics  
Eastern Virginia Medical School  
Chief, Department of Surgery  
Children's Hospital of The King's Daughters  
Norfolk, Virginia  
*20: Congenital Chest Wall Deformities*

**Curtis S. Koontz, MD**

Assistant Professor of Surgery  
University of Tennessee–Chattanooga  
Chattanooga, Tennessee  
*30: Lesions of the Stomach*

**Thomas M. Krummel, MD**

Emile Holman Professor and Chair  
Department of Surgery  
Stanford University School of Medicine  
Susan B. Ford Surgeon-in-Chief  
Lucile Packard Children's Hospital  
Stanford, California  
*9: Surgical Infectious Disease*

**Arlet G. Kurkchubasche, MD**

Associate Professor of Surgery and Pediatrics  
Brown University Medical School  
Hasbro Children's Hospital  
Providence, Rhode Island  
*73: Nevus and Melanoma*

**Jean-Martin Laberge, MD, FRCSC, FACS**

Professor of Surgery  
McGill University  
Senior Pediatric Surgeon  
Montreal Children's Hospital  
Montreal, Quebec, Canada  
*70: Teratomas, Dermoids, and Other Soft Tissue Tumors*

**Kevin P. Lally, MD, MS**

A. G. McNeese Chair and Professor  
Department of Pediatric Surgery  
University of Texas Medical School at Houston  
Surgeon-in-Chief  
Children's Memorial Hermann Hospital  
Houston, Texas  
*24: Congenital Diaphragmatic Hernia and Eventration*

**Jacob C. Langer, MD**

Professor of Surgery  
University of Toronto  
Chief, Pediatric General and Thoracic Surgery  
Hospital for Sick Children  
Toronto, Ontario, Canada  
*48: Congenital Abdominal Wall Defects*

**Joseph L. Lelli, Jr., MD, MBA**

Assistant Professor  
Wayne State Medical School  
Chief of Pediatric General and Thoracic Surgery  
Children's Hospital of Michigan  
Detroit, Michigan  
*11: Foreign Bodies*

**Marc A. Levitt, MD**

Associate Professor  
Department of Surgery  
University of Cincinnati  
Associate Director, Colorectal Center  
Cincinnati Children's Hospital Medical Center  
Cincinnati, Ohio  
*36: Imperforate Anus and Cloacal Malformations*  
*37: Fecal Incontinence and Constipation*

**Karen B. Lewing, MD**

Assistant Professor of Pediatrics  
University of Missouri–Kansas City School  
of Medicine  
Fellowship Program Director  
Division of Hematology/Oncology  
Children's Mercy Hospital  
Kansas City, Missouri  
*71: Lymphomas*

**Charles M. Leys, MD**

Assistant Professor of Surgery  
Indiana University School of Medicine  
Staff Surgeon  
Riley Hospital for Children  
Indianapolis, Indiana  
*53: The Acute Scrotum*

**Danny C. Little, MD**

Assistant Professor of Surgery  
Texas A&M University Health Center–College  
of Medicine  
Chief of Pediatric Surgery  
Children's Hospital at Scott & White  
Temple, Texas  
*32: Malrotation*

**Jennifer A. Lowry, MD**

Assistant Professor, Department of Pediatrics  
University of Missouri–Kansas City School  
of Medicine  
Medical Toxicologist and Clinical Pharmacologist  
Children's Mercy Hospital  
Kansas City, Missouri  
*12: Bites*

**Marcus M. Malek, MD**

Surgical Research Fellow  
Children's Hospital of Pittsburgh  
Pittsburgh, Pennsylvania  
*46: Lesions of the Pancreas*

**Thao T. Marquez, MD**

Senior Resident  
Department of Surgery  
University of Minnesota Medical School  
Minneapolis, Minnesota  
*1: Physiology of the Newborn*

**Nilesh M. Mehta, MD, DCH**

Instructor in Anesthesia  
Harvard Medical School  
Division of Critical Care Medicine  
Children's Hospital Boston  
Boston, Massachusetts  
*2: Nutritional Support of the Pediatric Patient*

**Gregory A. Mencio, MD**

Professor and Chief  
Pediatric Orthopaedics  
Vanderbilt University School of Medicine  
Monroe Carell Jr. Children's Hospital at Vanderbilt  
Nashville, Tennessee  
*18: Pediatric Orthopedic Trauma*

**Marc P. Michalsky, MD**

Assistant Professor of Clinical Surgery  
Ohio University College of Medicine  
Principal Investigator  
Center for Clinical and Translational Research  
Nationwide Children's Hospital  
Columbus, Ohio  
*23: Acquired Lesions of the Lung and Pleura*

**Eugene A. Minevich, MD**

Associate Professor of Surgery  
University of Cincinnati College of Medicine  
Cincinnati Children's Hospital Medical Center  
Cincinnati, Ohio  
*56: Urinary Tract Infection and Vesicoureteral Reflux*

**Michael E. Mitchell, MD**

Professor of Urology  
Medical College of Wisconsin  
Chief of Pediatric Urology  
Children's Hospital of Wisconsin  
Milwaukee, Wisconsin  
*59: Bladder and Cloacal Exstrophy*

**Go Miyano, MD**

Department of Pediatric General and Urogenital  
Surgery  
Juntendo University Hospital  
Tokyo, Japan  
*79: Bariatric Surgical Procedures in Adolescence*

**Takeshi Miyano, MD, PhD**

Emeritus Professor  
Pediatric General and Urogenital Surgery  
Juntendo University School of Medicine  
Tokyo, Japan  
*44: Biliary Tract Disorders and Portal Hypertension*

**Christopher R. Moir, MD**

Professor of Surgery  
Mayo Clinic  
Rochester, Minnesota  
*42: Inflammatory Bowel Disease and Intestinal Cancer*

**R. Lawrence Moss, MD, FACS**

Robert Pritzker Professor and Chief  
Pediatric Surgery  
Yale University School of Medicine  
Surgeon-in-Chief  
Yale New Haven Children's Hospital  
New Haven, Connecticut  
*34: Necrotizing Enterocolitis*

**J. Patrick Murphy, MD**

Professor of Surgery and Urology  
University of Missouri–Kansas City School of Medicine  
Section Chief, Urologic Surgery  
Children's Mercy Hospital  
Kansas City, Missouri  
*60: Hypospadias*

**Don K. Nakayama, MD, MBA**

Milford B. Hatcher Professor and Chair  
Department of Surgery  
Mercer University School of Medicine  
Program Director, Residency in Surgery  
Medical Center of Central Georgia  
Macon, Georgia  
*77: Breast Diseases*

**Jaimie D. Nathan, MD, MS**

Assistant Professor of Surgery and Pediatrics  
University of Cincinnati College of Medicine  
Cincinnati Children's Hospital Medical Center  
Cincinnati, Ohio  
*45: Solid Organ and Intestinal Transplantation*

**Kathleen A. Neville, MD, MS**

Assistant Professor of Pediatrics  
Divisions of Pediatric Hematology/Oncology and  
Pediatric Pharmacology and Medical Toxicology  
Children's Mercy Hospital  
Kansas City, Missouri  
*5: Coagulopathies and Sickle Cell Disease*

**Donald Nuss, MB, ChB, FRCS(C), FACS**

Professor of Surgery and Pediatrics  
Eastern Virginia Medical School  
Pediatric Surgeon  
Children's Hospital of The King's Daughters  
Norfolk, Virginia  
*20: Congenital Chest Wall Deformities*

**Keith T. Oldham, MD**

Professor and Chief  
Division of Pediatric Surgery  
Medical College of Wisconsin  
Marie Z. Uihlein Chair and Surgeon-in-Chief  
Children's Hospital of Wisconsin  
Milwaukee, Wisconsin  
*38: Acquired Anorectal Disorders*

**James A. O'Neill, Jr., MD**

J. C. Foshee Distinguished Professor  
 Chairman Emeritus, Section of Surgical Sciences  
 Department of Pediatric Surgery  
 Vanderbilt University School of Medicine  
 Monroe Carell Jr. Children's Hospital at Vanderbilt  
 Nashville, Tennessee  
*65: Renovascular Hypertension*

**Daniel J. Ostlie, MD**

Associate Professor of Surgery  
 University of Missouri–Kansas City School  
 of Medicine  
 Director, Surgical Critical Care  
 Children's Mercy Hospital  
 Kansas City, Missouri  
*29: Gastroesophageal Reflux*  
*31: Duodenal and Intestinal Atresia and Stenosis*

**H. Biemann Othersen, Jr., MD, BSM**

Professor of Surgery and Pediatrics  
 Emeritus Head, Division of Pediatric Surgery  
 Medical University of South Carolina  
 Charleston, South Carolina  
*21: Tracheal Obstruction and Repair*

**Alberto Peña, MD**

Professor, Department of Surgery  
 University of Cincinnati  
 Director, Colorectal Center  
 Cincinnati Children's Hospital Medical Center  
 Cincinnati, Ohio  
*36: Imperforate Anus and Cloacal Malformations*  
*37: Fecal Incontinence and Constipation*

**Kathy M. Perryman, MD, FAAP**

Associate Professor of Pediatric Anesthesiology  
 University of Missouri–Kansas City School  
 of Medicine  
 Children's Mercy Hospital  
 Kansas City, Missouri  
*3: Anesthetic Considerations*

**Craig A. Peters, MD**

John E. Cole Professor of Urology  
 University of Virginia School of Medicine  
 Chief, Division of Pediatric Urology  
 University of Virginia Children's Hospital  
 Charlottesville, Virginia  
*64: Urologic Laparoscopy*

**Devin P. Puapong, MD**

Chief Resident in Pediatric Surgery  
 University of Oklahoma Health Sciences Center  
 Children's Hospital  
 Oklahoma City, Oklahoma  
*15: Thoracic Trauma*

**Pramod S. Puligandla, MD, FRCSC, FACS**

Associate Professor of Surgery and Pediatrics  
 McGill University  
 Pediatric Surgery Training Program Director  
 Montreal Children's Hospital  
 Montreal, Quebec, Canada  
*70: Teratomas, Dermoids, and Other Soft Tissue Tumors*

**Stephen C. Raynor, MD**

Chief of Pediatric Surgery  
 Children's Hospital & Medical Center  
 Omaha, Nebraska  
*61: Circumcision*

**Frederick J. Rescorla, MD**

Lafayette L. Page Professor and Director  
 Section of Pediatric Surgery  
 Indiana University School of Medicine  
 Surgeon-in-Chief  
 Riley Hospital for Children  
 Indianapolis, Indiana  
*47: Splenic Conditions*

**Bradley M. Rodgers, MD**

Professor of Surgery and Pediatrics  
 University of Virginia Health Sciences Center  
 Chief of Pediatric Surgery  
 University of Virginia Children's Hospital  
 Charlottesville, Virginia  
*23: Acquired Lesions of the Lung and Pleura*

**Michael T. Rohmiller, MD**

Orthopedic Spine Surgeon  
 Cincinnati Spine Institute  
 Cincinnati, Ohio  
*18: Pediatric Orthopedic Trauma*

**Steven S. Rothenberg, MD**

Clinical Professor of Surgery  
 Columbia University College of Physicians  
 and Surgeons  
 New York, New York  
 Chief of Pediatric Surgery  
 The Rocky Mountain Hospital for Children  
 Denver, Colorado  
*28: Thoracoscopy in Infants and Children*

**Frederick C. Ryckman, MD**

Professor of Surgery and Pediatrics  
 University of Cincinnati College of Medicine  
 Vice-President, System Capacity and Perioperative  
 Operations  
 Cincinnati Children's Hospital Medical Center  
 Cincinnati, Ohio  
*45: Solid Organ and Intestinal Transplantation*

**Shawn D. St. Peter, MD**

Assistant Professor of Surgery  
University of Missouri–Kansas City School  
of Medicine  
Director, Center for Prospective Clinical Trials  
Children’s Mercy Hospital  
Kansas City, Missouri  
*43: Appendicitis*  
*80: Evidence-Based Medicine*

**Daniel A. Saltzman, MD, PhD**

Associate Professor of Surgery and Pediatrics

# PREFACE

This is the fifth edition of *Pediatric Surgery*, but the first edition without the insights and efforts of either Dr. Tom Holder or Dr. Keith Ashcraft. In 1980, these two master surgeons had the foresight to develop a reference text focusing on infants and children with surgical conditions. The current editors would like to dedicate this fifth edition to our founding editors, Drs. Tom Holder and Keith Ashcraft.

Drs. Holder and Ashcraft wanted to create a single-volume pediatric surgical work that was broad in scope and had some detail about each condition; however, they did not intend for this work to be encyclopedic. As they stated in their first Preface, “An effort has been made to provide sufficient information concerning physiology, embryology, and anatomy so that the reader may gain a thorough understanding of the patient, the disease process, its symptoms, diagnosis, and treatment. Authors were selected because they are acknowledged authorities in the area of their contribution.”

This concept of a single-volume text has persisted over the subsequent editions. The current editors have tried to maintain this book in the style originally conceived by Drs. Holder and Ashcraft. Although most of the chapters in this edition have the same title as those in the first edition, the information and knowledge in the field of pediatric surgery have dramatically evolved. More than half the illustrations in this fifth edition are new. Management of urologic conditions remains an important part of this book because many pediatric surgeons around the world also perform urologic operations in children. An effort has been made to use experts from all over the world to write the chapters, as this book is read worldwide by surgeons, pediatricians, residents, and medical students.

Many, if not most, operations are now performed using a minimally invasive approach. Thus, operative technique is emphasized more in this edition than in previous ones. Prenatal diagnosis is an entity now commonly encountered by pediatric surgeons. In addition, so much more about genetic predisposition to certain conditions and cancers is known now versus 30 years ago. Finally, in this fifth edition, a chapter on “Evidence Based Medicine” has made its way into a pediatric surgical textbook for the first time. As previously emphasized, a concerted effort has been made to keep this book to a single volume. However, as there is so much more information that is important and known

about pediatric surgical conditions than was available in 1980, we also need to allow for that growth. In an effort to limit the book to a single volume, references have been placed online on the associated *Expert Consult* website ([www.expertconsult.com](http://www.expertconsult.com)), rather than at the end of each chapter in the book itself. While some readers do not look at the references, those who do will find that they are easily accessible and linked to PubMed for easy access to abstracts and full text. By saving nearly 200 pages of text, we have helped to maintain the cost of the book. Also, the amount of paper needed was significantly reduced. In addition, the full text and color figures are also available on *Expert Consult*. Purchasers receive a PIN code and password with each copy of the book, making this edition the first pediatric surgery text that is available online. We hope our readers enjoy and appreciate this feature as we believe that a definite advantage of this book will be its portability. Whether in the office, the operating room, at home, or out of town, *Pediatric Surgery*, fifth edition, will be available online through a personal password.

In the fourth edition, videos were available on a DVD that accompanied the book. Since a companion book (*Atlas of Laparoscopy and Thoracoscopy*, Holcomb GW III, Georgeson KE, Rothenberg SS, editors) was recently published by Elsevier, access to videos from this atlas will also be available on *Expert Consult* to purchasers of this fifth edition.

The editors would like to thank all of the authors for their extraordinary efforts and time spent in writing their chapters. In addition, three of our colleagues (Kathy Smith, Linda Jankowski, and Barbara Juarez) have provided extraordinary technical support for this book. This book would not have been possible without their help. In addition, we would also like to thank the administration and leadership at The Children’s Mercy Hospital for their continued full support for this book for the past 30 years. Finally, the editors would also like to thank our colleagues at Elsevier for their timeless attention to detail and support throughout the process of editing and publishing this textbook. This book was truly a team effort by a great many people. We hope you will enjoy this fifth edition and find it helpful in treating your patients.

# PHYSIOLOGY OF THE NEWBORN

Mara Antonoff, MD • Thao Marquez, MD • Daniel Saltzman, MD, PhD

Newborns may be classified based on gestational age and weight. Preterm infants are those born before 37 weeks of gestation. Term infants are those born between 37 and 42 weeks of gestation, whereas post-term infants have a gestation that exceeds 42 weeks. Newborns whose weight is below the 10th percentile for age are considered small for gestational age (SGA), whereas those whose weight is at or above the 98th percentile are large for gestational age (LGA). The newborns whose weight falls between these extremes are appropriate for gestational age (AGA).

SGA newborns are thought to suffer intrauterine growth retardation as a result of placental, maternal, or fetal abnormalities. Conditions associated with deviation in intrauterine growth are shown in [Figure 1-1](#). SGA infants have a body weight below what is appropriate for their age, yet their body length and head circumference are age appropriate. To classify an infant as SGA, the gestational age must be confirmed by the physical findings summarized in [Table 1-1](#).

Although SGA infants may weigh the same as premature infants, they have different physiologic characteristics. Owing to intrauterine malnutrition, body fat levels are frequently below 1% of the total body weight. This lack of body fat increases the risk of cold stress with SGA infants. Hypoglycemia develops earlier in SGA infants owing to higher metabolic activity and reduced glycogen stores. The red blood cell (RBC) volume and the total blood volume are much higher in the SGA infant compared with the preterm average for gestational age or the non-SGA full-term infant. This rise in RBC volume frequently leads to polycythemia, with an associated rise in blood viscosity. Owing to the adequate length of gestation, the SGA infant has pulmonary function approaching that of a full-term infant or one who is average for gestational age.

Infants born before 37 weeks of gestation, regardless of birth weight, are considered premature. The physical examination of the premature infant reveals that the skin is thin and transparent with an absence of plantar creases. Fingers are soft and malleable, and ears have poorly developed cartilage. In females, the labia minora appear enlarged, but the labia majora are

small. In males, the testes are usually undescended and the scrotum is undeveloped. Special problems with the preterm infant include the following:

- Weak suck reflex
- Inadequate gastrointestinal absorption
- Hyaline membrane disease
- Intraventricular hemorrhage
- Hypothermia
- Patent ductus arteriosus
- Apnea
- Hyperbilirubinemia

## SPECIFIC PHYSIOLOGIC PROBLEMS OF THE NEWBORN

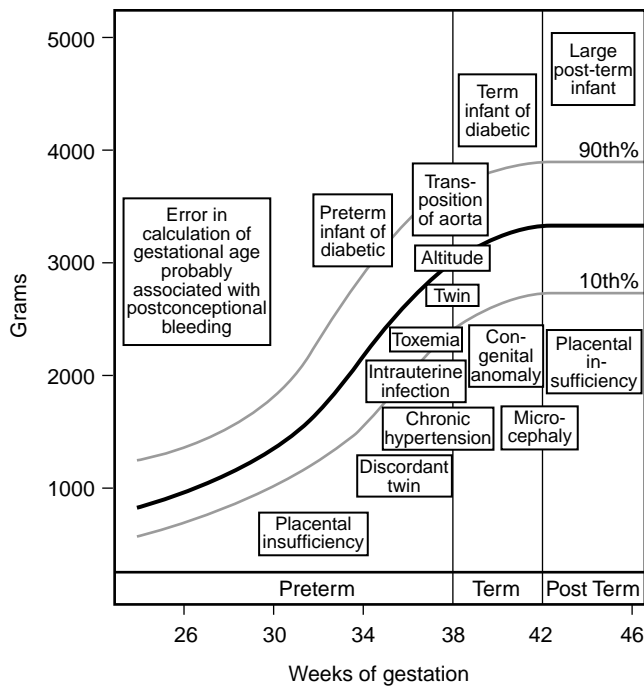

Fetal levels of glucose, calcium, and magnesium are carefully maintained by maternal regulation. The transition to extrauterine life can have profound effects on the physiologic well-being of the newborn.

### Glucose Metabolism

The fetus maintains a blood glucose value 70% to 80% of the maternal value by facilitated diffusion across the placenta. There is a buildup of glycogen stores in the liver, skeleton, and cardiac muscles during the later stages of fetal development but little gluconeogenesis. The newborn must depend on glycolysis until exogenous glucose is supplied. After delivery, the newborn depletes his or her hepatic glycogen stores within 2 to 3 hours. Glycogen stores are more rapidly reduced in premature and SGA newborns. The newborn is severely limited in his or her ability to use fat and protein as substrates to synthesize glucose.

### Hypoglycemia

Clinical signs of hypoglycemia are nonspecific and may include a weak or high-pitched cry, cyanosis, apnea, jitteriness, apathy, seizures, abnormal eye movements, temperature instability, hypotonia, and weak suck. Some infants, however, exhibit no signs, despite extremely low blood glucose levels.

**Figure 1-1.** Graph of conditions associated with deviations in intrauterine growth. The boxes indicate the approximate birth weight and gestational age at which the condition is likely to occur. (Adapted from Avery ME, Vilee D, Baker S, et al: Neonatology. In Avery ME, First LR [eds]: Pediatric Medicine. Baltimore, Williams & Wilkins, 1989, p 148.)

Neonatal hypoglycemia is generally defined as a glucose level lower than 40 mg/dL. After 72 hours of age, plasma glucose levels should be greater than or equal to 40 mg/dL.<sup>1</sup> Although there is not one specific threshold at which all infants will develop neurologic sequelae, features associated with adverse outcomes include blood glucose concentrations that are extremely low (<20 mg/dL) and/or persistently low (>1-2 hours).<sup>2</sup> Infants who are at high risk for developing hypoglycemia require frequent glucose monitoring. Because most newborns who require surgical procedures are at risk to develop hypoglycemia, a 10% glucose infusion is usually started on admission to the hospital and blood glucose levels are measured at the bedside and confirmed by periodic laboratory

determinations. If the blood glucose level falls below 40 mg/dL or if any signs of hypoglycemia are present, an hourly bolus infusion of 1 to 2 mL/kg (4 to 8 mg/kg/min) of 10% glucose is given intravenously. If central venous access is present, concentrations of up to 50% glucose may be used. During the first 36 to 48 hours after a major surgical procedure, it is not uncommon to see wide variations in serum glucose levels. Therefore, frequent blood and urine glucose determinations should be performed. Rarely, hydrocortisone, glucagon, or somatostatin is needed to treat persistent hypoglycemia.

### Hyperglycemia

Hyperglycemia is a common problem with the use of total parenteral nutrition (TPN) in very immature infants who are less than 30 weeks' gestation and weigh less than 1.1 kg at birth. These infants are usually younger than 3 days of age and are frequently septic.<sup>3</sup> This hyperglycemia appears to be associated with both insulin resistance and relative insulin deficiency, reflecting the prolonged catabolism seen in very low birth weight infants.<sup>4</sup> Hyperglycemia may cause intraventricular hemorrhage and water and electrolyte losses from glucosuria. The glucose concentration and infusion rate of the TPN must be adjusted based on serum glucose levels. Full parenteral caloric support is achieved with incremental increases in glucose, usually over several days. Occasionally, insulin, 0.001 to 0.01 U/kg/min, is given intravenously to maintain normoglycemia and may be helpful in achieving anabolism in infants of very low birth weight.<sup>4</sup>

### Calcium

Calcium is continuously delivered to the fetus by active transport across the placenta. Of the total amount of calcium transferred, 75% occurs after 28 weeks' gestation.<sup>5</sup> This observation partially accounts for the high incidence of hypocalcemia in extremely preterm infants. Any neonate has a tendency for hypocalcemia due to limited calcium stores, renal immaturity, and relative hypoparathyroidism secondary to suppression by high fetal calcium levels. Some infants are at further risk for neonatal calcium disturbances due to

Criteria	36 Wk (Premature)	37-38 Wk (Borderline Premature)	39 Wk (Term)
Plantar creases	Rare, shallow	Heel remains smooth	Creases throughout sole
Size of breast nodule	Not palpable to < 3 mm	4 mm	Visible (7 mm)
Head hair	Cotton wool quality		Silky; each strand can be distinguished
Earlobe	Shapeless, pliable with little cartilage		Rigid with cartilage
Testicular descent and scrotal changes	Small scrotum with rugal patch; testes not completely descended	Gradual descent	Enlarged scrotum creased with rugae; fully descended testes

Adapted from Avery ME, Vilee D, Baker S, et al: Neonatology. In Avery ME, First LR (eds): Pediatric Medicine. Baltimore, William & Wilkins, 1989, p148.

the presence of genetic defects, pathologic intrauterine conditions, or birth trauma.<sup>6</sup> Newborn calcium levels usually reach their nadir 24 to 48 hours after delivery, when parathyroid hormone responses become effective. Hypocalcemia is defined as an ionized calcium level of less than 1 mg/dL. At greatest risk for hypocalcemia are preterm infants, newborns requiring surgery, and infants of complicated pregnancies, such as those of diabetic mothers or those receiving bicarbonate infusions. Calcitonin, which inhibits calcium mobilization from the bone, is increased in premature and asphyxiated infants.

Exchange transfusions or massive transfusions of citrated blood can result in the formation of calcium citrate complexes, reducing the ionized serum calcium levels to dangerous or even fatal levels. Late-onset (>48 hours of age) hypocalcemia is less frequent now that most formulas are low in phosphate.

Signs of hypocalcemia may include jitteriness, seizures, cyanosis, vomiting, and myocardial depression, some of which are similar to the signs of hypoglycemia. Hypocalcemic infants have increased muscle tone, which helps differentiate infants with hypocalcemia from those with hypoglycemia. Ionized calcium levels are easily determined in most intensive care settings. Symptomatic hypocalcemia is treated with 10% calcium gluconate administered intravenously at a dosage of 1 to 2 mL/kg over 10 minutes while monitoring the electrocardiogram. Asymptomatic hypocalcemia is best treated with calcium gluconate in a dose of 50 mg of elemental calcium per kilogram per day added to the maintenance fluid; 1 mL of 10% calcium gluconate contains 9 mg of elemental calcium. Calcium mixed with sodium bicarbonate forms an insoluble precipitate. If possible, parenteral calcium should be given through a central venous line.

## Magnesium

Magnesium is actively transported across the placenta. Half of the total-body magnesium is in the plasma and soft tissues. Hypomagnesemia is observed with growth retardation, maternal diabetes, after exchange transfusions, and with hypoparathyroidism. Magnesium and calcium metabolism are interrelated. The same infants at risk for hypocalcemia are also at risk for hypomagnesemia. Whenever an infant who has seizures that are believed to be associated with hypocalcemia does not respond to calcium therapy, magnesium deficiency should be suspected and confirmed by obtaining a serum magnesium level. Emergent treatment consists of magnesium sulfate solution, 25 to 50 mg/kg IV every 6 hours, until normal levels are obtained.

## Blood Volume

Total RBC volume is at its highest point at delivery. Estimation of blood volume for premature infants, term neonates, and infants is summarized in Table 1-2. By about 3 months of age, total blood volume per

**Table 1-2** Estimation of Blood Volume

Group	Blood Volume (mL/kg)
Premature infants	85-100
Term newborns	85
>1 mo	75

kilogram is nearly equal to adult levels. The newborn blood volume is affected by shifts of blood between the placenta and the newborn before clamping the cord. Newborns with delayed cord clamping have higher hemoglobin levels.<sup>7</sup> A hematocrit greater than 50% suggests placental transfusion has occurred.

## Polycythemia

A central venous hemoglobin level greater than 22 g/dL or a hematocrit value greater than 65% during the 1st week of life is defined as polycythemia. After the central venous hematocrit value reaches 65%, further increases result in rapid exponential increases in blood viscosity. Neonatal polycythemia occurs in infants of diabetic mothers, infants of mothers with toxemia of pregnancy, or SGA infants. Polycythemia is treated using a partial exchange of the infant's blood with fresh whole blood or 5% albumin. This is frequently done when the hematocrit is greater than 65%. Capillary hematocrits are poor predictors of viscosity. Therefore, decisions to perform exchange transfusions should be based on central hematocrits only.

## Anemia

Anemia present at birth is due to hemolysis, blood loss, or decreased erythrocyte production.

### HEMOLYTIC ANEMIA

Hemolytic anemia is most often a result of placental transfer of maternal antibodies that are destroying the infant's erythrocytes. This can be determined by the direct Coombs test. The most common severe anemia is Rh incompatibility. Hemolytic disease in the newborn produces jaundice, pallor, and hepatosplenomegaly. The most severely affected infants manifest hydrops. This massive edema is not strictly related to the hemoglobin level of these infants. ABO incompatibility frequently results in hyperbilirubinemia but rarely causes anemia.

Congenital infections, hemoglobinopathies (sickle cell disease), and thalassemias produce hemolytic anemia. In a severely affected infant with a positive-reacting direct Coombs test result, a cord hemoglobin level of less than 10.5 g/dL, or a cord bilirubin level of greater than 4.5 mg/dL, immediate exchange transfusion is indicated. For less severely affected infants, exchange transfusion is indicated when the total indirect bilirubin level is greater than 20 mg/dL.

## HEMORRHAGIC ANEMIA

Significant anemia can develop from hemorrhage that occurs during placental abruption. Internal bleeding (intraventricular, subgaleal, mediastinal, intra-abdominal) in infants can also often lead to severe anemia. Usually, hemorrhage occurs acutely during delivery, and the newborn occasionally requires transfusion. Twin-twin transfusion reactions can produce polycythemia in one newborn and profound anemia in the other. Severe cases can lead to death in the donor and hydrops in the recipient.

## ANEMIA OF PREMATURITY

Decreased RBC production frequently contributes to anemia of prematurity. Erythropoietin is not released until a gestational age of 30 to 34 weeks has been reached. These infants, however, have large numbers of erythropoietin-sensitive RBC progenitors. Research has focused on the role of recombinant erythropoietin in treating anemia in preterm infants.<sup>8-10</sup> Successful increases in hematocrit levels using recombinant erythropoietin may obviate the need for blood transfusions and reduce the risk of bloodborne infections and reactions. Studies suggest that routine use of erythropoietin is probably helpful for the very low birth weight infant (<750 g), but its regular use for other preterm infants does not likely significantly reduce the transfusion rate.

## Hemoglobin

At birth, nearly 80% of circulating hemoglobin is fetal. When infant erythropoiesis resumes at about 2 to 3 months of age, most new hemoglobin is adult. When the oxygen level is 27 mm Hg, 50% of the bound oxygen is released from adult hemoglobin (P50). Therefore, the P50 of adult hemoglobin is 27 mm Hg. Reduction of hemoglobin's affinity for oxygen allows more oxygen to be released into the tissues at a given oxygen level.

Fetal hemoglobin has a P50 value 6 to 8 mm Hg higher than that of adult hemoglobin. This higher P50 value allows more efficient oxygen delivery from the placenta to the fetal tissues. In this situation, the hemoglobin equilibrium curve is considered to be shifted to the left of normal. This increase in P50 is believed to be due to the failure of fetal hemoglobin to bind 2,3-diphosphoglycerate to the same degree as does adult hemoglobin.<sup>11</sup> This is somewhat of a disadvantage to the newborn because lower peripheral oxygen levels are needed before oxygen is released from fetal hemoglobin. By 4 to 6 months of age in a term infant, the hemoglobin equilibrium curve gradually shifts to the right and the P50 value approximates that of a normal adult.

## Jaundice

In the hepatocyte, bilirubin created by hemolysis is conjugated to glucuronic acid and rendered water soluble. Conjugated (also known as direct) bilirubin is excreted in bile. Unconjugated bilirubin interferes with cellular respiration and is toxic to neural cells.

**Table 1-3** Causes of Prolonged Indirect Hyperbilirubinemia

Breast milk jaundice	Pyloric stenosis
Hemolytic disease	Crigler-Najjar syndrome
Hypothyroidism	Extravascular blood

Data from Maisels MJ: Neonatal jaundice. In Avery GB (ed): Neonatology. Pathophysiology and Management of the Newborn. Philadelphia, JB Lippincott, 1987, p 566.

Subsequent neural damage is termed *kernicterus* and produces athetoid cerebral palsy, seizures, sensorineural hearing loss, and, rarely, death.

The newborn's liver has a metabolic excretory capacity for bilirubin that is not equal to its task. Even healthy full-term infants usually have an elevated unconjugated bilirubin level. This peaks about the third day of life at 6.5 to 7.0 mg/dL and does not return to normal until the 10th day of life. A total bilirubin level greater than 7 mg/dL in the first 24 hours or greater than 13 mg/dL at any time in full-term newborns often prompts an investigation for the cause. Breast-fed infants usually have serum bilirubin levels 1 to 2 mg/dL greater than formula-fed infants. The common causes of prolonged indirect hyperbilirubinemia are listed in [Table 1-3](#).

Pathologic jaundice within the first 36 hours of life is usually due to excessive production of bilirubin. Hyperbilirubinemia is managed based on the infant's weight. Although specific cutoffs defining the need for therapy have not been universally accepted, the following recommendations are consistent with most practice patterns.<sup>12</sup> Phototherapy is initiated for newborns (1) less than 1500 g, when the serum bilirubin level reaches 5 mg/dL; (2) 1500 to 2000 g, when the serum bilirubin level reaches 8 mg/dL; or (3) 2000 to 2500 g, when the serum bilirubin level reaches 10 mg/dL. Formula-fed term infants without hemolytic disease are treated by phototherapy when levels reach 13 mg/dL. For hemolytic-related hyperbilirubinemia, phototherapy is recommended when the serum bilirubin level exceeds 10 mg/dL by 12 hours of life, 12 mg/dL by 18 hours, 14 mg/dL by 24 hours, or 15 mg/dL by 36 hours.<sup>13</sup> An absolute bilirubin level that triggers exchange transfusion is still not established, but most exchange transfusion decisions are based on the serum bilirubin level and its rate of rise.

The use of transcutaneous devices for measurement of plasma bilirubin levels has become increasingly common. However, these devices have limited reliability and accuracy in determination of bilirubin levels for those infants who are less than 28 weeks of gestational age or weigh less than 1000 g.<sup>14,15</sup> In these patients, the total serum bilirubin measurement should still be utilized.

## Retinopathy of Prematurity

Retinopathy of prematurity (ROP) develops during the active phases of retinal vascular development in the first 3 or 4 months of life. The exact causes are

unknown, but oxygen exposure (>93%-95%)<sup>16</sup> and extreme prematurity are the only risk factors that have been repeatedly and convincingly demonstrated. The risk of ROP is probably related to the degree of immaturity, length of exposure, and oxygen concentration. ROP is found in 1.9% of premature infants in large neonatal units.<sup>17</sup> Retrolental fibroplasia is the pathologic change observed in the retina and overlying vitreous after the acute phases of ROP subsides. A study conducted by the National Institutes of Health found that cryotherapy was effective in preventing retinal detachment, macular fold, and retrolental fibroplasia.<sup>18</sup> Treatment of ROP more recently with laser photocoagulation has been shown to have the added benefit of superior visual acuity and less myopia when compared with cryotherapy in long-term follow-up studies.<sup>19-21</sup> Both treatments reduce the incidence of blindness by approximately 25% but do not increase the chance of good visual acuity (<20/40).

The American Academy of Pediatrics guidelines recommend that all infants who received oxygen therapy who weigh less than 1500 g and are fewer than 32 weeks' gestation, and selected infants with a birth weight between 1500 and 2000 g or gestational age of more than 32 weeks with an unstable clinical course, including those requiring cardiorespiratory support and who are believed by their attending pediatrician or neonatologist to be at high risk, should undergo a screening examination for ROP.<sup>22</sup> A re-examination schedule determined by the examining ophthalmologist, based on visual examination findings,<sup>23</sup> should be closely followed.<sup>22</sup>

## Thermoregulation

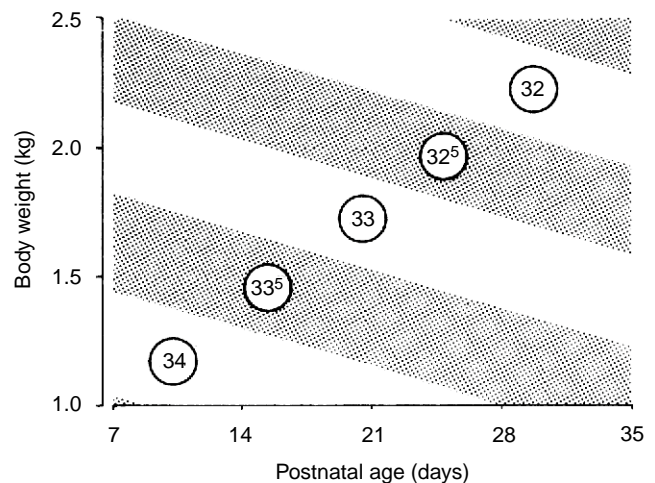

A homeotherm is a mammal that can maintain a constant deep body temperature. Although humans are homeothermic, newborns have difficulty maintaining constant deep body temperature owing to their relatively large surface area, poor thermal regulation, and small mass to act as a heat sink. Heat loss may occur from (1) evaporation (a wet newborn or a newborn in contact with a wet surface), (2) conduction (direct skin contact with a cool surface), (3) convection (air currents blowing over the newborn), and (4) radiation (the newborn radiates heat to a cooler surface without contact with this surface).

Of these, radiation is the most difficult to control. Infants produce heat by increasing metabolic activity either by shivering like an adult or by nonshivering thermogenesis, using brown fat. Brown-fat thermogenesis may be involved in thermoregulatory feeding and sleep cycles in the infant, with an increase in body temperature signaling an increase in metabolic demand.<sup>24</sup> Brown-fat thermogenesis may be rendered inactive by vasopressors, by anesthetic agents, and through nutritional depletion.<sup>25-28</sup> Thermoneutrality (the optimal thermal environment for the newborn) is the range of ambient temperatures in which the newborn with a normal body temperature and a minimal metabolic rate can maintain a constant body temperature by vasomotor control. The *critical temperature* is

**Figure 1-2.** Neutral thermal environment (°C) during the first week of life calculated from these measurements: Dew point of the air, 18°C; flow, 10 L/min. (From Sauer PJJ, Dane HJ, Visser HKA: New standards for neutral thermal environment of healthy very low birthweight infants in week one of life. Arch Dis Child 59:18-22, 1984.)

the temperature below which a metabolic response to cold is necessary to replace lost heat. The appropriate incubator temperature is determined by the patient's weight and postnatal age (Figs. 1-2 and 1-3). For low birth weight infants, thermoneutrality is 34° to 35°C up to 6 weeks of age and 31° to 32°C until 12 weeks of age. Infants who weigh 2 to 3 kg have a thermoneutrality zone of 31° to 34°C on the first day of life and 29° to 31°C until 12 days. Double-walled incubators

**Figure 1-3.** Neutral thermal environment (°C) from day 7 to 35. Dew point of air, 18°C; flow, 10 L/min. Body weight is current weight. Values for body weight greater than 2.0 kg are calculated by extrapolation. (From Sauer PJJ, Dane HJ, Visser HKA: New standards for neutral thermal environment of healthy very low birthweight infants in week one of life. Arch Dis Child 59:18-22, 1984.)

offer the best thermoneutral environment. Radiant warmers cannot prevent convection heat loss and lead to higher insensible water loss.

Failure to maintain thermoneutrality leads to serious metabolic and physiologic consequences. Special care must be exercised to maintain the body temperature within normal limits in the operating room.

## Fluids and Electrolytes

At 12 weeks of gestation, the fetus has a total body water content that is 94% of body weight. This amount decreases to 80% by 32 weeks' gestation and 78% by term (Fig. 1-4). A further 3% to 5% reduction in total body water content occurs in the first 3 to 5 days of life. Body water continues to decline and reaches adult levels (approximately 60% of body weight) by 1½ years of age. Extracellular water also declines by 1 to 3 years of age. These water composition changes progress in an orderly fashion in utero. Premature delivery requires the newborn to complete both fetal and term water unloading tasks. Surprisingly, the premature infant can complete fetal water unloading by 1 week after birth. Postnatal reduction in extracellular fluid volume has such a high physiologic priority that it occurs even in the presence of relatively large variations of fluid intake.<sup>29</sup>

### Glomerular Filtration Rate

The glomerular filtration rate (GFR) of newborns is slower than that of adults.<sup>30</sup> From 21 mL/min/1.73 m<sup>2</sup> at birth in the term infant, GFR quickly increases to

60 mL/min/1.73 m<sup>2</sup> by 2 weeks of age. GFR reaches adult levels by 1½ to 2 years of age. A preterm infant has a GFR that is only slightly slower than that of a full-term infant. In addition to this difference in GFR, the concentrating capacity of the preterm and the full-term infant is well below that of the adult. An infant responding to water deprivation increases urine osmolarity to a maximum of only 600 mOsm/kg. This is in contrast to the adult, whose urine concentration can reach 1200 mOsm/kg. It appears that the difference in concentrating capacity is due to the insensitivity of the collecting tubules of the newborn to antidiuretic hormone. Although the newborn cannot concentrate urine as efficiently as the adult, the newborn can excrete very dilute urine at 30 to 50 mOsm/kg. Newborns are unable to excrete excess sodium, an inability thought to be due to a tubular defect. Term infants are able to conserve sodium, but premature infants are considered "salt wasters" because they have an inappropriate urinary sodium excretion, even with restricted sodium intake.

### Insensible Water Loss

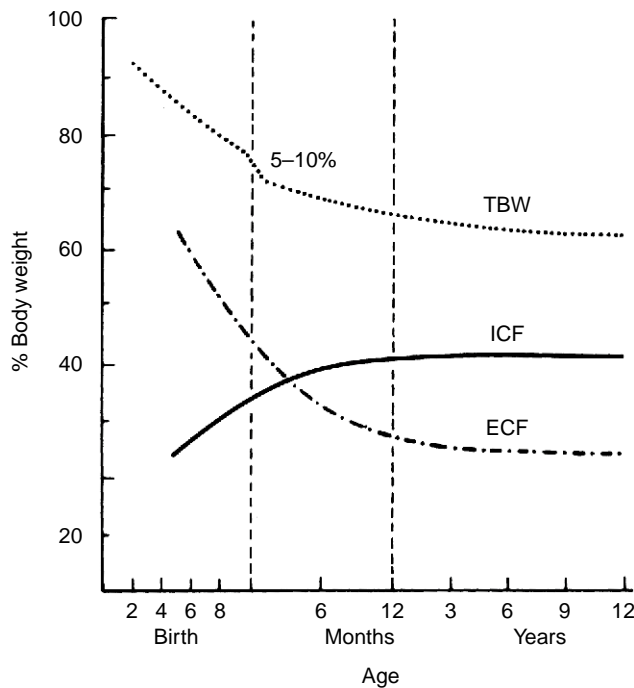

Insensible water loss from the lungs can be essentially eliminated by humidification of inspired air. Trans-epithelial water loss occurs by the diffusion of water molecules through the stratum corneum of the skin. Owing to the immature skin, preterm infants of 25 to 27 weeks' gestation can lose more than 120 mL/kg/day of water by this mechanism. Transepithelial water loss decreases as age increases.

### Neonatal Fluid Requirements

To estimate fluid requirements in the newborn requires an understanding of (1) preexisting fluid deficit or excess, (2) metabolic demands, and (3) losses.

Because these factors change quickly in the critically ill newborn, frequent adjustments in fluid management are necessary. Hourly monitoring of intake and output allows early recognition of fluid balance that will affect treatment decisions. This dynamic approach requires two components: an initial hourly fluid intake that is safe and a monitoring system to detect the patient's response to the treatment program selected. A table of initial volumes expressed in rates of milliliters per kilogram per 24 hours for various surgical conditions has been developed as a result of a study of a large group of infants followed during their first 3 postoperative days (Table 1-4). The patients were divided into three groups by condition: (1) moderate surgical conditions, such as colostomies, laparotomies, and intestinal atresia; (2) severe surgical conditions, such as midgut volvulus or gastroschisis; and (3) necrotizing enterocolitis with perforation of the bowel or bowel necrosis requiring exploration.

No "normal" urine output exists for a given neonate. Ideal urine output can be estimated by measuring the osmolar load presented to the kidney for excretion and calculating the amount of urine necessary to clear this load, if the urine is maintained at an isotonic level of 280 mOsm/dL (Table 1-5).

**Figure 1-4.** Friss-Hansen's classic chart relating total body weight (TBW) and extracellular (ECF) and intracellular fluid (ICF) to percentage of body weight, from early gestation to adolescence. (Adapted from Welch KJ, Randolph JG, Ravitch MM, et al [eds]: *Pediatric Surgery*, 4th ed. Chicago, Year Book Medical, 1986, p 24.)

Group	Day 1	Day 2	Day 3
Moderate surgical conditions (e.g., colostomies, laparotomies for intestinal atresia, Hirschsprung's disease)	80 ± 25	80 ± 30	80 ± 30
Severe surgical conditions (e.g., gastroschisis, midgut volvulus, meconium peritonitis)	140 ± 45	90 ± 20	80 ± 15
Necrotizing enterocolitis with perforation	145 ± 70	135 ± 50	130 ± 40

After administering the initial hourly volume for 4 to 8 hours, depending on the newborn's condition, he or she is reassessed by observing urine output and concentration. With these two factors, it is possible to determine the state of hydration of most newborns and their responses to the initial volume. In more difficult cases, changes in serial serum sodium (Na), blood urea nitrogen (BUN), creatinine, and osmolarity along with urine Na, creatinine, and osmolarity make it possible to assess the infant's response to the initial volume and to use fluid status to guide the next 4 to 8 hours' fluid intake.

### *Illustrative Examples*

#### **INSUFFICIENT FLUID**

A 1-kg premature infant, during the first 8 hours postoperatively, has 0.3 mL/kg/hr of urine output. Specific gravity is 1.025. Previous initial volume was 5 mL/kg/hr. Serum BUN has increased from 4 mg/dL to 8 mg/dL; hematocrit value has increased from 35% to 37%, without transfusion. This child is dry. The treatment is to increase the hourly volume to 7 mL/kg/hr for the next 4 hours and to monitor the subsequent urine output and concentration to reassess fluid status.

#### **INAPPROPRIATE ANTIDIURETIC HORMONE RESPONSE**

A 3-kg newborn with congenital diaphragmatic hernia during the first 8 hours postoperatively has a urine output of 0.2 mL/kg/hr, with a urine osmolarity of 360 mOsm/L. The previous initial volume was 120 mL/kg/day (15 mL/hr). The serum osmolarity value has decreased from 300 mOsm preoperatively to 278 mOsm/L; and BUN has decreased from 12 to 8 mg/dL. The inappropriate antidiuretic hormone response requires reduction in fluid volume from 120 to 90 mL/kg/day for the next 4 to 8 hours. Repeat urine and serum measurements will guide the further adjustment of fluid administration.

#### **OVERHYDRATION**

A 3-kg newborn, 24 hours after operative closure of gastroschisis, had an average urine output of 3 mL/kg/hr over the previous 4 hours. During that time period, the

Group	Day 1	Day 2	Day 3
Moderate surgical conditions (e.g., colostomies, laparotomies for intestinal atresia, Hirschsprung's disease)	2 ± 0.96	2.63 ± 1.71	2.38 ± 0.92
Severe surgical conditions (e.g., gastroschisis, midgut volvulus, meconium peritonitis)	2.67 ± 0.92	2.96 ± 0.54	2.96 ± 1.0
Necrotizing enterocolitis with perforation	2.58 ± 1.04	3.17 ± 1.67	3.46 ± 1.46

infant received fluids at a rate of 180 mL/kg/day. The specific gravity of the urine has decreased to 1.006; serum BUN is 4 mg/dL; hematocrit value is 30%, down from 35% preoperatively. The total serum protein concentration is 4.0 mg/dL, down from 4.5 mg/dL. This child is being overhydrated. The treatment is to decrease the fluids to 3 mL/kg/hr for the next 4 hours and then to reassess urine output and concentration.

#### **RENAL FAILURE**

A 5-kg infant with severe sepsis secondary to Hirschsprung's enterocolitis has had a urine output of 0.1 mL/kg/hr for the past 8 hours. The specific gravity is 1.012; serum sodium, 150 mg/dL; BUN, 25 mg/dL; creatinine, 1.5 mg/dL; urine sodium, 130 mEq; and urine creatinine, 20 mg/dL.

Fractional Na excretion (FE Na) is shown by the following equation:

$$\begin{aligned} \text{FE Na} &= \frac{(\text{UNa} \times \text{PCr})}{(\text{PNa}) \times (\text{UCr})} = \frac{130 \times 1.5}{150 \times 20} \\ &= \frac{195}{3000} \times 100 \\ &= 6.5\% (\text{normal} = 2\% \text{ to } 3\%) \end{aligned}$$

FE Na less than 2% usually indicates a prerenal cause of oliguria, whereas greater than 3% usually implies a renal cause (e.g., acute tubular necrosis). This patient is in acute renal failure. The plan is to restrict fluids to insensible losses plus measured losses for the next 4 hours and to then reassess the plan using both urine and serum studies.

### **PULMONARY SYSTEM OF THE NEWBORN**

The dichotomous branching of the bronchial tree is usually completed by 16 weeks' gestation. No actual alveoli are seen until 24 to 26 weeks' gestation. Therefore, should the fetus be delivered at this age, the air-blood surface area for gas diffusion is limited.

Between 24 and 28 weeks, the cuboidal and columnar cells become flatter and start differentiating into type I (lining cells) and/or type II (granular) pneumocytes. Between 26 and 32 weeks of gestation, terminal air sacs begin to give way to air spaces. From 32 to 36 weeks, further budding of these air spaces occurs and alveoli become numerous. At the same time, the phospholipids that constitute pulmonary surfactant begin to line the terminal lung air spaces. Surfactant is produced by type II pneumocytes and is extremely important in maintaining alveolar stability.

The change in the ratio of the amniotic phospholipids, lecithin and sphingomyelin, is used to assess fetal lung maturity. A ratio greater than 2 is considered compatible with mature lung function. Absence of adequate surfactant leads to hyaline membrane disease or respiratory distress syndrome. Hyaline membrane disease is present in nearly 10% of all premature infants and is the leading cause of morbidity and mortality (30%) among premature infants in the United States. Other conditions associated with pulmonary distress in the newborn include delayed fetal lung absorption (wet lung syndrome), intrauterine aspiration pneumonia (meconium aspiration), and intrapartum pneumonia. In all of these conditions, endotracheal intubation and mechanical ventilation may be required for hypoxia, CO<sub>2</sub> retention, or apnea. Ventilator options and management are discussed in Chapter 7.

## Surfactant

Surfactant deficiency is believed to be the major cause of hyaline membrane disease. Surfactant replacement therapy improves effective oxygenation. Three surfactant preparations have been under investigation: (1) surfactant derived from bovine or porcine lung, (2) human surfactant extracted from amniotic fluid, and (3) artificial surfactant. Multicenter-based, randomized trials for modified bovine surfactant (Survanta)<sup>31</sup> and artificial surfactant (Exosurf Neonatal)<sup>32</sup> have been published.

In one study, Survanta was given as a single dose via an endotracheal tube an average of 12 minutes after birth. The patients who received Survanta demonstrated less severe radiographic changes at 24 hours of age compared with infants who received placebo. However, there was no clinical difference at 7 and 28 days after treatment compared with placebo.

In the Exosurf Neonatal study, the premature infants were randomized to receive one dose of the artificial surfactant or air placebo. In this study a significant reduction was noted in the surfactant-treated infants compared with the control group in all of the following: number of deaths attributed to hyaline membrane disease, incidence of pulmonary air leaks, oxygen requirements, and mean airway pressure.

An uncontrolled case series, in which surfactant was given to full-term newborns with pneumonia and meconium aspiration, showed a significant improvement in oxygenation after treatment.<sup>33</sup> Although these and other reports are promising, further studies are needed to determine the most effective dose, the number of

doses, and the optimal timing for surfactant treatment. Regardless, surfactant therapy is an important addition to the pulmonary care of the preterm newborn.

One multicenter study reported that surfactant therapy early in the course of full-term newborn respiratory failure resulted in a significantly lower requirement for extracorporeal membrane oxygenation and produced no additional morbidity. Prophylactic treatment as well as rescue treatment with surfactant has proved to reduce the incidence and severity of respiratory distress syndrome, air leaks, and mortality in preterm infants (<30 weeks' gestational age).<sup>34</sup> Additionally, infants suspected of respiratory distress syndrome have been shown to have improved outcomes with early (<2 hour) administration of surfactant when compared with delayed treatment (2-6 hours).<sup>35</sup> This strategy has been shown to be particularly beneficial in those infants with a low rate of exposure to antenatal steroids.<sup>36,37</sup> Several recent multicenter studies compared the efficacy and complication rates of synthetic versus calf-lung cannula surfactant therapies for neonatal respiratory failure.<sup>38-41</sup>

Both natural and synthetic surfactant have been shown to be effective in the treatment and prevention of respiratory distress syndrome. In comparative trials with synthetic surfactant, natural surfactant has demonstrated earlier improvement in ventilator requirements, fewer pneumothoraces, a marginal decrease in bronchopulmonary dysplasia, and decreased mortality.<sup>42</sup> Natural surfactant has been noted to have a marginal increase in intraventricular hemorrhage, but without a difference in more serious (grade 3 to 4) intraventricular hemorrhage. However, support exists for the synthetic surfactant preparations. This support is based on the theoretical advantage of a possibly reduced risk of intraventricular hemorrhage, less exposure to animal antigen with subsequent reactions, and lower overall cost. Newer-generation synthetic surfactant preparations containing peptides that mimic the action of human surfactant protein-B (SP-B) are currently being investigated. In recent randomized, multi-center trials, Lucinactant (Discovery Laboratories, Warrington, PA), an SP-B protein-containing synthetic surfactant, was similar in efficacy and safety in the prevention and treatment of respiratory distress syndrome when compared with porcine-derived (poractant alpha) surfactant, was more effective than nonprotein synthetic preparations, and resulted in decreased respiratory distress syndrome-related mortality rates versus the bovine-derived Survanta.<sup>43,44</sup> It is hoped that future studies will provide additional insight into the appropriate applications of the available agents.

## Monitoring

Continuous monitoring of physiologic indices provides data that assist in assessing response to therapy and trends that may be used to predict catastrophe. Many episodes of "sudden deterioration" in critically ill patients are viewed, in retrospect, as changes in the clinical condition that had been occurring for some time.

## Arterial Blood Gases and Derived Indices

Arterial oxygen tension ( $P_{aO_2}$ ) is most commonly measured by obtaining an arterial blood sample and by measuring the partial pressure of oxygen with a polarographic electrode. Defining normal parameters for  $P_{aO_2}$  depends on the maturation and age of the patient. In the term newborn, the general definition for hypoxia is a  $P_{aO_2}$  less than 55 mm Hg, whereas that for hyperoxia is a  $P_{aO_2}$  greater than 80 mm Hg.

Capillary blood samples are "arterialized" by topical vasodilators or heat to increase blood flow to a peripheral site. Blood must be freely flowing and collected quickly to prevent exposure to the atmosphere. Blood flowing sluggishly and exposed to atmospheric oxygen falsely raises the  $P_{aO_2}$  from a capillary sample, especially in the range of 40 to 60 mm Hg.<sup>45</sup> Capillary blood pH and carbon dioxide tension ( $P_{CO_2}$ ) correlate well with arterial samples, except when perfusion is poor.  $P_{aO_2}$  is the least reliable of all capillary blood gas determinations. In patients receiving oxygen therapy in whom  $P_{aO_2}$  exceeds 60 mm Hg, the capillary  $P_{aO_2}$  correlates poorly with the arterial measurement.<sup>46,47</sup>

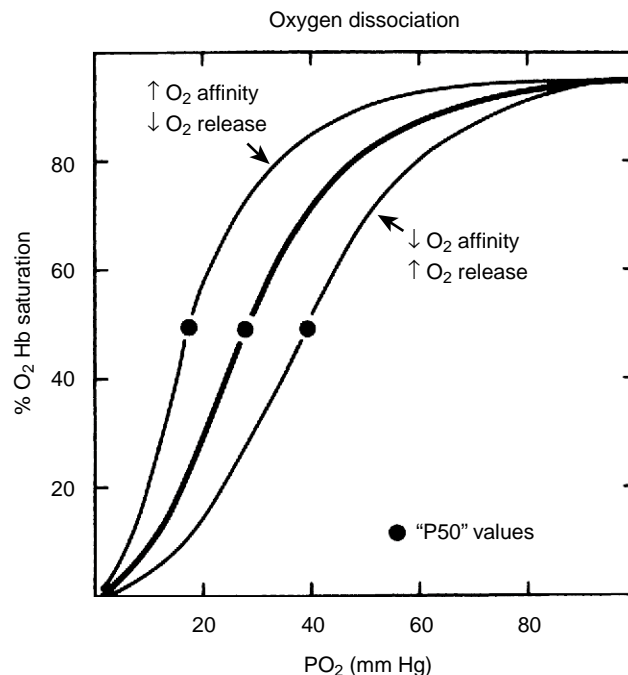

In newborns, umbilical artery catheterization can provide arterial access. The catheter tip should rest at the level of the diaphragm or below L3. The second most frequently used arterial site is the radial artery. Complications of arterial blood sampling include repeated blood loss and anemia. Changes in oxygenation are such that intermittent blood gas sampling may miss critical episodes of hypoxia or hyperoxia. Because of the drawbacks of ex-vivo monitoring, several in-vivo monitoring systems have been used.

### Pulse Oximetry

The noninvasive determination of oxygen saturation ( $S_{aO_2}$ ) gives moment-to-moment information regarding the availability of oxygen to the tissues. If the  $P_{aO_2}$  is plotted against the oxygen saturation of hemoglobin, the S-shaped hemoglobin dissociation curve is obtained (Fig. 1-5). Referring to this curve, hemoglobin is 50% saturated at 25 mm Hg  $P_{aO_2}$  and 90% saturated at 50 mm Hg. Pulse oximetry has a rapid (5 to 7 seconds) response time, requires no calibration, and may be left in place continuously.

Pulse oximetry is not possible if the patient is in shock, has peripheral vasospasm, or has vascular constriction due to hypothermia. Inaccurate readings may occur in the presence of jaundice, direct high-intensity light, dark skin pigmentation, and greater than 80% fetal hemoglobin. Oximetry is not a sensitive guide to gas exchange in patients with high  $P_{aO_2}$  due to the shape of the oxygen dissociation curve. As an example, on the upper horizontal portion of the curve, large changes in  $P_{aO_2}$  may occur with little change in  $S_{aO_2}$ . An oximeter reading of 95% could represent a  $P_{aO_2}$  between 60 and 160 mm Hg.

A study to compare  $S_{aO_2}$  from pulse oximetry with  $P_{aO_2}$  determined from indwelling arterial catheters has shown that  $S_{aO_2}$  greater than or equal to 85% corresponds to a  $P_{aO_2}$  greater than 55 mm Hg and that  $S_{aO_2}$  less than or equal to 90% corresponds to a  $P_{aO_2}$  less

**Figure 1-5.** The oxygen dissociation curve of normal adult blood. The P50, the oxygen tension at 50% oxygen saturation, is approximately 27 mm Hg. As the curve shifts to the right, the oxygen affinity of hemoglobin decreases and more oxygen is released at a given oxygen tension. With a shift to the left, the opposite effects are observed. A decrease in pH or an increase in temperature reduces the affinity of hemoglobin for oxygen. (Modified from Glancette V, Zipursky A: Neonatal hematology. In Avery GB [ed]: Neonatology. Philadelphia, JB Lippincott, 1986, p 663.)

than 80 mm Hg.<sup>48</sup> Guidelines for monitoring infants using pulse oximetry have been suggested for the following three conditions:

1. In the infant with acute respiratory distress without direct arterial access, saturation limits of 85% (lower) and 92% (upper) should be set.
2. In the older infant with chronic respiratory distress who is at low risk for retinopathy of prematurity, the upper saturation limit may be set at 95%; the lower limit should be set at 87% to avoid pulmonary vasoconstriction and pulmonary hypertension.
3. Because the concentration of fetal hemoglobin in newborns affects the accuracy of pulse oximetry, infants with arterial access should have both  $P_{aO_2}$  and  $S_{aO_2}$  monitored closely. A graph should be kept at the bedside documenting the  $S_{aO_2}$  each time the  $P_{aO_2}$  is measured. Limits for the  $S_{aO_2}$  alarm can be changed because the characteristics of this relationship change.

### Carbon Dioxide Tension

Arterial carbon dioxide tension ( $P_{aCO_2}$ ) is a direct reflection of gas exchange in the lungs and of the metabolic rate. In most clinical situations, changes in  $P_{aCO_2}$  are due to changes in ventilation. For this reason, serial measurement of  $P_{aCO_2}$  is a practical method to assess the adequacy of ventilation. The discrepancy

among venous, capillary, and arterial carbon dioxide tensions is not great under most conditions, although one study noted a significant increase in  $\text{PaCO}_2$  in venous samples compared with simultaneous arterial samples.<sup>49</sup>

Because it is possible to monitor  $\text{PaCO}_2$  and pH satisfactorily with venous or capillary blood samples and because pulse oximetry is now commonly used to assess oxygenation, many infants with respiratory insufficiency no longer require arterial catheters for monitoring.

### End-tidal Carbon Dioxide

Measuring expired  $\text{CO}_2$  by capnography provides a noninvasive means of continuously monitoring alveolar  $\text{PCO}_2$ . Capnometry measures  $\text{CO}_2$  by an infrared sensor either placed in line between the ventilator circuit and the endotracheal tube or off to the side of the air flow, both of which are applicable only to the intubated patient. A comparative study of end-tidal  $\text{CO}_2$  in critically ill neonates demonstrated that both sidestream and mainstream end-tidal  $\text{CO}_2$  measurements approximated  $\text{PaCO}_2$ .<sup>50</sup> When the mainstream sensor was inserted into the breathing circuit, the  $\text{PaCO}_2$  increased an average of 2 mm Hg. Although this is not likely to significantly affect infants who are ventilated, it might create fatigue in weaning infants from mechanical ventilation. The accuracy of the end-tidal  $\text{CO}_2$  is diminished with small endotracheal tubes.

### Central Venous Catheter

Indications for central venous catheter placement include (1) hemodynamic monitoring, (2) inability to establish other venous access, (3) TPN, and (4) infusion of inotropic drugs or other medications that cannot be given peripherally. Measurement of central venous pressure to monitor volume status is frequently used in the resuscitation of a critically ill patient. A catheter placed in the superior vena cava or right atrium measures the filling pressure of the right side of the heart, which usually reflects left atrial and filling pressure of the left ventricle. Often, a wide discrepancy exists between left and right atrial pressure when pulmonary disease, overwhelming sepsis, or cardiac lesions are present. To utilize the data effectively, continuous measurements must be taken with a pressure transducer connected to a catheter accurately placed in the central venous system. Positive-pressure ventilation, pneumothorax, abdominal distention, or pericardial tamponade all elevate central venous pressure.

### Pulmonary Artery Catheter

The pulmonary artery pressure catheter has altered the care of the child with severe cardiopulmonary derangement by allowing direct measurement of cardiovascular variables at the bedside. The indications for pulmonary catheter placement are listed in Table 1-6. With this catheter, it is possible to monitor central venous pressure, pulmonary artery pressure,

**Table 1-6** Indications for Pulmonary Artery Catheter Placement

Inadequate systemic perfusion in the presence of elevated central venous pressure
Fluid management in noncardiogenic pulmonary edema
Evaluation of therapeutic interventions, such as changes in positive end-expiratory pressure, use of vasoactive drugs, or assisted circulation
Hemodynamic evaluation in children with pulmonary hypertension
Severe pulmonary disease with profound hypoxemia

Adapted from Perkin RM: Invasive monitoring in the pediatric intensive care unit. In Nussbaum E (ed): *Pediatric Intensive Care*, 2nd ed. Mt. Kisco, NY, Futura Publishing, 1989, p 259.

pulmonary wedge pressure, and cardiac output. A 4-French, double-lumen catheter and a 5- to 8-French, triple-lumen catheter are available. The catheter is usually placed by percutaneous methods (as in the adult) except in the smallest pediatric patient, in whom a cutdown is sometimes required.

When the tip of the catheter is in a distal pulmonary artery and the balloon is inflated, the resulting pressure is generally an accurate reflection of left atrial pressure because the pulmonary veins have no valves. This pulmonary “wedge” pressure represents left ventricular filling pressure, which is used as a reflection of preload. The monitors display phasic pressures, but treatment decisions are made based on the electronically derived mean central venous pressure. A low pulmonary wedge pressure suggests that blood volume must be expanded. A high or normal pulmonary wedge pressure in the presence of continued signs of shock suggests left ventricular dysfunction.

Cardiac output is usually measured in liters per minute. When related to body surface area, the output is represented as the *cardiac index*, which is simply the cardiac output divided by the body surface area. The normalized cardiac index allows the evaluation of cardiac performance without regard to body size. The usual resting value for cardiac index is between 3.5 and 4.5 L/min/m<sup>2</sup>. The determination of cardiac output by the thermodilution technique, which is possible with a Swan-Ganz pulmonary artery catheter, is widely used and has a good correlation with other methods. Accurate cardiac output determination depends on rapid injection, accurate measurement of injectant temperature and volume, and absence of shunting. Because ventilation affects the flow into and out of the right ventricle, three injections should be made at a consistent point in the ventilatory cycle, typically at end expiration.

Doppler measurement of aortic flow velocity allows measurement of cardiac output by the following formula:

$$\text{Cardiac output (mL/min)} = \text{Mean aortic blood flow velocity (cm/sec)} \times \text{Aortic cross-sectional area (cm}^2\text{)} \times 60$$

Aortic cross-sectional area is determined by standard ultrasonographic techniques. Using this cross-sectional

measurement, pulsed Doppler aortic flow velocity is measured by a transducer placed at the suprasternal notch, in the esophagus, or in the trachea to derive cardiac output. Studies are underway to determine if cardiac output measured by this technique correlates well with thermodilution or the Fick method in critically ill pediatric patients. Previous studies have shown that cardiac output measured by intermittent Doppler measurement at the suprasternal notch was not of sufficient reliability to be employed for hemodynamic monitoring in critically ill children.<sup>51</sup>

Impedance cardiography (bioimpedance) is another noninvasive technique that measures stroke volume on a beat-by-beat basis.<sup>52</sup> Bioimpedance employs a low-level current applied to the thorax, where changes in the volume and velocity of blood flow in the thoracic aorta result in detectable changes in thoracic conductivity. Previous application of this technique in critically ill patients met with only limited success.<sup>53</sup> Late refinements in electrode configuration, algorithms, and microprocessors have produced more acceptable results. Studies in pigs demonstrated a good correlation of bioimpedance-derived cardiac output with thermodilutional cardiac output over a wide hemodynamic range.<sup>54,55</sup> These techniques have yet to be validated or proved effective in children.

Another study concluded that using right-sided heart catheters in treating critically ill adult patients resulted in an increased mortality.<sup>56</sup> However, a consensus committee report documents the continued safety and efficacy of right-sided heart catheters in the care of critically ill children.<sup>57</sup>

### Venous Oximetry

Mixed venous oxygen saturation ( $S\bar{V}O_2$ ) is an indicator of the adequacy of oxygen supply and demand in perfused tissues. Oxygen consumption is defined as the amount of oxygen consumed by the tissue as calculated by the Fick equation:

$$O_2 \text{ Consumption} = \text{Cardiac output} \times \text{Arterial} - \text{venous oxygen content difference}$$

Reflectance spectrophotometry is currently used for continuous venous oximetry. Multiple wavelengths of light are transmitted at a known intensity by means of fiberoptic bundles in a special pulmonary artery or right atrial catheter. The light is reflected by red blood cells flowing past the tip of the catheter. The wavelengths of light are chosen so that both oxyhemoglobin and deoxyhemoglobin are measured to determine the fraction of hemoglobin saturated with oxygen. The system requires either in-vitro calibration by reflecting light from a standardized target that represents a known oxygen saturation or in-vivo calibration by withdrawing blood from the pulmonary artery catheter and measuring the saturation by laboratory co-oximetry.

Mixed venous oxygen saturation values within the normal range (68%-77%) indicate a normal balance between oxygen supply and demand, provided that

vasoregulation is intact and distribution of peripheral blood flow is normal. Values greater than 77% are most commonly associated with syndromes of vasoderegulation, such as sepsis. Uncompensated changes in  $O_2$  saturation, hemoglobin level, or cardiac output lead to a decrease in  $S\bar{V}O_2$ . A sustained decrease in  $S\bar{V}O_2$  greater than 10% should lead to measuring  $SaO_2$ , hemoglobin level, and cardiac output to determine the cause of the decline.<sup>58</sup> The most common sources of error in measuring  $S\bar{V}O_2$  are calibration and catheter malposition. The most important concept in  $S\bar{V}O_2$  monitoring is the advantage of continuous monitoring, which allows early warning of a developing problem.<sup>59</sup>

Although most clinical experience has been with pulmonary artery catheters, right atrial catheters are more easily placed and may thus provide better information to detect hemodynamic deterioration earlier and permit more rapid treatment of physiologic derangements.<sup>60</sup> A study has shown that when oxygen consumption was monitored and maintained at a consistent level, the right atrial venous saturation was thought to be an excellent measure.<sup>61</sup>

## SHOCK

Shock is a state in which the cardiac output is insufficient to deliver adequate oxygen to meet metabolic demands of the tissues. Cardiovascular function is determined by preload, cardiac contractility, heart rate, and afterload. Shock may be classified broadly as hypovolemic, cardiogenic, or septic.

### Hypovolemic Shock

Preload is a function of the volume of blood presented to the ventricles. Because of the impracticality of measuring volume, preload is commonly monitored by atrial pressure measurements. In most clinical situations, right atrial pressure or central venous pressure is the index of cardiac preload. In situations in which left ventricular or right ventricular compliance is abnormal, or in certain forms of congenital heart disease, right atrial pressure may not correlate well with left atrial pressure. In infants and children, most shock situations are the result of reduced preload secondary to fluid loss, such as from diarrhea, vomiting, or trauma.

Virtually all forms of pediatric shock have significant intravascular and functional interstitial fluid deficits. Hypovolemia results in decreased venous return to the heart. Preload is reduced, cardiac output falls, and the overall result is a decrease in tissue perfusion. Invasive infection and hypovolemia are the most common causes of shock in both children and adults. The first step in treating all forms of shock is to correct existing fluid deficits. Inotropic drugs should not be initiated until adequate intravascular fluid volume has been established. The speed and volume of the infusate are determined by the patient's responses, particularly changes in blood pressure, pulse rate, urine output, and central venous pressure. Shock resulting from

acute hemorrhage is initially treated with the administration of 10 to 20 mL/kg of Ringer's lactate solution or normal saline as fluid boluses. If the patient does not respond, a second bolus of crystalloid is given. Type-specific or crossmatched blood is given as needed.

The choice of resuscitation fluid in shock that results from sepsis or from loss of extracellular fluid (from conditions such as peritonitis, intestinal obstruction, and pancreatitis) is less clear. Our initial resuscitation fluids include Ringer's lactate or normal saline in older infants and children and half-strength Ringer's or 0.5 normal saline in the newborn. Despite our reluctance to use colloid-containing solutions for shock, we make an exception in the desperately ill newborn or premature infant with septicemia. To correct the reduced serum factors, for example in those children with a coagulopathy, we use fresh frozen plasma or specific factors as the resuscitation fluid.

The rate and volume of resuscitation fluid given is adjusted based on data obtained from monitoring the effects of the initial resuscitation. After the initial bolus is given, the adequacy of the replacement is assessed by monitoring urine output, urine concentration, plasma acidosis, oxygenation, arterial pressure, central venous pressure, and pulmonary wedge pressure, if indicated. When cardiac failure is present, continued vigorous delivery of large volumes of fluid may cause a further increase in preload to the failing myocardium and accelerate the downhill course. In this setting, as outlined previously, inotropic agents are given while monitoring cardiac and pulmonary function.

## Cardiogenic Shock

Myocardial contractility is usually expressed as the ejection fraction, which is the proportion of ventricular volume that is pumped. Myocardial contractility is reduced with hypoxemia and acidosis. Inotropic drugs increase cardiac contractility but have their best effect when hypoxemia and acidosis are corrected.

Adrenergic receptors are important in regulating calcium flux, which, in turn, is important in controlling myocardial contractility. The  $\alpha$ - and  $\beta$ -adrenergic receptors are proteins present in the sarcolemma of myocardial and vascular smooth muscle cells.  $\beta_1$  receptors are predominantly in the heart and, when stimulated, result in increased contractility of myocardium.  $\beta_2$  receptors are predominantly in respiratory and vascular smooth muscle. When stimulated, these receptors result in bronchodilation and vasodilation.  $\alpha_1$ -Adrenergic receptors are located on vascular smooth muscle and result in vascular constriction when stimulated.  $\alpha_2$ -Adrenergic receptors are found mainly on prejunctional sympathetic nerve terminals. The concept of dopaminergic receptors has also been used to account for the cardiovascular effects of dopamine not mediated through  $\alpha$  or  $\beta$  receptors. Activation of dopaminergic receptors results in decreased renal and mesenteric vascular resistance and, usually, increased blood flow. The most commonly used inotropic drugs are listed in Table 1-7.

## Epinephrine

Epinephrine is an endogenous catecholamine with  $\alpha$ - and  $\beta$ -adrenergic effects. At low doses, the  $\beta$ -adrenergic effect predominates. These effects include an increase in heart rate, cardiac contractility, cardiac output, and bronchiolar dilation. Blood pressure rises, in part, not only due to increased cardiac output but also due to increased peripheral vascular resistance, which is noted with higher doses at which  $\alpha$ -adrenergic effects become predominant. Renal blood flow may increase slightly, remain unchanged, or decrease depending on the balance between greater cardiac output and the changes in peripheral vascular resistance, which lead to regional redistribution of blood flow. Cardiac arrhythmias can be seen with epinephrine, especially with higher doses. Dosages for treating compromised cardiovascular function range from 0.05 to 1.0  $\mu\text{g}/\text{kg}/\text{min}$ . Excessive doses of epinephrine can cause worsening cardiac ischemia and dysfunction from increased myocardial oxygen demand.

## Isoproterenol

Isoproterenol is a  $\beta$ -adrenergic agonist. It increases cardiac contractility and heart rate, with little change in systemic vascular resistance. The peripheral vascular  $\beta$ -adrenergic effect and lack of a peripheral vascular  $\alpha$ -adrenergic effect may allow reduction of left ventricular afterload. Isoproterenol's intense chronotropic effect produces tachycardia, which can limit its usefulness. Isoproterenol is administered intravenously at a dosage of 0.1 to 0.3  $\mu\text{g}/\text{kg}/\text{min}$ .

## Dopamine

Dopamine is an endogenous catecholamine with  $\beta$ -adrenergic,  $\alpha$ -adrenergic, and dopaminergic effects. It is both a direct and an indirect  $\beta$ -adrenergic agonist. Dopamine elicits positive inotropic and chronotropic responses by direct interaction with the  $\beta$  receptor (direct effect) and by stimulating the release of norepinephrine from the sympathetic nerve endings, which interacts with the  $\beta$  receptor (indirect effect). At low dosages ( $<3 \mu\text{g}/\text{kg}/\text{min}$ ), the dopaminergic effect of the drug predominates, resulting in reduced renal and mesenteric vascular resistance and improved blood flow to these organs. The  $\beta$ -adrenergic effects become more prominent at intermediate dosages (3 to 10  $\mu\text{g}/\text{kg}/\text{min}$ ), producing a higher cardiac output. At relatively high dosages ( $>15$  to 20  $\mu\text{g}/\text{kg}/\text{min}$ ), the  $\alpha$ -adrenergic effects become prominent with peripheral vasoconstriction.

Experience with the use of dopamine in pediatric patients suggests that it is effective in increasing blood pressure in neonates, infants, and children. The precise dosages for these desired hemodynamic effects are not known. The effects of low dosages of dopamine on blood pressure, heart rate, and renal function were studied in 18 hypotensive, preterm infants.<sup>62</sup> The blood pressure and diuretic effects were observed at 2, 4, and 8  $\mu\text{g}/\text{kg}/\text{min}$ . Elevations in heart rate were seen only

**Table 1-7** Vasoactive Medications Commonly Used in the Newborn

Vasoactive Agent	Principal Modes of Action	Major Hemodynamic Effects	Administration and Dosage	Indications
Epinephrine	$\alpha$ and $\beta$ agonist	Increases heart rate and myocardial contractility by activating $\beta_1$ receptors	0.1 mL/kg of 1:10,000 solution given IV intracardial, or endotracheal 0.05-1.0 $\mu\text{g}/\text{kg}/\text{min}$ IV	Cardiac resuscitation; short-term use when severe heart failure resistant to other drugs
Dopamine, low dose	Stimulates dopamine receptors	Decrease in vascular resistance in splanchnic, renal, and cerebral vessels	<2 $\mu\text{g}/\text{kg}/\text{min}$ IV	Useful in managing cardiogenic or hypovolemic shock or after cardiac surgery
Dopamine, intermediate dose	Stimulates $\beta_1$ receptors; myocardial	Inotropic response	2-10 $\mu\text{g}/\text{kg}/\text{min}$ IV	Blood pressure unresponsive to low dose
Dopamine, high dose	Stimulates $\alpha$ receptors	Increased peripheral and renal vascular resistance	>10 $\mu\text{g}/\text{kg}/\text{min}$ IV	Septic shock with low systemic vascular resistance
Dobutamine	Synthetic $\beta_1$ agonist in low doses; $\alpha$ and $\beta_2$ effects in higher doses	Increased cardiac output, increased arterial pressure; less increase in heart rate than with dopamine	1-15 $\mu\text{g}/\text{kg}/\text{min}$ IV	Useful alternative to dopamine if increase in heart rate undesirable
Isoproterenol	$\beta_1$ and $\beta_2$ agonist	Increased cardiac output by positive inotropic and chronotropic action and increase in venous return; systemic vascular resistance generally reduced; pulmonary vascular resistance generally reduced	0.1-0.3 $\mu\text{g}/\text{kg}/\text{min}$ IV	Useful in low-output situations, especially when heart rate is slow
Sodium nitroprusside	Direct-acting vasodilator that relaxes arteriolar and venous smooth muscle	Afterload reduction; reduced arterial pressure	1-10 $\mu\text{g}/\text{kg}/\text{min}$ IV (for up to 10 min); 0.5-2.0 $\mu\text{g}/\text{kg}/\text{min}$ IV	Hypertensive crisis; vasodilator therapy
Milrinone	Phosphodiesterase inhibitor relaxes arteriolar and venous smooth muscle via calcium/cyclic adenosine monophosphate	Increased cardiac output, slight decreased blood pressure, increased oxygen delivery	75 $\mu\text{g}/\text{kg}$ bolus IV, then 0.75-1.0 $\mu\text{g}/\text{kg}/\text{min}$ IV	Useful as an alternative or in addition to dopamine (may act synergistically) if increased heart rate undesirable

Adapted from Lees MH, King DH: Cardiogenic shock in the neonate. *Pediatr Rev* 9:263, 1988.

at 8  $\mu\text{g}/\text{kg}/\text{min}$ . Further work is needed to better characterize the pharmacokinetics and pharmacodynamics of dopamine in children, especially in newborns.

Recent clinical evidence has demonstrated some beneficial effects from orally administered levodopa for treating cardiac failure in pediatric patients. Because enteral medications for heart failure are currently limited to digoxin and diuretics, using levodopa may improve our ability to treat heart failure without using parenteral inotropes.<sup>63</sup>

### Dobutamine

Dobutamine, a synthetic catecholamine, has predominantly  $\beta$ -adrenergic effects with minimal  $\alpha$ -adrenergic effects. The hemodynamic effect of dobutamine in infants and children with shock has been studied.<sup>64</sup> Dobutamine infusion significantly increased cardiac index, stroke index, and pulmonary capillary wedge pressure, and it decreased systemic vascular resistance.

The drug appears more efficacious in treating cardiogenic shock than septic shock. The advantage of dobutamine over isoproterenol is its lesser chronotropic effect and its tendency to maintain systemic pressure. The advantage over dopamine is dobutamine's lesser peripheral vasoconstrictor effect. The usual range of dosages for dobutamine is 2 to 15  $\mu\text{g}/\text{kg}/\text{min}$ . One study found dobutamine significantly increased systemic blood flow in preterm infants when compared with dopamine. However, it did not demonstrate differences in outcomes.<sup>65,66</sup> The combination of dopamine and dobutamine has been increasingly used. However, little information regarding their combined advantages or effectiveness in pediatric patients has been published.

### Milrinone

Milrinone, a phosphodiesterase inhibitor, is a potent positive inotrope and vasodilator that has been shown to improve cardiac function in infants and children.<sup>67-69</sup>

The proposed action is due, in part, to an increase in intracellular cyclic adenosine monophosphate and calcium transport secondary to inhibition of cardiac phosphodiesterase. This effect is independent of  $\beta$ -agonist stimulation and, in fact, may act synergistically with a  $\beta$  agonist to improve cardiac performance. Milrinone increases cardiac index and oxygen delivery without affecting heart rate, blood pressure, or pulmonary wedge pressure. Milrinone is administered as a 75- $\mu$ g/kg bolus followed by infusion of 0.75 to 1.0  $\mu$ g/kg/min.

## Septic Shock

Afterload represents the force against which the left ventricle must contract to eject blood. It is related to systemic vascular resistance and myocardial wall stress. Systemic vascular resistance is defined as the systemic mean arterial blood pressure minus right arterial pressure divided by cardiac output. Cardiac contractility is affected by systemic vascular resistance and afterload. In general, increases in afterload reduce cardiac contractility and decreases in afterload increase cardiac contractility.

Septic shock is a distributive form of shock that differs from other forms of shock. Cardiogenic and hypovolemic shock lead to increased systemic vascular resistance and decreased cardiac output. Septic shock results from a severe decrease in systemic vascular resistance and a generalized maldistribution of blood and leads to a hyperdynamic state.<sup>70</sup> The pathophysiology of septic shock begins with a nidus of infection. Organisms may invade the bloodstream, or they may proliferate at the infected site and release various mediators into the bloodstream. Evidence now supports the finding that substances produced by the microorganism, such as lipopolysaccharide, endotoxin, exotoxin, lipid moieties, and other products, can induce septic shock by stimulating host cells to release cytokines, leukotrienes, and endorphins.

Endotoxin is a lipopolysaccharide found in the outer membrane of gram-negative bacteria. Functionally, the molecule is divided into three parts: (1) the highly variable O-specific polysaccharide side chain (conveys serotypic specificity to bacteria and can activate the alternate pathway of complement); (2) the R-core region (less variable among different gram-negative bacteria; antibodies to this region could be cross protective); and (3) lipid-A (responsible for most of the toxicity of endotoxin). Endotoxin stimulates tumor necrosis factor (TNF) and can directly activate the classic complement pathway in the absence of antibody. Endotoxin has been implicated as an important factor in the pathogenesis of human septic shock and gram-negative sepsis.<sup>71</sup> Therapy has focused on developing antibodies to endotoxin to treat septic shock. Antibodies to endotoxin have been used in clinical trials of sepsis with variable results.<sup>72-74</sup>

Cytokines, especially TNF, play a dominant role in the host's response. Endotoxin and exotoxin both induce TNF release in vivo and produce many other toxic effects via this endogenous mediator.<sup>75-77</sup> TNF is released primarily from monocytes and macrophages;

however, it is also released from natural killer cells, mast cells, and some activated T lymphocytes. Other stimuli for its release include viruses, fungi, parasites, and interleukin-1 (IL-1). In sepsis, the effects of TNF release may include cardiac dysfunction, disseminated intravascular coagulation, and cardiovascular collapse. TNF release also causes the release of granulocyte-macrophage colony-stimulating factor (GM-CSF), interferon alfa, and IL-1. Antibodies against TNF protect animals from exotoxin and bacterial challenge.<sup>78,79</sup>

Previously known as the endogenous pyrogen, IL-1 is produced primarily by macrophages and monocytes and plays a central role in stimulating a variety of host responses, including fever production, lymphocyte activation, and endothelial cell stimulation to produce procoagulant activity and to increase adhesiveness. IL-1 also causes the induction of the inhibitor of tissue plasminogen activator and the production of GM-CSF. These effects are balanced by the release of platelet-activating factor and arachidonic metabolites.

IL-2, also known as T-cell growth factor, is produced by activated T lymphocytes and strengthens the immune response by stimulating cell proliferation. Its clinically apparent side effects include capillary leak syndrome, tachycardia, hypotension, increased cardiac index, decreased systemic vascular resistance, and decreased left ventricular ejection fraction.<sup>80,81</sup>

Studies done on dogs have suggested that, in immature animals, septic shock is more lethal and has different mechanisms of tissue injury.<sup>82</sup> These include more dramatic aberrations in blood pressure (more constant decline), heart rate (progressive, persistent tachycardia), blood sugar level (severe, progressive hypoglycemia), acid-base status (severe acidosis), and oxygenation (severe hypoxemia). These changes are significantly different from those seen in the adult animals that also experience improved survival of almost 600% (18.5 vs. 3.1 hours) compared with the premature animal.

The neonate's host defense can usually respond successfully to ordinary microbial challenge. However, defense against major challenges appears limited and provides an explanation for the high mortality rate with major neonatal sepsis. As in adults, the immune system consists of four major components: cell-mediated immunity (T cells), complement system, antibody-mediated immunity (B cells), and macrophage-neutrophil phagocytic system. The two most important deficits in newborn host defenses that seem to increase the risk of bacterial sepsis are the quantitative and qualitative changes in the phagocytic system and the defects in antibody-mediated immunity.

The proliferative rate of the granulocyte-macrophage precursor has been reported to be at near-maximal capacity in the neonate. However, the neutrophil storage pool is markedly reduced in the newborn compared with the adult. After bacterial challenge, newborns fail to increase stem cell proliferation and soon deplete their already reduced neutrophil storage pool. Numerous in-vitro abnormalities have been demonstrated in neonatal polymorphonuclear neutrophils, especially in times of stress or infection.<sup>83</sup> These abnormalities include

decreased deformability, chemotaxis, phagocytosis, C3b receptor expression, adherence, bacterial killing, and depressed oxidative metabolism. Chemotaxis is impaired in neonatal neutrophils in response to various bacterial organisms and antigen-antibody complexes.<sup>84</sup> Granulocytes are activated by their interaction with endothelial cells followed by entry into secondary lymphoid tissues via the endothelial venules. Initial adhesion of granulocytes is dependent on their expression of L-selectin, a cell adhesion molecule expressed on the granulocyte cell surface. Evaluation of cord blood has demonstrated a significantly lower expression of L-selectin on granulocyte surfaces when compared with older newborn (5 days old) and adult samples, indicating a depressed level of interaction with vascular endothelial cells at the initial stage of adhesion.<sup>85</sup> Although phagocytosis has additionally been demonstrated to be abnormal in neonatal phagocytes, it appears that this phenomenon is most likely secondary to decreased opsonic activity rather than an intrinsic defect of the neonatal polymorphonuclear neutrophils.<sup>86,87</sup> Currently, there is inconclusive evidence to support or refute the routine use of granulocyte transfusions in the prevention or treatment of sepsis in the neonate.<sup>88</sup>

Preterm and term newborns have poor responses to various antigenic stimuli, reduced gamma globulin levels at birth, and reduced maternal immunoglobulin supply from placental transport. Almost 33% of infants with a birth weight less than 1500 g develop substantial hypogammaglobulinemia.<sup>89</sup> IgA and IgM are also low due to the inability of these two immunoglobulins to cross the placenta. Neonates, therefore, are usually more susceptible to pyogenic bacterial infections because most of the antibodies that opsonize pyogenic bacterial capsular antigens are IgG and IgM. In addition, neonates do not produce type-specific antibodies, which appears to be secondary to a defect in the differentiation of B lymphocytes into immunoglobulin-secreting plasma cells and T lymphocyte-mediated facilitation of antibody synthesis. In the term infant, total hemolytic complement activity, which measures the classic complement pathway, constitutes approximately 50% of adult activity.<sup>90</sup> Owing to lower levels of factor B, the activity of the alternative complement pathway is also decreased in the neonate.<sup>91</sup> Fibronectin, a plasma protein that promotes reticuloendothelial clearance of invading microorganisms, is deficient in neonatal cord plasma.<sup>92</sup>

Using intravenous immunoglobulins (IVIGs) for the prophylaxis and treatment of sepsis in the newborn, especially the preterm, low birth weight infant, has been studied in numerous trials with varied outcomes. In one study, a group of infants weighing 1500 g was treated with 500 mg/kg of IVIG each week for 4 weeks and compared with infants who were not treated with IVIG.<sup>93</sup> The mortality rate was 16% in the IVIG-treated group compared with 32% in the untreated group. Another recent analysis examined the role of IVIG to prevent and treat neonatal sepsis.<sup>94</sup> A significant benefit was noted from the prophylactic use of IVIG to prevent sepsis in low birth weight premature infants. However, using IVIG to treat neonatal sepsis produced a greater than 6% decrease in the mortality rate.

A review of 19 randomized controlled trials found a 3% decrease in the incidence of neonatal sepsis in preterm infants without a significant difference in all-cause and infection-related mortality when prophylactic IVIG was administered. Based on the marginal reduction of neonatal sepsis without a reduction in mortality, routine use of prophylactic IVIG cannot be recommended.<sup>95</sup>

Colony-stimulating factors are a family of glycoproteins that stimulate proliferation and differentiation of hematopoietic cells of various lineages. GM-CSF and granulocyte colony-stimulating factor (G-CSF) have similar physiologic actions. Both stimulate the proliferation of bone marrow myeloid progenitor cells, induce the release of bone marrow neutrophil storage pools, and enhance mature neutrophil effect or function.<sup>94,96</sup> Preliminary studies of GM-CSF in neonatal animals demonstrate enhancement of neutrophil oxidative metabolism, as well as priming of neonatal neutrophils for enhanced chemotaxis and bacterial killing. Both GM-CSF and G-CSF induce peripheral neutrophilia within 2 to 6 hours of intraperitoneal administration. This enhanced affinity for neutrophils returns to normal baseline level by 24 hours.<sup>97</sup> Recent studies confirm the efficacy and safety of G-CSF therapy for neonatal sepsis and neutropenia.<sup>98</sup> Other studies have demonstrated no long-term adverse hematologic, immunologic, or developmental effects from G-CSF therapy in the septic neonate. Prolonged prophylactic treatment in the very low birth weight neonate with recombinant GM-CSF has been shown to be well tolerated and have a significant decrease in the rate of nosocomial infections.<sup>99,100</sup> Confirmatory studies are currently being performed. The current recommended daily pediatric dose is 5  $\mu\text{g}/\text{kg}/\text{dose}$  given subcutaneously.

Unique to the newborn in septic shock is the persistence of fetal circulation and resultant pulmonary hypertension.<sup>101</sup> In fact, the rapid administration of fluid can further exacerbate this issue by causing left-to-right shunting through a patent ductus arteriosus and subsequent congestive heart failure from ventricular overload. Infants in septic shock with a new heart murmur should receive indomethacin and undergo a cardiac echocardiogram to evaluate the heart. A single institution randomized trial demonstrated an improved outcome from ventricular overload with pentoxifylline in extremely premature infants.<sup>102</sup>

The critical care of a patient in septic shock can be challenging. Septic shock has a distinctive clinical presentation and is characterized by an early compensated stage where one can see a decreased systemic vascular resistance, an increase in cardiac output, tachycardia, warm extremities, and an adequate urine output. Later in the clinical presentation, septic shock is characterized by an uncompensated phase in which the patient develops a decrease in intravascular volume, myocardial depression, high vascular resistance, and a decreasing cardiac output.<sup>103</sup> Care of these patients is based on the principles of source control, antibiotics, and supportive care. Patients with severe septic shock often do not respond to conventional forms of volume loading and cardiovascular supportive

medications. Recently, the administration of arginine vasopressin has been shown to decrease mortality in adult patients with recalcitrant septic shock.<sup>104-106</sup> Vasopressin, also known as antidiuretic hormone, is made in the posterior pituitary and plays a primary role in water regulation by the kidneys. The U.S. Food and Drug Administration (FDA)-approved uses of vasopressin and its derivatives are for diabetes. Other non-FDA-approved uses for vasopressin include gastrointestinal hemorrhage and in bleeding disorders such as type I von Willebrand's disease.<sup>106</sup> In septic shock, vasopressin has profound effects on increasing

blood pressure in intravascular depleted states. The mechanisms behind this observation appear to be mediated by the ability of vasopressin to potentiate the catecholamine effects on blood vessels. Several observational and nonrandomized prospective studies have demonstrated the efficacy of terlipressin, an arginine vasopressin analog, to be effective as rescue therapy in catecholamine-resistant shock in children and neonates.<sup>107,108</sup> A single randomized, double-blinded, placebo-controlled study has been conducted that demonstrated a beneficial effect of vasopressin in recalcitrant septic shock.<sup>109</sup>

# NUTRITIONAL SUPPORT OF THE PEDIATRIC PATIENT

Nilesh Mehta, MD, DCH • Tom Jaksic, MD, PhD

Despite advances in the field of nutritional support, the prevalence of malnutrition among hospitalized patients, especially those with a protracted clinical course, has remained largely unchanged over the past 2 decades.<sup>1</sup> The provision of optimal nutritional therapy requires a careful assessment of energy needs and the provision of macronutrients and micronutrients via the most suitable feeding route. The profound and stereotypic metabolic response to injury places unique demands on the hospitalized child. Standard equations available for estimating energy needs have proved to be unreliable in this population.<sup>2,3</sup> In addition, children with critical illness have marked net protein catabolism and often lack adequate nutritional support.<sup>4</sup> Ultimately, an individualized nutritional regimen should be tailored for each child and reviewed regularly during the course of illness. An understanding of the metabolic events that accompany illness and surgery in the child is the first step in implementing appropriate nutritional support.

## THE METABOLIC RESPONSE TO STRESS

The metabolic response to illness due to stressors such as trauma, surgery, or inflammation has been well described. Cuthbertson was the first investigator to realize the primary role that whole-body protein catabolism plays in the systemic response to injury.<sup>5</sup> Based on his work, the metabolic stress response has been conceptually divided into two phases. The initial brief ebb phase is characterized by decreased enzymatic activity, reduced oxygen consumption, low cardiac output, and a core temperature that may be subnormal. This is followed by the hypermetabolic flow phase, characterized by increased cardiac output, oxygen consumption, and glucose production. During this phase, fat and protein mobilization is manifested by increased urinary nitrogen excretion and weight loss. This catabolic phase is mediated by a surge in cytokines and the characteristic endocrine response to

trauma or surgery that results in an increased availability of substrates essential for healing and enhanced glucose production.

Neonates and children share similar qualitative metabolic responses to illness as adults, albeit with significant quantitative differences. The metabolic stress response is beneficial in the short term, but the consequences of sustained catabolism are significant because the child has limited tissue stores and substantial nutrient requirements for growth. Thus, the prompt institution of nutritional support is a priority in sick neonates and children. The goal of nutrition in this setting is to augment the short-term benefits of the pediatric metabolic response to injury while minimizing any long-term consequences. In general, the metabolic stress response is characterized by an increase in net muscle protein degradation and enhanced movement of free amino acids through the circulation (Fig. 2-1). These amino acids serve as the building blocks for the rapid synthesis of proteins that act as mediators for the inflammatory response and structural components for tissue repair. Remaining amino acids not used in this way are channeled through the liver where their carbon skeletons are utilized to create glucose through gluconeogenesis. The provision of additional dietary protein may slow the rate of net protein loss but does not eliminate the overall negative protein balance associated with injury.<sup>6</sup>

Carbohydrate and lipid turnover is also increased severalfold during the pediatric metabolic response. Although these metabolic alterations would be expected to increase overall energy requirements, data show that such an increase is quantitatively variable, modest, and evanescent. Overall, the energy needs of the critically ill or injured child are governed by the severity and persistence of the underlying illness or injury. Accurate assessment of energy requirements in individual patients allows optimal caloric supplementation and avoids the deleterious effects of both underfeeding and overfeeding. Children with critical illness demonstrate a unique hormonal and cytokine profile characterized by an elevation in serum levels

**Figure 2-1.** The metabolic changes associated with the pediatric stress response to critical illness and injury are illustrated. In general, net protein catabolism predominates and amino acids are transported from muscle stores to the liver, where they are converted to inflammatory proteins and glucose through the process of gluconeogenesis.

of insulin, the catabolic hormones (glucagon, cortisol, catecholamines), and specific cytokines known to interact with the inflammatory process.<sup>7</sup> Novel ways to manipulate these hormonal and cytokine alterations with an aim to minimize the deleterious consequences induced by the stress response are the focus of significant research.

### BODY COMPOSITION AND NUTRIENT RESERVES

The body composition of the young child contrasts to that of the adult in several ways that significantly affect nutritional requirements. Table 2-1 lists the macronutrient stores of the neonate, child, and adult as a percentage of total body weight.<sup>8,9</sup> Carbohydrate stores are limited in all age groups and provide only a short-term supply of glucose when utilized. Despite this fact, neonates have a high demand for glucose and have shown elevated rates of glucose turnover when compared with those of the adult.<sup>10</sup> This is thought to be related to the neonate's increased brain-to-body mass ratio because glucose is the primary energy source for the central nervous system. Neonatal glycogen stores are even more limited in the early postpartum period, especially in the preterm infant.<sup>11</sup> Short periods of fasting can predispose the newborn to hypoglycemia. Thus, when infants are burdened with illness or injury, they must rapidly turn to the breakdown of

protein stores to generate glucose through the process of gluconeogenesis. Lipid reserves are low in the neonate, gradually increasing with age. Premature infants have the lowest proportion of lipid stores because the majority of polyunsaturated fatty acids accumulate in the third trimester.<sup>12</sup> This renders lipid less useful as a potential fuel source in the young child.<sup>13</sup>

The most dramatic difference between adult and pediatric patients is in the relative quantity of stored protein. The protein reserve of the adult is nearly twofold that of the neonate. Thus, infants cannot afford to lose significant amounts of protein during the course of protracted illness or injury. An important feature of the metabolic stress response, unlike in starvation, is that the provision of dietary glucose does not halt gluconeogenesis. Consequently, the catabolism of muscle protein to produce glucose continues unabated.<sup>14</sup> Neonates and children also share much higher baseline energy requirements. Studies have demonstrated that the resting energy expenditure for neonates is two to three times that of adults when standardized for body weight.<sup>13,15,16</sup> Clearly, the child's need for rapid growth and development is a large component of this increase in energy requirement. Moreover, the relatively large body surface area of the young child may increase heat loss and further contributes to elevations in energy expenditure.

The basic requirements for protein and energy in the healthy neonate, child, and adult, based on recent recommendations by the National Academy of Sciences, are listed in Table 2-2.<sup>17</sup> As illustrated, the recommended protein provision for the neonate is almost three times that of the adult. In premature infants, a minimum protein allotment of 2.8 g/kg/day is required to maintain in-utero growth rates.<sup>18</sup> The increased metabolic demand and limited nutrient reserves of the infant mandates early nutritional support in times of traumatic injury and critical illness in order to avoid untoward nutritional consequences.

Accurate assessment of body composition is necessary for planning nutritional intake, monitoring dynamic changes in the body compartments (e.g., the

**Table 2-1** The Body Composition of Neonates, Children, and Adults as a Percentage of Total Body Weight

Age	Protein (%)	Fat (%)	Carbohydrate (%)
Neonates	11	14	0.4
Children (age 10 yr)	15	17	0.4
Adults	18	19	0.4

**Table 2-2** Estimated Requirements for Energy and Protein in Healthy Humans of Different Age Groups

Age	Protein (g/kg/day)	Energy (kcal/kg/day)
Neonates	2.2	120
Children (age 10 yr)	1.0	70
Adults	0.8	35

loss of lean body mass), and assessing the adequacy of nutritional supportive regimens during critical illness. Ongoing loss of lean body mass is an indicator of inadequate dietary supplementation and may have clinical implications in the hospitalized child. However, current methods of body composition analysis (e.g., anthropometry, weight, and biochemical parameters) are either impractical for clinical use or inaccurate in a subgroup of hospitalized children with critical illness. One of the principal problems in critically ill children is the presence of capillary leak, which is manifested as edema and large fluid shifts. These make anthropometric measurements invalid, and other bedside techniques have not been validated.

## ENERGY EXPENDITURE DURING ILLNESS

For children with illness or undergoing operative intervention, knowledge of energy requirements is important for the design of appropriate nutritional strategies. Dietary regimens that both underestimate and overestimate energy needs are associated with injurious consequences. Owing to the high individual variability in energy expenditure, particularly in the most critically ill patients, the actual measurement of resting energy expenditure (REE) is recommended.

The components of total energy expenditure (TEE) for a child, in order of magnitude are (1) REE, (2) energy expended during physical activity, and (3) diet-induced thermogenesis (the heat generated by the consumption of food products). The sum of these components determines the energy requirement for an individual. In general, REE rates decline with age from infancy to young adulthood, at which time the rate becomes stable. In children with critical illness, the remaining factors in the determination of TEE are of reduced significance, because physical activity is low and diet-induced thermogenesis may not be significant.

REE can be measured using direct or indirect methods. The direct calorimetric method measures the heat released by a subject at rest and is based on the principle that all energy is eventually converted to heat. In practice, the patient is placed in a thermally isolated chamber and the heat dissipated is measured for a given period of time.<sup>19</sup> This method is the true gold standard for measured energy expenditure. Direct calorimetry is not practical for most hospitalized children, and REE is often estimated using standard equations. Unfortunately, REE estimates using standardized World Health

Organization (WHO) predictive equations are unreliable, particularly in underweight subjects.<sup>19-21</sup>

REE estimation is difficult in critically ill or postoperative children. Their energy requirements show individual variation and are dependent on severity of injury. For instance, an infant with respiratory distress on pressure support is likely to have a high energy requirement owing to increased work of breathing. The same patient, when started on mechanical ventilation with muscle relaxants, is unlikely to have sustained high energy requirements. Infants with congenital diaphragmatic hernia on extracorporeal membrane oxygenation (ECMO) support have been shown to have energy expenditures of approximately 90 kcal/kg/day. After extubation, the same patients may have energy requirements as high as 140 kcal/kg/day. Although stress factors ranging from 1.0 to 2.7 have been applied to correct for these variations, calculated standardized energy expenditure equations have not been satisfactorily validated in critically ill children.<sup>22-25</sup>

Indirect calorimetry measures  $\text{VO}_2$  (the volume of oxygen consumed) and  $\text{VCO}_2$  (the volume of  $\text{CO}_2$  produced) and uses a correlation factor based on urinary nitrogen excretion to calculate the overall rate of energy production.<sup>26</sup> The measurement of energy needs is “indirect” because it does not use direct temperature changes to determine energy needs. Indirect calorimetry, usually with the aid of a “metabolic cart,” provides a measurement of the overall respiratory quotient (RQ), defined as the ratio of  $\text{CO}_2$  produced to  $\text{O}_2$  consumed ( $\text{VCO}_2/\text{VO}_2$ ), for a given patient. Oxidation of carbohydrate yields an RQ of 1.0, whereas fatty acid oxidation gives an RQ of 0.7. However, the role of the RQ as a marker of substrate use and as an indicator of underfeeding or overfeeding is limited. The body’s ability to metabolize substrate may be impaired during illness, making assumptions of RQ values and substrate oxidation invalid. Although RQ is not a sensitive marker for the adequacy of feeding in individual cases, RQ values greater than 1.0 are generally associated with lipogenesis secondary to overfeeding.<sup>27,28</sup> A recent study has suggested the utility of extremes of RQ in monitoring feeding adequacy.<sup>29</sup> An RQ higher than 0.85 reliably indicates the absence of underfeeding, and an RQ higher than 1.0 reliably indicates the presence of overfeeding. However, numerous factors, related and unrelated to feeding, can alter the value of a measured RQ in critically ill patients. Some of these factors include hyperventilation, acidosis effects of cardiotoxic agents and neuromuscular blocking agents, and an individual response to a given substrate load, injury, or disease.<sup>30</sup> Furthermore, in the setting of wide diurnal and day-to-day variability of REE in critically ill individuals, the extrapolation of short-term calorimetric REE measurements to 24-hour REE may introduce errors. The use of steady-state measurements may decrease these errors. *Steady state* is defined by change in  $\text{VO}_2$  and  $\text{VCO}_2$  of less than 10% over a period of 5 consecutive minutes. The values for the mean REE from this steady-state period may be used as an accurate representation of the 24-hour TEE in patients with low levels of physical activity.<sup>31</sup> In a patient who

fails to achieve steady state and is metabolically unstable, more prolonged testing is required (minimum of 60 minutes), and 24-hour indirect calorimetry should be considered. With the advent of newer technology, the application of indirect calorimetry at the bedside for continuous monitoring shows promise.

Indirect calorimetry is not accurate in the setting of air leaks around the endotracheal tube, the ventilator circuit, or through a chest tube, or in patients on ECMO support. High, inspired oxygen fraction ( $\text{FiO}_2 > 0.6$ ) will also affect indirect calorimetry. Indirect calorimetry is difficult to use in infants on ECMO because a large proportion of the patient's oxygenation and ventilation is performed through the membrane oxygenator. The use of indirect calorimetry for assessment and monitoring of nutrition intake requires attention to its limitations as well as expertise in the interpretation. Nonetheless, its application in children at high risk for underfeeding and overfeeding appears to be warranted.<sup>32,33</sup>

Nonradioactive stable isotope techniques have been used to measure REE in the pediatric patient. Stable isotope technology has been available for many years and was first applied for energy expenditure measurement in humans in 1982.<sup>34,35</sup> Both  $^{13}\text{C}$ -labeled bicarbonate and doubly labeled water ( $^2\text{H}_2^{18}\text{O}$ ) have been used to measure TEE in pediatric surgical patients<sup>32,35</sup> and have been shown to correlate well with indirect calorimetry.<sup>36</sup> The  $^{13}\text{C}$ -labeled bicarbonate method allows the calculation of REE solely on the basis of infusion rate and the ratio of labeled to unlabeled  $\text{CO}_2$  in expired breath samples.<sup>36</sup> Orally administered stable isotopes of water ( $^2\text{H}_2\text{O}$  and  $\text{H}_2^{18}\text{O}$ ) mix with the body water, and the  $^{18}\text{O}$  is lost from the body as both water and  $\text{CO}_2$ , while the  $^2\text{H}$  is lost from the body only as water. The difference in the rates of loss of the isotopes  $^{18}\text{O}$  and  $^2\text{H}$  from the body reflects the rate of  $\text{CO}_2$  production, which can be used to calculate the TEE.<sup>37,38</sup> However, the doubly labeled water method has its limitations in children with active capillary leak, decreased urine output, fluid overload, and diuretic use.<sup>37</sup>

In general, any increase in energy expenditure during illness or after surgery is variable. Recent studies suggest that the increase is far less than originally hypothesized. In children with severe burns, the initial REE during the flow phase of injury is increased by 50% but then returns to normal during convalescence.<sup>39</sup> In neonates with bronchopulmonary dysplasia in which the illness increases the patient's work of breathing, a 25% elevation in energy requirement is evident.<sup>40</sup> Newborns undergoing major surgery have only a transient 20% increase in energy expenditure that returns to baseline values within 12 hours postoperatively, provided that no major complications develop.<sup>41,42</sup> Stable, extubated neonates 5 days after surgery have been shown to have REE comparable to normal infants.<sup>43</sup> Effective anesthetic and analgesic management may play a significant role in muting the stress response of the neonate. Studies have demonstrated no discernable increase in REE in neonates undergoing patent ductus arteriosus ligation who received intraoperative fentanyl anesthesia and postoperative

intravenous analgesic regimens.<sup>42</sup> A retrospective stratification of surgical infants into low- and high-stress cohorts based on the severity of underlying illness found that high-stress infants undergo moderate short-term elevations in energy expenditure after surgical intervention.<sup>44</sup> Low-stress infants do not manifest any increase in energy expenditures during the course of illness. Finally, by using stable isotopic methods, it has been found that the mean energy expenditures of critically ill neonates on ECMO are nearly identical to age- and diet-matched nonstressed controls.<sup>45</sup>

These studies suggest that critically ill neonates have only a small and usually short-term increase in energy expenditure. Although children have increased energy requirements from increased metabolic turnover during illness, their caloric needs may be lower than previously considered owing to possible halted or slow growth<sup>46</sup> and the use of sedation and muscle paralysis.<sup>47</sup> This could result in overfeeding when energy intake is based on presumed or estimated energy expenditure with stress factors. On the other hand, unrecognized hypermetabolism in select individuals results in underfeeding with nutritional consequences.<sup>32</sup> The variability in energy requirements may result in cumulative energy imbalances in the intensive care unit (ICU) over a period of time.<sup>33</sup> A direct relation has been reported between cumulative caloric imbalance and mortality rate in critically ill surgical patients.<sup>48</sup>

For practical purposes, the recommended dietary caloric intake for healthy children may represent a reasonable starting point for the upper limit of caloric allotment in the hospitalized child.<sup>17</sup> However, as discussed earlier, energy requirement estimates in select groups of patients remain variable and possibly overestimated, mandating an accurate estimation using measured energy expenditure where available. Regular anthropometric measurements plotted on a growth chart to assess the adequacy of caloric provision will allow relatively prompt detection of underfeeding or overfeeding in most cases. However, some critically ill children may be too sick for regular weights or have changes in body water that make anthropometric measurements unreliable.

## MACRONUTRIENT INTAKE

### Review of Protein Metabolism and Requirement during Illness

Amino acids are the key building blocks required for growth and tissue repair. The vast majority (98%) are found in existing proteins, and the remainder reside in the free amino acid pool. Proteins are continually degraded into their constituent amino acids and resynthesized through the process of protein turnover. The reutilization of amino acids released by protein breakdown is extensive. Synthesis of proteins from the recycling of amino acids is more than two times greater than that from dietary protein intake. An advantage of high protein turnover is that a continuous flow of

amino acids is available for the synthesis of new proteins. This allows the body tremendous flexibility in meeting ever-changing physiologic needs. However, the process of protein turnover requires the input of energy to power both protein degradation and synthesis. At baseline, infants are known to have higher rates of protein turnover than adults. Healthy newborns have a protein turnover rate of 6 to 12 g/kg/day compared with 3.5 g/kg/day in adults.<sup>49</sup> Even greater rates of protein turnover have been measured in premature and low birth weight infants.<sup>50</sup> For example, it has been demonstrated that extremely low birth weight infants receiving no dietary protein can lose in excess of 1.2 g/kg/day of endogenous protein.<sup>51</sup> At the same time, infants must maintain a positive protein balance to attain normal growth and development, whereas the healthy adult can subsist with a neutral protein balance.

In the metabolically stressed patient, such as the child with severe burn injury or cardiorespiratory failure requiring ECMO, protein turnover is doubled when compared with that in normal subjects.<sup>35,49</sup> A study of critically ill infants and children found an 80% increase in protein turnover, which correlated with the duration of the critical illness.<sup>52</sup> This process redistributes amino acids from skeletal muscle to the liver, wound site, and tissues taking part in the inflammatory response. The factors required for the inflammatory response—acutely needed enzymes, serum proteins, and glucose—are thereby synthesized from degraded body protein stores. The well-established increase in hepatically derived acute phase proteins (including C-reactive protein, fibrinogen, transferrin, and  $\alpha_1$ -acid glycoprotein), along with the concomitant decrease in transport proteins (albumin and retinol-binding protein) is evidence of this protein redistribution. As substrate turnover is increased during the stress response, rates of both whole-body protein degradation and whole-body protein synthesis are accelerated. However, protein breakdown predominates, thereby leading to a hypercatabolic state with ensuing net negative protein and nitrogen balance.<sup>27</sup> Protein loss is evident in elevated levels of excreted urinary nitrogen during critical illness. For example, infants with sepsis demonstrate a severalfold increase in the loss of urinary nitrogen that directly correlates with the degree of illness.<sup>53</sup> Clinically, severe protein loss can be manifested by skeletal muscle wasting, weight loss, delayed wound healing, and immune dysfunction.<sup>54</sup> In addition to the reprioritization of protein for tissue repair, healing and inflammation, the body appears to have an increased need for glucose production during times of metabolic stress.<sup>55</sup> The accelerated rate of gluconeogenesis during illness and injury is seen in both children and adults, and this process appears to be accentuated in infants with low body weight.<sup>13,54</sup> The increased production of glucose during illness is necessary, because glucose represents a versatile energy source for tissues taking part in the inflammatory response. For example, it has been shown that glucose utilization by leukocytes is significantly increased in inflammatory conditions.<sup>56</sup> Unfortunately, the provision

of additional dietary glucose does not suppress the body's need for increased glucose production. Therefore, net protein breakdown continues to predominate.<sup>14,57,58</sup>

Specific amino acids are transported from muscle to the liver to facilitate hepatic glucose production. The initial step of amino acid catabolism involves removal of the toxic amino group ( $\text{NH}_3$ ). Through transamination, the amino group is transferred to  $\alpha$ -ketoglutarate, thereby producing glutamate. The addition of another amino group converts glutamate to glutamine, which is subsequently transported to the liver. Here, the amino groups are removed from glutamine and detoxified to urea through the urea cycle. The amino acid carbon skeleton can then enter the gluconeogenesis pathway. Alternatively, in skeletal muscle, the amino group can be transferred to pyruvate, thereby forming the amino acid alanine. When alanine is transported to the liver and detoxified, pyruvate is re-formed and can be converted to glucose through gluconeogenesis. The transport of alanine and pyruvate between peripheral muscle tissue and the liver is termed the *glucose-alanine cycle*.<sup>59</sup> Hence the transport amino acid systems involving glutamine and alanine provide carbon backbones for gluconeogenesis while facilitating the hepatic detoxification of ammonia by the urea cycle.

Increased muscle protein catabolism is a successful short-term adaptation during critical illness but is limited and ultimately harmful to the pediatric patient with reduced protein stores and elevated protein demands. Without elimination of the inciting stress, the progressive breakdown of diaphragmatic, cardiac, and skeletal muscle can lead to respiratory compromise, fatal arrhythmia, and loss of lean body mass. Moreover, a prolonged negative protein balance may have a significant impact on the child's growth and development. Healthy, nonstressed neonates require a positive protein balance of nearly 2 g/kg/day.<sup>48,60</sup> In contrast, critically ill, premature neonates requiring mechanical ventilation have a negative protein balance of  $-1$  g/kg/day.<sup>62,63</sup> Critically ill neonates who require ECMO have exceedingly high rates of protein loss, with a net negative protein balance of  $-2.3$  g/kg/day.<sup>61</sup> It has been well established that the extent of protein catabolism correlates with the ultimate morbidity and mortality of the surgical patient.

Fortunately, amino acid supplementation tends to promote increased nitrogen retention and positive protein balance in critically ill patients.<sup>59,62</sup> The mechanism appears to be an increase in protein synthesis while rates of protein degradation remain constant.<sup>60,63</sup> Therefore, the provision of dietary protein sufficient to optimize protein synthesis, facilitate wound healing and the inflammatory process, and preserve skeletal muscle mass is the single most important nutritional intervention in critically ill children. The quantity of protein needed to enhance protein accrual is greater in hospitalized sick children than in healthy children. Table 2-3 lists recommended quantities of dietary protein provision for hospitalized children. Extreme cases of physiologic stress, including the child with extensive burns or the neonate on ECMO, may

**Table 2-3** Recommended Protein Requirements for Critically Ill Infants and Children

Age (yr)	Estimated Protein Requirement (g/kg/day)
0-2	2.0-3.0
2-13	1.5-2.0
13-18	1.5

necessitate additional protein supplementation to meet metabolic demands. It should be noted that toxicity from excessive protein administration has been reported, particularly in children with impaired renal and hepatic function. The provision of protein at levels greater than 3 g/kg/day is rarely indicated and is often associated with azotemia. In premature neonates, the possible beneficial effects of protein allotments of 3.0 to 3.5 g/kg/day are being actively investigated in an effort to replicate intrauterine growth rates. Studies using protein provisions of 6 g/kg/day in children have demonstrated significant morbidity, including azotemia, pyrexia, strabismus, and lower IQ scores.<sup>62,64</sup>

### Protein Quality

In addition to the sufficient quantity of dietary protein, an increased focus has been placed on the quality of protein in nutritional feeding. The specific amino acid formulation that is best to increase whole-body protein balance has yet to be fully determined, although numerous clinical and basic science research projects are actively researching this topic. It is known that infants have an increased requirement per kilogram for the essential amino acids compared with the adult.<sup>65</sup> In particular, neonates have immature biosynthetic pathways that may temporarily alter their ability to synthesize specific amino acids. One example is the amino acid histidine, which has been shown to be a conditionally essential amino acid in infants up to age 6 months. Recent data suggest that cysteine, taurine, and proline also may be of limited capacity in the premature neonate.<sup>66-69</sup> Interest has also been expressed in the use of arginine as an “immunonutrient” to enhance the function of the immune system in critically ill patients. Although preliminary studies show that arginine supplementation may reduce the risk of infectious complications, its safety and efficacy in the pediatric population has yet to be established.<sup>70</sup>

The restricted availability of the amino acid cysteine may have clinical relevance in the critically ill child. Cysteine is a required substrate for the production of glutathione, the body’s major antioxidant. In critically ill children, cysteine turnover is increased significantly. At the same time, rates of glutathione synthesis are decreased by 60%. In this way, cysteine may become a conditionally essential amino acid in the sick child. Recent experiments have demonstrated that the enteral feeding of cysteine in small quantities to rats dependent on total parenteral nutrition (TPN) significantly increases the hepatic concentration of

glutathione.<sup>71</sup> The enteral supplementation of cysteine in a pediatric nutritional regimen warrants further investigation.

Glutamine is another amino acid that has been studied extensively in both pediatric and adult patients in the ICU. Glutamine is an important amino acid source for gluconeogenesis, intestinal energy production, and ammonia detoxification. In healthy subjects, glutamine is a nonessential amino acid, although it has been hypothesized that glutamine may become conditionally essential in critically ill patients. Because it is difficult to keep glutamine soluble in solution, standard TPN formulations do not include glutamine in the amino acid mixture. Although the preliminary data on glutamine supplementation in the clinical setting are encouraging, numerous problems with study methodology have been noted.<sup>72</sup> Additional prospective, randomized trials are needed to define its utility fully in both the adult and pediatric population.

In summary, during illness and recovery from trauma or surgery, there is increased protein catabolism. The short-term adaptive benefit of this response is, in time, outweighed by the loss of protein in critical organs and the consequent morbidity seen after the exhaustion of limited protein reserves. This sustained protein breakdown cannot be stopped by increasing caloric provision alone (as is the case in starvation), but protein balance may be restored by optimal (probably individual and disease specific) quantities of protein intake during this state. Future studies may also elucidate if specific amino acid mixtures may be of benefit to select subpopulations.

### Modulating Protein Metabolism

The dramatic increase in protein breakdown during critical illness, coupled with the known association between protein loss and patient mortality and morbidity, has stimulated a wide array of research efforts. The measurement of whole-body nitrogen balance through urine and stool was once the only way to investigate changes in protein metabolism. New and validated stable isotope tracer techniques now exist to measure the precise rates of protein turnover, breakdown, and synthesis.<sup>73</sup> However, the modulation of protein metabolism in critically ill patients has proved difficult. Dietary supplementation of amino acids does increase protein synthesis but appears to have no effect on protein-breakdown rates. Thus, investigators have recently focused on the use of alternative anabolic agents to decrease protein catabolism. Studies have used various pharmacologic tools to achieve this goal, including growth hormone, insulin-derived growth factor I (IGF-I), and testosterone, with varying degrees of success.<sup>74-76</sup> One of the more promising agents, however, may be the anabolic hormone insulin. Multiple studies have used insulin to reduce protein breakdown in healthy volunteers and adult burn patients.<sup>50,77</sup> In children with extensive burns, intravenous insulin has been shown to increase lean body mass and mitigate peripheral muscle catabolism.<sup>78</sup> A recent prospective, randomized trial of more than

1500 adult postoperative patients in the ICU demonstrated significant reductions in mortality and morbidity with the use of intravenous insulin.<sup>79</sup> Preliminary stable isotopic studies demonstrate that an intravenous insulin infusion may reduce protein breakdown by over 30% in critically ill neonates on ECMO.<sup>80</sup> The use of intensive insulin therapy for critically ill children and adults continues to be another active area of clinical investigation. More recent studies examining the role of insulin for tight glycemic control in critically ill patients have been less encouraging and are discussed in the next section.

## A Review of Carbohydrate Metabolism and Requirement during Illness

Glucose production and availability are a priority in the pediatric metabolic stress response. Glucose is the primary energy source for the brain, erythrocyte, and renal medulla and also is used extensively in the inflammatory response. Injured and septic adults demonstrate a threefold increase in glucose turnover, glucose oxidation, and gluconeogenesis.<sup>16</sup> This increase is of particular concern in neonates who have an elevated glucose turnover at baseline.<sup>10</sup> Moreover, glycogen stores provide only a limited endogenous supply of glucose in adults and an even smaller reserve in the neonate. Thus, the critically ill neonate has a greater glucose demand and reduced glucose stores. During illness, the administration of exogenous glucose does not halt the elevated rates of gluconeogenesis. Thus, net protein catabolism continues unabated.<sup>14</sup> It is clear, however, that a combination of dietary glucose and amino acids can effectively improve protein balance during critical illness, primarily through an augmentation of protein synthesis.

In the past, nutritional support regimens for critically ill patients used large amounts of glucose in an attempt to reduce endogenous glucose production. Unfortunately, excess glucose increases CO<sub>2</sub> production, engenders fatty liver, and results in no reduction in endogenous glucose turnover.<sup>81</sup> Therefore, a surplus of carbohydrate may increase the ventilatory burden on the critically ill patient. Adult patients in the ICU fed with high-glucose TPN demonstrate a 30% increase in oxygen consumption, a 57% increase in CO<sub>2</sub> production, and a 71% elevation in minute ventilation.<sup>82</sup> In critically ill infants, the conversion of excess glucose to fat has also been correlated with increased CO<sub>2</sub> production and higher respiratory rates.<sup>83</sup> In addition, excessive carbohydrate provision may play a role in the genesis of TPN-associated cholestatic liver injury. Finally, some data in critically ill neonates have shown that excess caloric allotments of carbohydrate are paradoxically associated with an increased rate of net protein breakdown.<sup>84</sup>

When designing a nutritional regimen for the critically ill child, excessive carbohydrate calories should be avoided. A mixed fuel system, with both glucose and lipid substrates, should be used to meet the patient's caloric requirements. When the postoperative neonate is fed a high-glucose diet, the corresponding

RQ is approximately 1.0, and may be higher than 1.0 in selected patients, signifying increased lipogenesis.<sup>85</sup> A mixed dietary regimen of glucose and lipid (at 2 to 4 g/kg/day) lowers the effective RQ in neonates to 0.83.<sup>86</sup> This approach will provide the child with full nutritional supplementation while alleviating an increased ventilatory burden and difficulties with hyperglycemia.

Administration of high caloric (glucose load) diets in the early phase of critical illness may exacerbate hyperglycemia, increase CO<sub>2</sub> generation with increased load on the respiratory system, promote hyperlipidemia resulting from increased lipogenesis, and result in a hyperosmolar state. Recent reports have linked hyperglycemia with increased mortality and established the role of insulin-assisted tight glycemic control in improving outcomes in the critically ill adults.<sup>79,87,88</sup> A remarkable 43% reduction in mortality was reported in post-cardiac surgery patients in an adult ICU by implementing strict glycemic control (arterial blood glucose levels below 110 mg/dL) using insulin infusion in the treatment group compared with patients in the control group (average blood glucose level of 150-160 mg/dL).<sup>79</sup> The precise mechanism(s) responsible for this beneficial effect of tight glycemic control with insulin protocol remains unanswered. A recent meta-analysis of studies examining the role of tight glycemic control in adult ICUs has shown a high incidence of hypoglycemia in the treatment group and less impressive benefit.<sup>89</sup> Although the incidence of hyperglycemia in the pediatric population is high and may be associated with increased mortality and length of stay,<sup>90</sup> no data exist currently for similar benefits of tight glycemic control in the pediatric age group. Studies examining the role of tight glycemic control strategy (its benefits and risks) in the pediatric population are currently underway. Although it is prudent to avoid prolonged hyperglycemia in the pediatric ICU patients, in the absence of definitive data, aggressive glycemic control cannot yet be recommended in the critically ill children outside of a clinical trial setting.

## A Review of Lipid Metabolism and Requirement during Illness

Along with protein and carbohydrate metabolism, the turnover of lipid is generally increased by critical illness, major surgery, and trauma in the pediatric patient.<sup>91</sup> During the early ebb phase, triglyceride levels may initially increase as the rate of lipid metabolism decreases. However, this process reverses itself in the predominant flow phase. During this time, critically ill adult patients have demonstrated twofold to fourfold increases in lipid turnover.<sup>92</sup> Recently it was shown that critically ill children on mechanical ventilation have increased rates of fatty acid oxidation.<sup>93</sup> The increased lipid metabolism is thought to be proportional to the overall degree of illness. The process of lipid turnover involves the conversion of free fatty acids and their glycerol backbone into, and hydrolytic cleavage from, triglycerides. Thirty to 40 percent of free fatty acids are oxidized for energy. RQ values may

decline during illness, reflecting an increased utilization of fat as an energy source.<sup>94</sup> This suggests that fatty acids are a prime source of energy in metabolically stressed pediatric patients. In addition to the rich energy supply from lipid substrate, the glycerol moiety released from triglycerides may be converted to pyruvate and used to manufacture glucose. As seen with the other catabolic changes associated with illness and trauma, the provision of dietary glucose does not decrease fatty acid turnover in times of illness. The increased demand for lipid utilization in critical illness coupled with the limited lipid stores in the neonate puts the metabolically stressed child at high risk for the development of essential fatty acid deficiency.<sup>95,96</sup>

Preterm infants have been shown to develop biochemical evidence of essential fatty acid deficiency 2 days after the initiation of a fat-free nutritional regimen.<sup>97</sup> In the human, the polyunsaturated fatty acids linoleic and linolenic acid are considered essential fatty acids because the body cannot manufacture them by desaturating other fatty acids. Linoleic acid is used by the body to synthesize arachidonic acid, an important intermediary in prostaglandin synthesis. The prostaglandin family includes the leukotrienes and thromboxanes, all of which serve as mediators in such wide-ranging processes as vascular permeability, smooth muscle reactivity, and platelet aggregation. If an individual lacks dietary linoleic acid, the formation of arachidonic acid (a tetraene, with four double bonds) cannot occur and eicosatrienoic acid (a triene, with three double bonds) accumulates in its place. Clinically, a fatty acid profile can be performed on human serum. An elevated triene-to-tetraene ratio greater than 0.4 is characteristic of biochemical essential fatty acid deficiency, although this value is somewhat variable and dependent on the specific laboratory assay utilized. Signs of fatty acid deficiencies include dermatitis, alopecia, thrombocytopenia, increased susceptibility to infection, and overall failure to thrive. To avoid essential fatty acid deficiency in neonates, the allotment of linoleic and linolenic acid is recommended at concentrations of 4.5% and 0.5% of total calories, respectively. In addition, some evidence exists that the long-chain fatty acid docosahexaenoic acid (DHA), a derivative of linolenic acid, also may be deficient in preterm and formula-fed infants. At present, clinical trials are actively seeking to determine whether supplementation with long-chain polyunsaturated fatty acids will be of clinical benefit in this population.

Parenterally delivered lipid solutions also limit the need for excessive glucose provision. These lipid emulsions provide a higher quantity of energy per gram than does glucose (9 kcal/g vs. 4 kcal/g). This reduces the overall rate of CO<sub>2</sub> production, the RQ value, and the incidence of hepatic steatosis.<sup>98</sup> Some risks must be considered when starting a patient on intravenous lipid administration. These include hypertriglyceridemia, a possible increased risk of infection, and decreased alveolar oxygen-diffusion capacity.<sup>99-101</sup> Most institutions, therefore, initiate lipid provisions in children at 0.5 to 1.0 g/kg/day and advance over a period of days

to 2 to 4 g/kg/day. During this time, triglyceride levels are monitored closely. Lipid administration is generally restricted to 30% to 40% of total caloric intake in ill children in an effort to obviate immune dysfunction, although this practice has not been validated in a formal clinical trial.

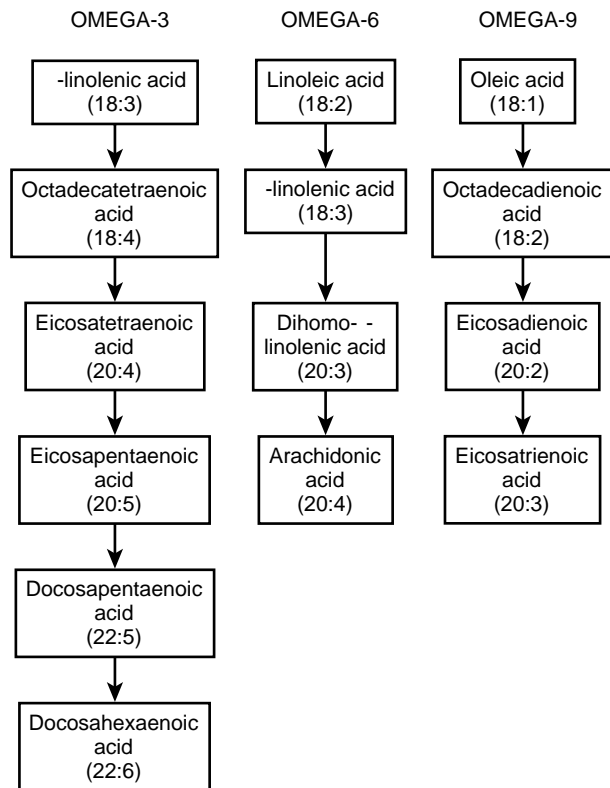

In settings of prolonged fasting or uncontrolled diabetes mellitus, the accelerated production of glucose depletes the hepatocyte of needed intermediaries in the citric acid cycle. When this occurs, the acetyl-coenzyme A (CoA) generated from the breakdown of fatty acids cannot enter the citric acid cycle. Instead, it forms the ketone bodies acetoacetate and  $\beta$ -hydroxybutyrate. These ketone bodies are released by the liver to extrahepatic tissues, in particular, skeletal muscle and the brain, where they can be used for energy production in place of glucose. During surgical illness, however, ketone formation is relatively inhibited secondary to elevated serum insulin levels.<sup>102</sup> Therefore, in surgical patients, ketone bodies do not significantly supplant the need for glucose and do not play a major role in the metabolic management of the pediatric stress response.

In addition to their nutritional role, fatty acids profoundly influence inflammatory and immune events by changing lipid mediators and inflammatory protein and coagulation protein expression. After ingestion, omega-6 and omega-3 fats are metabolized by an alternating series of desaturase and elongase enzymes that transform them into the membrane-associated lipids arachidonic acid, eicosapentaenoic (EPA), and docosahexaenoic (DHA) acids, respectively (Figs. 2-2 and 2-3).<sup>103</sup> Substitution of the intralipid component of TPN (rich in proinflammatory omega-6 fatty acids) with fish oil (a source of omega-3 fatty acids) may alleviate some of the toxic effects of long-term parenteral nutrition on the liver.<sup>104</sup> The beneficial effects of omega-3 fatty acids have been shown in animal and human models. Omega-3 fatty acids have an anti-inflammatory effect, with decreased cytokine production shown in some models.<sup>103</sup> More recently, a commercially available omega-3 fatty acid for parenteral administration has been used in children with exciting results. In a cohort of TPN-dependent children with TPN-associated hyperbilirubinemia, Omegaven (Fresenius Kabi, Hamburg, Germany), at a low lipid allocation of 1 g/kg/day, was associated with a normalization of bilirubin levels.<sup>105</sup> A clinical trial to test the relative benefits of Omegaven versus reduced omega-6 lipid allotments alone is underway in surgical neonates.

## ROUTES OF NUTRITIONAL PROVISION

### Enteral Nutrition

After the estimation of energy expenditure and macronutrient requirement in the hospitalized child, the next challenge is to facilitate the provision of this nutritional support. In most pediatric patients with a functioning gastrointestinal tract, the enteral route

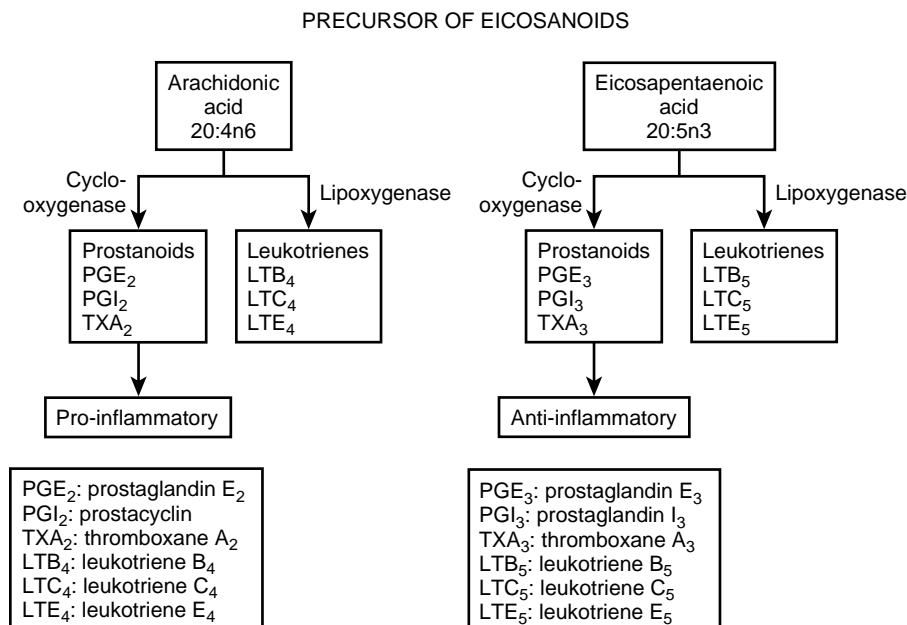

**Figure 2-2.** Fatty acid synthesis from omega-3, omega-6, and omega-9 fats. (From Lee S, Gura KM, Kim S, et al: Current clinical applications of omega-6 and omega-3 fatty acids. *Nutr Clin Pract* 21:323-341, 2006.)

of nutrient administration is preferable to parenteral nutrition. Enteral nutrition is physiologic and has been shown to be more cost effective without the added risk of nosocomial infection inherent in TPN. Early enteral nutrition has been shown to decrease infectious

episodes and decrease the length of hospitalization in critically ill patients.<sup>106</sup> Based on level 1 and level 2 evidence in adult critical care literature, the Canadian Clinical Practice Guidelines for Nutrition Support have strongly recommended the use of early enteral feeding (within 24-48 hours after ICU admission).<sup>107</sup> The optimal route of nutrient delivery has not been systematically studied in children. In the absence of a randomized controlled trial comparing the effects of enteral versus parenteral nutrition, many centers have adopted institutional guidelines. Current practice includes the initiation of gastric or postpyloric enteral feeding within 48 to 72 hours after admission. Parenteral nutrition is being used to supplement or replace enteral nutrition in those patients in whom enteral nutrition alone is unable to meet their nutritional goals.

In children on enteral nutrition, there are insufficient data to make recommendations regarding the site of enteral feeding (gastric vs. postpyloric). Both enteral routes have been successfully used for nutritional support of the critically ill child.<sup>108-110</sup> In a study examining the role of small bowel feeding in 74 critically ill children randomized to receive either gastric or postpyloric feeds, no significant difference was observed in microaspiration, tube displacement, and feeding intolerance between the two groups.<sup>111</sup> The study was not powered to detect differences in mortality and enteral feedings were interrupted in a large number of subjects in this study. Moreover, caloric goals were met in only a small percentage of the population studied. A higher percentage of subjects in the small bowel group achieved their daily caloric goal when compared with the gastric fed group. Critically ill children receiving early (<24 hours after ICU admission) postpyloric feedings have been shown to have better feeding tolerance (decreased incidence of abdominal distention) compared with those in whom postpyloric

**Figure 2-3.** The pro- and anti-inflammatory products that are generated from the metabolism of arachidonic acid and eicosapentaenoic acid. (From Lee S, Gura KM, Kim S, et al: Current clinical applications of omega-6 and omega-3 fatty acids. *Nutr Clin Pract* 21:323-341, 2006.)

feeding was initiated late.<sup>112</sup> It may be prudent to consider postpyloric alimentation in patients who do not tolerate gastric feeding or those who are at a high risk of aspiration. Intolerance to enteral feeds may be a limiting factor, and supplementation with parenteral nutrition in this group of patients allows for improved nutritional intake.<sup>113</sup>

Prospective cohort studies and retrospective chart reviews have reported the inability to achieve daily caloric goal in many critically ill children.<sup>4,114</sup> The most common reasons for suboptimal enteral nutrient delivery in these studies are fluid restriction, procedures interrupting feeds, and feeding intolerance. In a study examining the endocrine and metabolic response of children with meningococcal sepsis, goal nutrition was achieved in only 25% of the cases.<sup>7</sup> Similar observations have been made in a group of 95 children in a pediatric ICU where patients received a median of 58.8% (range 0-277%) of their estimated energy requirements. In this review, enteral feedings were interrupted on 264 occasions to allow clinical procedures. In another review of nutritional intake in 42 patients in a tertiary-level pediatric ICU over 458 days, actual energy intake was compared with estimated energy requirement.<sup>4</sup> Only 50% of patients were reported to have received full estimated energy requirements after a median of 7 days in the ICU. Prolonged fluid resuscitation was a major factor hindering the achievement of estimated energy requirements despite maximizing the energy content of feeds.

Feeding protocols for transpyloric feeding tubes and changing from bolus to continuous feeds during brief periods of intolerance are strategies that may help achieve estimated energy goals in this population. Consistently underachieved enteral nutrition goals are thought to be one of the reasons for the absence of beneficial effect in multiple studies and meta-analyses on the efficacy of immunonutrition in preventing infection.<sup>115</sup> Addressing preventable interruptions in enteral feeding in critically ill children is essential to attaining goal feedings. At this time, there is not enough evidence to recommend the use of prokinetic medications, motility agents (for feeding intolerance or to facilitate enteral tube placement), prebiotics, probiotics, or synbiotics in critically ill children. Randomized studies comparing enteral feeds administered by bolus or continuously are also lacking.

In summary, enteral nutrition must be initiated early in hospitalized children with established peristalsis. Postpyloric enteral nutrition may be utilized in children with a high risk of aspiration or when gastric feeding is either contraindicated or has failed. Enterally administered feeds meet nutritional requirements in critically ill children with a functional gastrointestinal system and have the advantages of low cost, manageability, safety, and preservation of hepatic and other gastrointestinal function. Early introduction of enteral feeding in critically ill patients helps to achieve positive protein and energy balance and restores nitrogen balance during the acute state of illness. It maintains gut integrity and elicits release of growth factors and hormones that maintain gut integrity and function.<sup>116</sup>

Despite its perceived benefits, current practice in ICUs shows a significant proportion of eligible patients deprived of enteral feeds.<sup>117</sup> Figure 2-4 offers an algorithm for initiating and advancing enteral nutrition in children admitted to the multidisciplinary ICU at Children's Hospital, Boston.

## PARENTERAL NUTRITION

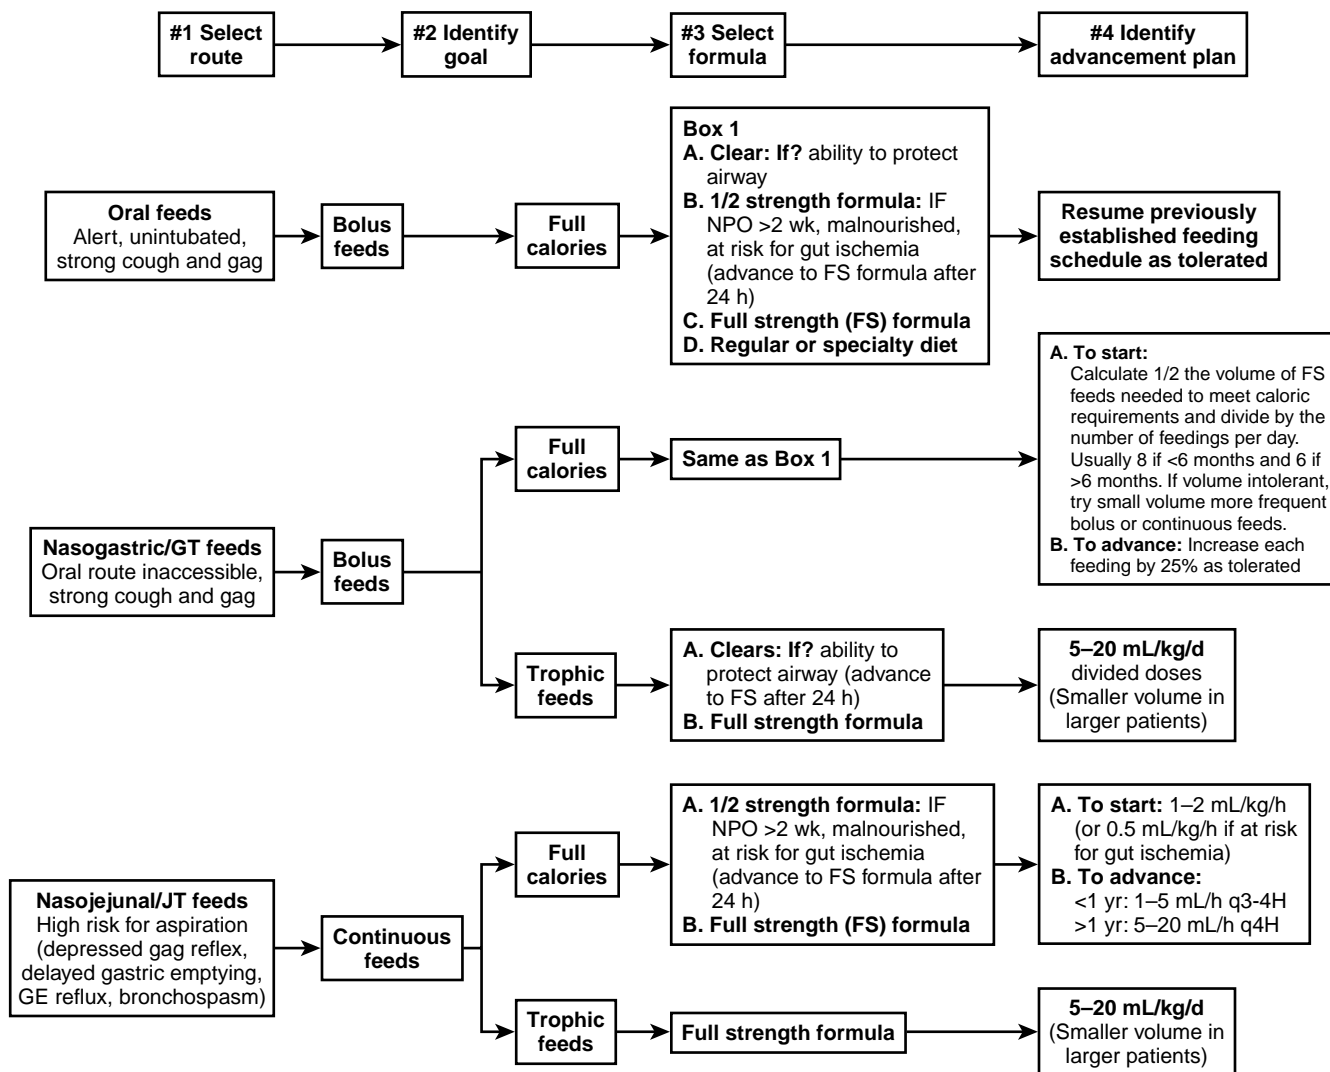

TPN bypasses the gut and provides intravenous administration of macronutrients and micronutrients to meet the nutritional requirements. TPN is indicated in children who are unable to tolerate enteral feeding for a prolonged period of time. Intravenous feeding may supplement enteral feeding or replace it entirely. Although widespread in its application, TPN is associated with mechanical, infectious, and metabolic complications and hence should only be used in carefully selected patients. In the setting of intact intestinal function, TPN is not indicated if enteral feeds alone can maintain nutrition.

The decision to initiate TPN is based on the anticipated length of fasting, the underlying nutritional status of the individual, and a careful examination of the risks associated with TPN use in relation to the consequences of poor nutritional intake. If the expected period during which there will be minimal or no enteral nutrition is longer than 5 days, the use of TPN is probably beneficial. In children with underlying malnutrition, prematurity, or conditions associated with hypermetabolism, TPN can be initiated earlier. The main limiting factor for provision of full nutritional support in the form of TPN is the availability of central access. Administration of full TPN requires a central venous catheter with its tip placed at the junction of the superior vena cava and right atrium. If a lower extremity central line is utilized, the tip of the catheter should be positioned at the junction of the inferior vena cava and right atrium. The large vessel diameter and maximal blood flow rate at these sites allows for the safe administration of the hypertonic TPN. To avoid the complications associated with malpositioned tips of central venous catheters, the practice at our institution is to document the location of the central venous catheter tip and the entry site before its use. Peripheral administration of TPN in the absence of an ideally located central venous catheter requires dilution (maximum 900 mOsm/L with 10% dextrose and 2% amino acids) to avoid the risks of phlebitis and sclerosis. The osmolarity of the TPN solution can be calculated using available on-line calculators or simple equations such as  $\{(dextrose [g/L] \times 5) + (protein [g/L] \times 10) + (lipid [g/L] \times 1.5) + [(mEq/L \text{ of } Na^+ + K^+ + Ca^{2+} + Mg^{2+}) \times 5]\}$ .

The fluid and electrolytes status will guide the initial TPN prescription. The patient's hydration, size, age, and underlying disease will dictate the amount of the fluid to be administered. Fluid requirements in the pediatric age group are routinely estimated based on the Holliday-Segar method (Table 2-4). TPN should not routinely be used for replacing ongoing losses.

MSICU ENTERAL FEEDING ALGORITHM

Unless contraindicated,\* begin enteral nutrition support within 24 h of admission to the MSICU.

\***Contraindications** include potential for endotracheal intubation/extubation within 4 hours; hemodynamically unstable requiring escalation of therapy; postoperative ileus, upper gastrointestinal bleeding, at risk for NEC/intestinal ischemia, intestinal obstruction, post-allogenic BMT who have GVHD or post-BMT patients prior to gut recontamination and in patients in whom care is being redirected. If contraindicated, see Parenteral Nutrition CPG.

**Figure 2-4.** Example of an algorithm for a feeding regimen and route for patients admitted to a multidisciplinary intensive care unit. (Courtesy of Children’s Hospital, Boston.)

Body Weight	Maintenance Daily Fluid Requirement
0-10 kg	100 mL/kg
10-20 kg	1000 mL + 50 mL/kg > 10 kg
> 20 kg	1500 mL + 20 mL/kg > 20 kg

Fluid shifts, increased insensible losses, drainage of bodily secretions, and renal failure can complicate electrolyte management in these patients. Parenteral nutrition should be ordered daily after reviewing the basic electrolytes ( $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Cl}^-$ ,  $\text{HCO}_3^-$ ,  $\text{Ca}^{2+}$ ) and blood sugar to allow adjustments in the macronutrient and micronutrient composition. In sick patients with significant gastrointestinal fluid loss (gastric, pancreatic, small intestinal, or bile), the actual measurement of electrolytes from the drained fluid is recommended. However, urgent changes in serum electrolytes should not be managed by changes in TPN infusion rate or composition because these represent imprecise methods to treat a potentially serious electrolyte abnormality. In addition, careful attention to phosphate and magnesium levels is also important. Hypophosphatemia may lead to hemolytic anemia, respiratory muscle dysfunction, and cardiac failure. A significant decrease in serum phosphate also may be seen with the re-feeding syndrome. In contrast, renal failure can result in the retention of phosphate and potassium and nutritional allotments must be reduced accordingly. Deficiency of magnesium can cause a fatal cardiac arrhythmia in both children and adults. Abnormalities of acid-base physiology also can influence the nutritional regimen of the hospitalized child. If a metabolic alkalosis develops from active diuresis or gastric suction, chloride administration should be used to correct the alkalosis. Severe, untreated alkalemia may inhibit the patient's respiratory drive, shift potassium intracellularly, decrease ionized calcium concentrations by increasing the affinity of albumin for calcium, and promote refractory cardiac arrhythmias. Metabolic acidosis is often seen in critically ill children and may be associated with hypotension, ischemia, or renal failure. In this case, the provision of acetate instead of chloride in the parenteral nutrition regimen may be useful.<sup>118</sup>

The three main macronutrients in TPN are carbohydrate, lipid, and protein. Lipid and dextrose are the principal sources of energy in TPN, whereas protein is utilized for lean body accretion. Protein is administered in the form of crystalline amino acids starting at 0.5 g/kg/day in preterm neonates and 1 g/kg/day in others. The protein intake is advanced daily in increments of 1 g/kg/day until the goal intake is achieved. Table 2-3 lists recommended quantities of dietary protein for hospitalized children. Dextrose provides the main source of energy in TPN and is initiated at a rate of 5 mg/kg/min using a 5% to 10% concentration. The glucose infusion rate in milligrams per kilogram per minute can be calculated with the help of the equation:  $[(\% \text{ dextrose}) \times (1 \text{ dL}/100 \text{ mL}) \times (1000 \text{ mg}/1 \text{ g}) (\text{hourly rate in mL/hr}) \times (1 \text{ hr}/60 \text{ min}) \times (1/\text{weight in kg})]$ . Infusion rates higher than 12 mg/kg/min are infrequently required. Moreover, overfeeding with carbohydrate is associated with lipogenesis ( $\text{RQ} > 1.0$ ), hepatic steatosis, hyperglycemia, and osmotic diuresis. Three to 5 percent of the energy needs must be met using intravenous lipids, which are usually initiated at a rate of 1 g/kg/day and advanced in increments to reach a maximum of 3 g/kg/day, or 50% of the total energy intake. Intravenous lipids prevent essential

fatty acid deficiency and are a concentrated and isotonic source of energy. Triglyceride levels should be monitored, and the intralipid infusion rate is lowered when hypertriglyceridemia is found. As noted previously, available evidence suggests that limiting lipids to 1 g/kg/day may be indicated in patients with intestinal failure-associated parenteral nutrition cholestasis or in those susceptible patients (i.e., neonates) who are likely to require a protracted course of TPN.<sup>119</sup>

The vitamin and micronutrient (trace element) needs of healthy children and neonates are relatively well defined in the literature.<sup>17</sup> In the neonate and child, required vitamins include the fat-soluble vitamins (A, D, E, and K) as well as the water-soluble vitamins (ascorbic acid, thiamine, riboflavin, pyridoxine, niacin, pantothenate, biotin, folate, and vitamin  $\text{B}_{12}$ ). Because vitamins are not consumed stoichiometrically in biochemical reactions but instead act as catalysts, the administration of large vitamin supplements in metabolically stressed states is not logical from a nutritional standpoint. The trace elements required for normal growth and development include zinc, iron, copper, selenium, manganese, iodide, molybdenum, and chromium. Trace elements are usually used in the synthesis of the active sites of a ubiquitous and extraordinarily important class of enzymes called metalloenzymes. More than 200 zinc metalloenzymes alone exist. Both DNA and RNA polymerase are included in this group. As with vitamins, the role of metalloenzymes is to act as catalytic agents. Unless specific mineral losses occur, such as enhanced zinc loss with severe diarrhea, large nutritional requirements would not be anticipated during critical illness. Selenium and carnitine may be added after 30 days of exclusive TPN administration. The addition of copper and manganese in TPN of children with cholestasis is controversial. Usually, the dose is halved due to their biliary excretion. The pharmacologic use of vitamins and trace minerals in pediatric illness has not been adequately studied. Reviews of both vitamin and trace mineral toxicity clearly demonstrate that excessive dosage is a health risk.<sup>120,121</sup>

Careful biochemical monitoring is mandatory to prevent acute and long-term complications from TPN therapy. A TPN profile is recommended at initiation of therapy and then weekly. The profile includes serum levels of sodium, potassium, chloride, glucose, carbon dioxide, blood urine nitrogen, creatinine, albumin, magnesium, phosphate, total and direct bilirubin, and transaminases. For children requiring TPN longer than 30 days, selenium, iron, zinc, copper, and carnitine levels should be checked. It is essential to monitor daily vital statistics and routine anthropometry to ensure adequate growth and development. Critical care units benefit from the expertise of a dedicated nutritionist who should be consulted on a regular basis to guide optimal nutritional intake of patients.

## Immune-Enhancing Diets

Immunomodulation is thought to play a significant role in the response to infectious insult and impacts outcome in children with sepsis. In 1997, Bone and

colleagues outlined the role of the compensatory anti-inflammatory response that follows the initial proinflammatory response engendered by trauma or infection.<sup>122</sup> Therapies aimed at modulating or stimulating the immune response have been a focus of recent nutritional studies.

Unfortunately, investigations examining the role of immune enhancing diets in critically ill patients are marred by heterogeneous clinical populations,

methodologic flaws, and the use of nutritional formulations that often contain multiple potentially active components. Thus, studies and meta-analyses often offer conflicting conclusions.<sup>69,114,121-123</sup> Furthermore, there are no published studies specifically evaluating the role of immunonutrition in critically ill children. Potentially promising, but unproven, additives include arginine, glutamine, cysteine, nucleic acids, and omega-3 fatty acids.

# ANESTHETIC CONSIDERATIONS

Kathy M. Perryman, MD • Adam J. Schow, MD • Robert E. Binda, Jr., MD

Anesthetizing children is an increasingly safe undertaking. When discussing the risks and benefits of a surgical intervention with a child and his or her family, surgeons should feel confident that their pediatric anesthesiology colleagues can provide an anesthetic conducive to the demands of the surgery while safeguarding the child's health. As such, whether it is a question of appropriateness for outpatient surgery or how to manage a difficult clinical problem, surgeons and anesthesiologists should collaborate. This chapter is designed to inform surgeons of the considerations important to anesthesiologists. It is hoped that with better understanding between surgical and anesthesiology services, efficiency of case planning and operative patient care will improve.

## PREANESTHETIC CONSIDERATIONS

### Risk

In an effort to reduce patient complications, anesthesiologists have carefully analyzed their specialty over the past generation. The Pediatric Perioperative Cardiac Arrest (POCA) Registry, the Anesthesiology Patient Safety Foundation (APSF), and the American Society of Anesthesiologists (ASA) Closed Claims Project are among the important initiatives that have resulted in significant reductions in risk to patients undergoing anesthesia. Whereas anesthesia was historically considered a dangerous adventure, serious complications are now relatively rare. The reasons for this improvement include advances in pharmacology, improved monitoring technology and standards, increased rigor of subspecialty training, and the ability to target problems with the aforementioned risk analysis strategy.

Quantifying risk in pediatric anesthesia is fraught with difficulty owing to the inherent vagaries of determining just what complications are attributable to an anesthetic and to what degree. The risk of cardiac arrest for children undergoing anesthesia has been estimated at 1:10,000.<sup>1,2</sup> However, this number is hardly applicable universally because it does not discriminate based on patient co-morbidity or surgical disease. The risk of

a healthy child suffering arrest during myringotomy tube placement would be dramatically smaller than the likelihood of a child with complex cardiac disease succumbing during a prolonged cardiac repair.<sup>3</sup>

A recent review of cardiac arrests in anesthetized children compared 193 events from 1998-2004 to 150 events from 1994-1997.<sup>4</sup> Medication-caused arrests decreased from 37% to 18%, which was attributed to a corresponding fall in halothane use and its attendant myocardial depression. It is interesting to note the dramatic reduction in unrecognized esophageal intubation as a leading cause of arrest, due in large part to the advent of pulse oximetry and an increased awareness of the problem. Another notable finding was the predominance of arrests due to inadequate response to hypovolemia or hyperkalemia associated with transfusion, frequently in spinal and craniofacial surgery. These events highlight the preventable nature of the most common arrests, with adequate vascular access and early recognition of bleeding as key to their avoidance.

### Anesthesia Consultation

In some centers, all children are evaluated by an anesthesiologist prior to the day of surgery. In others, only selected patients are referred for anesthesia consultation. Any child with an ASA classification (Table 3-1) of 3 or greater should be seen by an anesthesiologist in consultation before the day of surgery. This may be modified in cases of hardship due to travel or when the patient is well known to the anesthesia service and the child's health is unchanged. Certain medical conditions are of particular interest to the anesthesiologist. Although this list is by no means exhaustive, such diseases would include any family history of malignant hyperthermia, abnormal airways, cardiac defects, pulmonary disease, neuromuscular disorders, or any other hypotonic condition. That being stated, whenever an organ system is moderately dysfunctional, consultation is desirable. Open consultation policies reduce frustration and delay on the day of surgery by resolving problems and concerns ahead of time.

At the time of consultation, selected laboratory studies may be ordered, but routine laboratory work is not

**Table 3-1** ASA Physical Status Classification

ASA Classification	Patient Status
1	A normal healthy patient
2	A patient with mild systemic disease
3	A patient with severe systemic disease
4	A patient with severe systemic disease that is a constant threat to life
5	A moribund patient who is not expected to survive without the operation
6	A declared brain-dead patient whose organs are being removed for donor purposes
E	An emergency modifier for any ASA classification when failure to immediately correct a medical condition poses risk to life or organ viability

indicated. Medications should be individually assessed as to whether their schedule needs to be altered. In general, seizure medications, cardiac medications, and pulmonary medications should be continued even while NPO (nothing per os). Exceptions may include angiotensin-converting enzyme (ACE) inhibitors and diuretics; the latter may also require blood chemistries. Insulin-dependent diabetics have a particular urgency to be carefully evaluated before elective surgery. Their history of glucose control along with the length of NPO time and surgical stress require careful planning.

### Upper Respiratory Tract Infections

Upper respiratory tract infections (URIs) deserve special mention. It is not uncommon for some patients to spend much of their childhood contracting, suffering from, or recovering from a URI. Historically, such patients' surgeries were cancelled due to concern over severe postoperative pulmonary morbidity.<sup>5</sup> Modern studies indicate that such morbidity is rare,<sup>6,7</sup> although transient complications are possible. These typically include postoperative stridor, laryngospasm, hypoxia, and coughing. While potentially worrisome, the vast majority of such complications are readily treatable and can be expected to resolve in the first postoperative day.

The decision to cancel or postpone a scheduled surgery (usually a delay of 4-6 weeks given concern for prolonged hyperreactivity of the bronchi) should not be made lightly. Families have often sacrificed time away from work, taken children out of school, arranged child care for other children, or have planned vacation around the surgical timing, and these social considerations deserve respectful attention. In one study, cases were more likely cancelled by anesthesia staff with more than 10 years of practice experience.<sup>8</sup> Factors to be considered include severity of illness, with intractable or productive cough, malaise, fever, or hypoxia by pulse oximetry. All these factors weigh toward cancellation. Also, a smaller child is exponentially more likely to struggle with bronchospasm because airway resistance is inversely proportional to the fourth power of the radius of the airway.

In contrast, clear rhinorrhea with a simple cough is not usually sufficient grounds for cancellation, provided the family understands the small chance of the need for postoperative supplemental oxygen and bronchodilator therapy. These complications may lead to delay in discharge or require inpatient admission for overnight observation. When the decision to cancel is uncertain, the best general guideline is probably to ask whether the child is in his or her usual state of health. If not, is the child reasonably likely to be better if surgery is postponed? Together with consultation with the surgeon, the answer to that question must in turn be weighed with the urgency of the surgery.

To summarize, some decisions are easy: a child with fever, malaise, hypoxia, or a severe cough should have elective surgery postponed. Similarly, a child with only clear rhinorrhea or a dry, intermittent cough can usually proceed to the operating room. Special attention should be paid to a child with a history of reactive airway disease when the absence of optimal management is more likely to lead to cancellation. For the patients who fall into the gray spectrum, surgeon, anesthesiologist, and parents must consider the urgency of the surgery, the likelihood of improvement of symptoms if the procedure is rescheduled, and the family's ability to accommodate a cancellation.

### NPO

The most common cause for surgical delay or cancellation is a violation of NPO guidelines. These rules stipulate preoperative fasting for 6 hours from all oral intake (except breast milk for 4 hours and clear liquids for 2 hours). The rigidity of this rule can be a source of frustration to all. While the risk of aspiration is generally small, it is a real risk of severe morbidity or death. At this time, while some would wish to liberalize fasting guidelines, there are no data to support such changes and the difficulty in obtaining such data is likely prohibitive.

Mitigating circumstances for NPO rules are limited to emergent surgical intervention. In some cases, NPO carries a risk of morbidity from dehydration. One example would include children with single-ventricle cardiac physiology for whom prolonged fasting in the setting of hypotension with an inhalational induction could be fatal. When in question, NPO fasting should be compensated with intravenous hydration. Insulin-dependent diabetics and infants are among those requiring careful planning so that NPO times are not extended. They should be scheduled as the first case of the day when possible.

## OUTPATIENT ANESTHESIA

### Criteria for Ambulatory Surgery

Ambulatory surgery comprises 70% or more of the case load in most pediatric centers. Multiple factors should be considered when evaluating whether a child is suitable for outpatient surgery. In most cases, the child

should be free of severe systemic disease (ASA class 1 or 2). Other factors that may determine the suitability of a child for outpatient surgery are family and social dynamics. For instance, will this child be cared for by a responsible and capable adult? Is the child to be cared for by a single parent who must work? How far must the child travel to receive appropriate medical attention, if needed?

Well-controlled systemic illnesses do not necessarily preclude outpatient surgery, but these questions must be answered in advance in a cooperative fashion between surgical and anesthesia services. If a child has a moderate degree of impairment but the disease is stable and the surgical procedure is of minimal insult, outpatient surgery may be acceptable. However, ASA class 3 children who present for surgery without prior evaluation run the risk of delaying the turnover of cases where efficiency is often at a premium.

### The Former Preterm Infant

The potential dangers in performing outpatient surgery on former premature infants were first published in 1982.<sup>9</sup> The most life-threatening hazard is apnea after the surgical procedure, normally within the first 12 to 18 hours. Factors that contribute to the increased risk are not completely understood but may include immature neurologic development, particularly in the brain stem respiratory center, and less developed diaphragmatic musculature that leads to easier fatigability.<sup>10</sup> The age after birth at which this increased risk of apnea disappears is still being debated, despite numerous studies of this issue. A meta-analysis of pertinent studies was reported in 1995.<sup>11</sup> The results of this analysis indicated that a significant reduction occurred in the incidence of apnea at 52 to 54 weeks' postconceptual age, depending on the gestational age. A hematocrit less than 30% was identified as a risk factor, and it was recommended that infants with this degree of anemia be hospitalized postoperatively for observation no matter what the age. However, conclusions drawn from meta-analyses have been challenged for their validity. Moreover, the sample size of this study may not have been large enough to draw valid conclusions.<sup>12</sup>

No anesthetic technique appears to be clearly superior to other techniques, although some evidence has suggested an advantage to spinal anesthesia.<sup>13</sup> By far, general anesthesia is still the preferred anesthetic in most institutions.<sup>14</sup> Likewise, no medications can predictably prevent apnea, although caffeine may hold some promise.<sup>15</sup> Until more patients are systematically studied, the choice of when former preterm infants can undergo operation as outpatients is up to the discretion and personal bias of the anesthesiologist and surgeon. Institutional policies most commonly mention ages of 44 to 46 weeks, 50 weeks, or 60 weeks postconceptual age. Whereas the risk of postanesthesia apnea for preterm children varies widely depending on the degree of prematurity, the postconceptual age at presentation, and the significance of co-morbidities, one blanket rule for postoperative observation and monitoring is usually applied. Indeed, a recent survey

of surgical practices showed that approximately one third of the surgeons chose to wait until 50 weeks' postconceptual age and that one third waited until 60 weeks if possible.<sup>15</sup> Legal issues direct such practices in some institutions, but regardless of the postconceptual age at time of surgery, an infant should be hospitalized if any safety concerns arise during the operative or recovery period.

## INTRAOPERATIVE MANAGEMENT

### Monitoring

Standard monitoring in pediatric anesthesia follows the ASA "Standards for Basic Anesthetic Monitoring."<sup>16</sup> The requirements are to continually evaluate the patient's oxygenation, ventilation, circulation, and temperature. This can be accomplished by the use of oximetry, capnography, electrocardiography, and blood pressure measurement. Temperature monitoring is indicated in most pediatric anesthetics.

Oxygenation is measured indirectly by pulse oximetry with an audible and variable pitch tone and low threshold alarm, which is also audible to the anesthesiologist. Adequate illumination and exposure of the patient to allow assessment of color is recommended. Measurement of inspired oxygen concentration is standard with the use of an anesthesia machine.

Besides traditional methods of ventilation assessment, such as chest rise, movement of the reservoir breathing bag, and auscultation of breath sounds, continual monitoring of expired carbon dioxide (CO<sub>2</sub>) is required, unless there are special circumstances. A disconnect alarm device must be used in conjunction with mechanical ventilators.

Precordial or esophageal stethoscopes have been used for many years during all phases of general anesthesia as well as during transport of anesthetized children. Continuous auscultation provides the anesthesiologist with immediate detection of changes in heart rate and character and breath sounds. The precordial stethoscope is placed on the left anterior chest, enabling detection of changes in breath sounds that may indicate a change in endotracheal tube position (e.g., a right main-stem bronchus intubation) or critical changes in hemodynamics.<sup>17,18</sup>

### The Difficult Pediatric Airway

As demonstrated in the POCA registry, many cardiac arrests result from respiratory complications. The difficult pediatric airway is implicated as an important cause in a significant number of these cases. Most difficult airways in the pediatric age group can be anticipated; and, unlike in adults, it is rare to encounter an unanticipated difficult airway in a normal-appearing child.

Another major difference between adult and pediatric difficult airways is that awake intubations are rarely feasible in children. Special equipment in multiple sizes is needed, and each anesthesiologist must be

proficient in several techniques.<sup>19</sup> The ASA developed practice guidelines for management of the difficult airway along with the ASA Difficult Airway Algorithm. This guideline and the algorithm are continually updated and well known to anesthesiologists.<sup>20,21</sup> These references emphasize the importance of having a clear primary plan with multiple back-up contingency plans.

Many congenital syndromes are associated with difficult airway management, including Beckwith-Wiedemann, trisomy 21, Pierre Robin sequence, Treacher Collins, Goldenhar's, Apert, Freeman-Shelden, Klippel-Feil, Crouzon, and others.<sup>19</sup> Most difficult pediatric airways involve obstruction or lack of mobility of the airway above the glottis, with difficulty ventilating the patient due to the upper airway obstruction after the induction of anesthesia. Preservation of spontaneous ventilation and the use of continued positive airway pressure (CPAP) by mask are tools commonly used by pediatric anesthesiologists in the anesthetic management of these patients.

There are many useful techniques available to secure the airway: the lighted stylet, the fiberoptic intubating stylet, the flexible fiberoptic bronchoscope, direct laryngoscopy with intubating stylet, fiberoptic rigid laryngoscopy, digital intubation, the Bullard scope, an anterior commissure scope, the laryngeal mask airway (LMA), retrograde wire techniques, cricothyrotomy, and surgical tracheostomy. When a difficult airway is anticipated, it is important to have all necessary airway equipment present in the operating room before induction of anesthesia. Equally important, it is essential to have an individual experienced in pediatric bronchoscopy and difficult airway management and a second individual who is skilled in cricothyrotomy and/or tracheostomy. Indirect intubation methods should be utilized rather than repeated attempts at direct laryngoscopy because airway edema and bleeding increase with each attempt, decreasing the likelihood of success with subsequent indirect methods.<sup>19</sup>

## Anesthetic Management of Anterior Mediastinal Masses

It has been recognized for many years that the anesthetic management of the child with an anterior mediastinal mass is very challenging and fraught with the risk of sudden airway and cardiovascular collapse. Signs and symptoms of airway compression and cardiovascular dysfunction may or may not be present, but the absence of signs and symptoms does not preclude the possibility of life-threatening collapse of the airway or cardiovascular obstruction.<sup>22-24</sup>

The inherent conflict between the need to obtain an accurate and timely tissue diagnosis and the very real concern regarding the safe conduct of the anesthetic requires an open dialogue between the consultants and the oncologists to reach an agreement on strategies to achieve these goals. Many experts recommend the development and utilization of an algorithm for anesthetic management of the child with an

anterior mediastinal mass (Fig. 3-1). The algorithms address assessment of signs and symptoms, evaluation of cardiopulmonary compromise, and treatment options.<sup>25-27</sup>

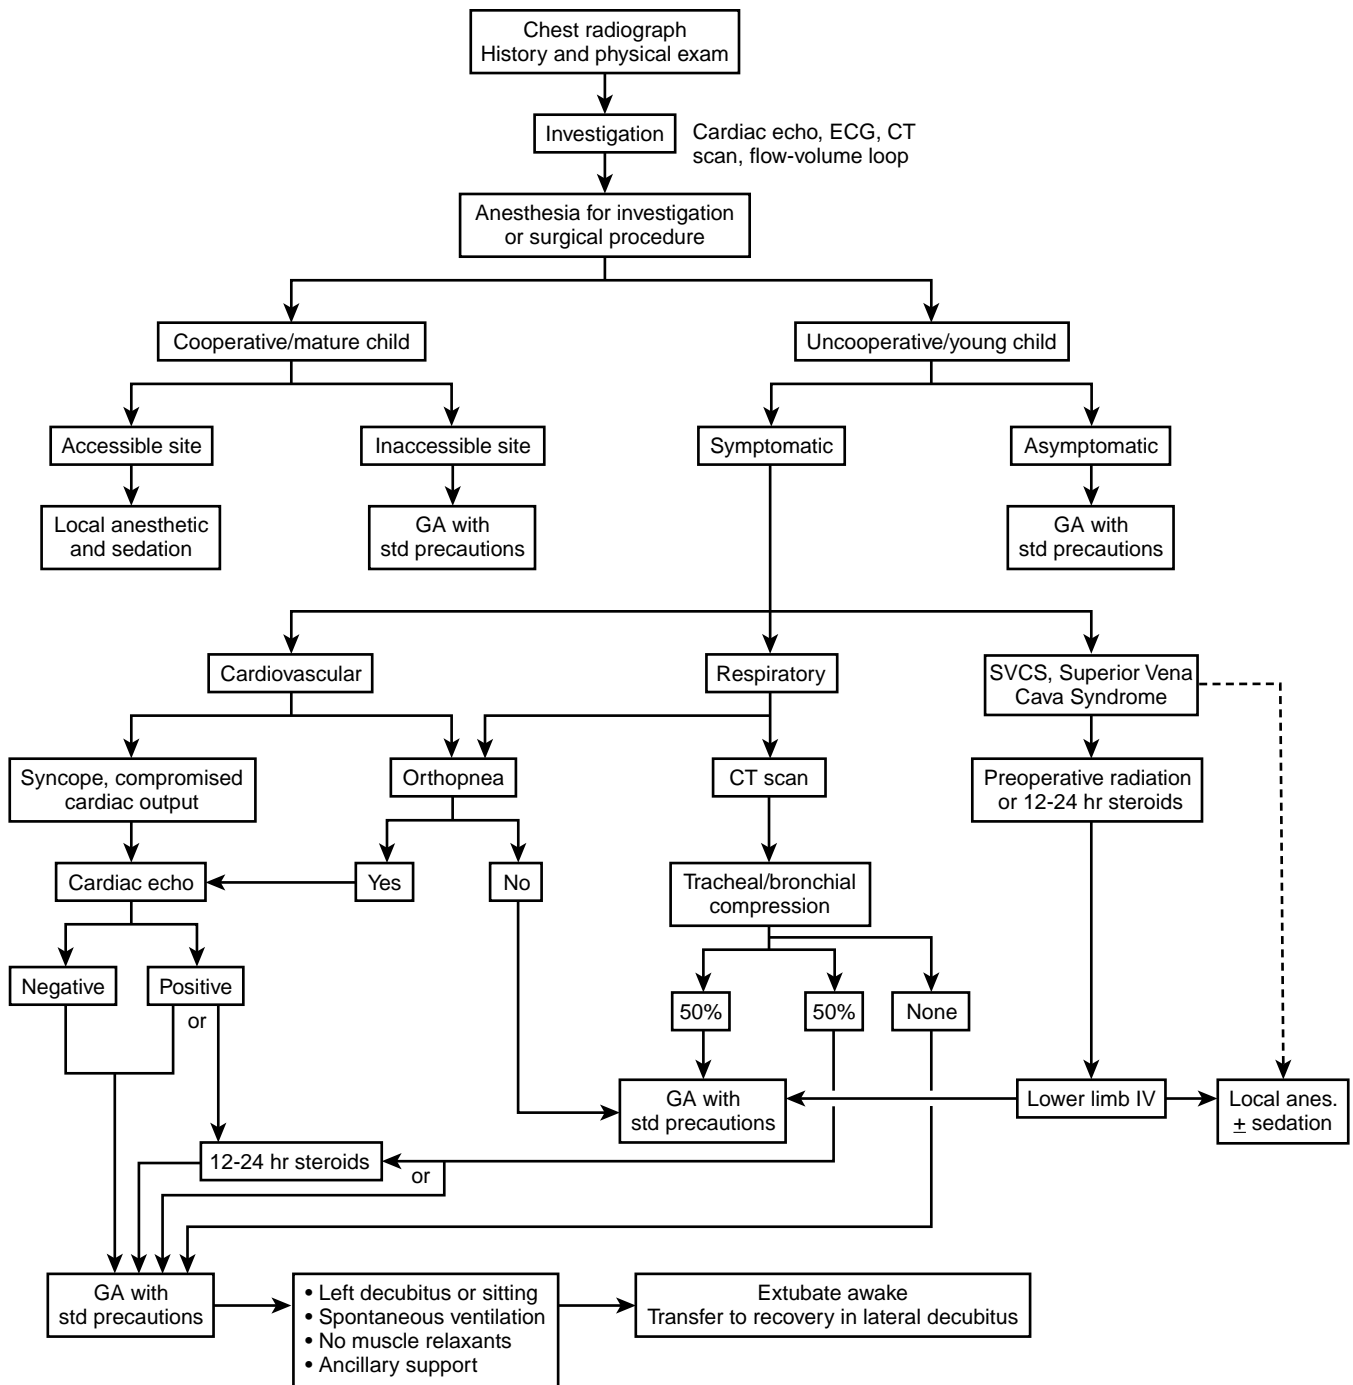

Common symptoms of tracheal compression and tracheomalacia include cough, dyspnea, chest pain, dysphagia, orthopnea, and recurrent pulmonary infections. Cardiovascular symptoms may result from infiltration of the pericardium and myocardium or compression of the pulmonary artery or superior vena cava. Tumor-associated superior vena cava syndrome develops rapidly and is poorly tolerated. Emergency radiation therapy is the treatment of choice for this life-threatening condition.<sup>26</sup>

The diagnostic evaluation includes posteroanterior and lateral chest radiographs and computed tomography (CT) scans. Echocardiography is also an essential investigative tool to assess pericardial status, myocardial contractility, and compression of the cardiac chambers and major vessels, such as the pulmonary artery. Flow-volume loops and fiberoptic bronchoscopy can provide a dynamic assessment of airway compression that other tests cannot assess.

Local anesthesia for biopsy is recommended for patients with airway and/or cardiovascular obstruction (orthopnea or superior vena cava syndrome), abnormal echocardiogram, tracheal cross-sectional area less than 50% predicted and peak expiratory flow rate less than 50% predicted, or symptoms of stridor or wheezing (Fig. 3-2). If biopsy under local anesthesia is not feasible for a patient with any of these abnormalities, radiation therapy or steroid pulse therapy is recommended to reduce the tumor burden.<sup>22,26,27</sup>

The anesthetic plan depends on the age of the patient, possible peripheral tissue and fluid accessibility, severity of symptoms, and the presence or absence of cardiopulmonary compromise demonstrated on the diagnostic tests. The anesthetic choices include local anesthesia, sedation, and general anesthesia. Most children will require general anesthetics for invasive procedures. Children who present with symptoms should be considered strongly for preoperative treatment of the tumor to reduce its size and improve cardiopulmonary compromise. Premedication is inadvisable in most circumstances because any loss of airway muscle tone may upset the balance between negative intrathoracic pressure and gravity, resulting in airway collapse. Once the decision is made to sedate or anesthetize a child, the recommended plan includes maintenance of spontaneous respiration regardless of induction technique, which may be intravenous, inhalational, or a combination of these. It is essential to avoid the use of muscle relaxants because the resultant airway collapse can be fatal. Depending on the surgical procedure and the stability of the airway, the child may be intubated or a laryngeal mask airway may be used.

Positioning of the child is an important part of the anesthetic plan. The sitting position favors gravitational pull of the tumor toward the abdomen rather than allowing gravity to pull the tumor posteriorly onto the airway and major vessels in the supine position.

**Figure 3-1.** This algorithm describes management of the patient with a large anterior mediastinal mass. GA, general anesthesia. SVCS, superior vena cava syndrome. (Adapted from Cheung S, Lerman J: Mediastinal masses and anesthesia in children. In Riazi J [ed]: The Difficult Pediatric Airway. Anesthesiol Clin North Am 16:893-910, 1998.)

However, this position makes intubation challenging. Positioning the child in the lateral decubitus position is recommended even before induction for those who are symptomatic. Turning the child prone and lifting the sternum have been successful maneuvers to alleviate acute deterioration in ventilatory parameters or cardiovascular collapse secondary to tumor compression.<sup>26</sup> A rigid bronchoscope may also be used to relieve tracheal obstruction. Performing a median

sternotomy and placing the child on cardiopulmonary bypass has been reported as an emergency measure but does not seem to be a practical alternative considering the time constraints of performing this procedure in the face of extreme hypoxia and hypotension. It is extremely important that the anesthesia, surgery, and the nursing teams be prepared with contingency plans to intervene emergently with alternative positioning and airway interventions.

**Figure 3-2.** A 13-year-old girl presented with dyspnea and cervical adenopathy. As part of the evaluation, the CT scan showed this relatively large anterior mediastinal mass. The anesthesiologist did not believe that the child should undergo general endotracheal anesthesia because of concerns about tracheal compression from the mass. Therefore, she underwent cervical lymph node biopsy in the sitting position under local anesthesia.

## Laparoscopic Surgery in Pediatric Patients

The successful application of minimally invasive surgical techniques in adults is commonplace now in the pediatric population. The cardiopulmonary effects of laparoscopic insufflation have been studied and published in adults and infants and deserve discussion here.

Laparoscopic fundoplication has gained in popularity in infants and children compared with open fundoplication because laparoscopic operations have been shown to reduce both short-term postoperative morbidity and long-term complications such as intestinal obstruction. In a comparison study of these two techniques in 212 children over 5 years, the laparoscopic operative time was longer, but the average hospital stay was reduced from 8.1 days to 3.5 days compared with the open approach.<sup>28</sup> Additional advantages are reduced discomfort and better cosmetic outcome.<sup>29</sup> It may be important to note that in spite of the many advantages of minimally invasive procedures, the systemic stress response is the same as for open surgeries.<sup>30</sup> Additionally, a recent study measured respiratory gas exchange intraoperatively in 19 open and 20 laparoscopic procedures and found a steady increase in oxygen consumption and core temperature in the laparoscopic group. This hypermetabolic response was more pronounced in younger children.<sup>31</sup>

An appreciation of the physiologic cardiocirculatory and pulmonary consequences during and after a laparoscopic operation is an important part of careful patient selection (Table 3-2). The widely varying nature of coexistent disease mandates close inspection

**Table 3-2** Physiologic Effects of Creation of a Pneumoperitoneum

of the potential impact of these laparoscopic-induced physiologic changes on each patient.

Two critical factors create unique considerations for the anesthetic management of infants and children undergoing laparoscopic procedures: (1) the creation of a pneumoperitoneum with the resulting elevation of intra-abdominal pressure, and (2) the extremes of patient positioning that may be required for optimal exposure of intra-abdominal structures.<sup>32</sup>

Carbon dioxide remains the gas of choice because, unlike air, nitrous oxide, and oxygen, it does not promote combustion. In addition, CO<sub>2</sub> is also cleared more rapidly than the other choices. The cardiovascular consequences of intravascular gas embolism are relatively less risky than an insoluble gas such as helium. CO<sub>2</sub> uptake may be significantly greater in children, owing to the greater absorptive area of the peritoneum in relation to body weight and the smaller distance between capillaries and peritoneum. Hypercarbia has been demonstrated in adult and pediatric studies during CO<sub>2</sub> insufflation for laparoscopy.<sup>33</sup> Increases in minute ventilation by as much as 60% may be required to maintain baseline end-tidal CO<sub>2</sub> (ETCO<sub>2</sub>). Potentially deleterious consequences of hypercarbia are sympathetic nervous system activation with resultant increases in blood pressure and heart rate, along with increases in myocardial contractility and oxygen consumption. Hypercarbia sensitizes the myocardium to catecholamines and can predispose to cardiac arrhythmias.<sup>32</sup> ETCO<sub>2</sub> is not a reliable estimator of arterial CO<sub>2</sub> in children during laparoscopic surgery,<sup>34</sup> underestimating the value in as many as 30% of pediatric patients, so it is important to take this into consideration when planning for high-risk patients and include intra-arterial monitoring of blood gases in their management.

Some physiologic responses to hypercarbia are uniquely hazardous to infants, particularly neonates. Hypercarbia is a potent cerebrovascular dilator that, coupled with increased venous pressure due to increased intra-abdominal pressure, can result in increased intracranial pressure.<sup>30,32</sup> This presents the risk of intracranial hemorrhage in infants. Newborns are also at risk for reactive pulmonary hypertension when exposed to the stress of surgery, hypoxia, or hypercarbia. Infants with many forms of congenital heart disease are particularly vulnerable to the development of pulmonary hypertension.

Patients with preexisting ventriculoperitoneal shunts have been shown to develop acute intracranial pressure increases with concurrent decreases in cerebral perfusion pressure with an intra-abdominal pressure of 10 mm Hg or less.<sup>35</sup> This was ameliorated by monitored removal of cerebrospinal fluid. It is important to monitor intracranial pressure intraoperatively in patients with ventriculoperitoneal shunts, to avoid Trendelenburg positioning, and to use as low as possible intra-abdominal pressure to prevent neurosurgical complications.<sup>34</sup> In normal young children, creation of pneumoperitoneum results in an increase in middle cerebral artery blood flow velocity independent from hypercapnia, and CO<sub>2</sub> reactivity is maintained in the normal range.<sup>36</sup>

The increase in intra-abdominal pressure seen with laparoscopy results in well-documented cardiorespiratory changes. Respiratory derangements occur due to cephalad displacement of the diaphragm. This results in reduction in lung volume, ventilation-perfusion mismatch, and altered gas exchange. Bozkurt and coworkers demonstrated statistically significant decreases in pH and PaO<sub>2</sub> and increased PaCO<sub>2</sub> after 30 minutes of pneumoperitoneum.<sup>30</sup> Also, a 20% reduction in functional residual capacity occurs with induction of general anesthesia with an additional 20% decrease in functional residual capacity during laparoscopic surgery in adults.<sup>30</sup> The magnitude of the pulmonary effects correlates directly with intra-peritoneal pressures.<sup>37</sup> Pediatric patients have a lower functional residual capacity relative to oxygen consumption and a higher closing volume than adults. Accordingly, infants have a smaller margin of safety and are less likely to tolerate the adverse respiratory effects of increased intra-abdominal pressure.

Significant cardiovascular changes have been demonstrated in response to increased intra-abdominal pressure and patient position. In the supine or Trendelenburg position, the venous return is augmented when the intra-abdominal pressure is kept below 15 mm Hg. The position preferred for upper abdominal procedures is reverse-Trendelenburg or supine. The head-up position reduces venous return and cardiac output.<sup>38</sup> Several pediatric studies have utilized echocardiography (supine),<sup>39</sup> impedance cardiography (15-degree head-down),<sup>40</sup> and continuous esophageal aortic blood flow echo-Doppler (supine)<sup>41</sup> to assess hemodynamic changes during laparoscopic surgery. These studies demonstrated significant reductions of stroke volume and cardiac index along with a significant increase in systemic vascular resistance. Pneumoperitoneum was found to be associated with significant increases in left ventricular end-diastolic volume, left ventricular end-systolic volume, and left ventricular end-systolic meridional wall stress.<sup>39</sup> All three studies demonstrated a decrease in cardiac performance and an increase in vascular resistance in healthy patients undergoing laparoscopy for lower abdominal procedures. The cardiovascular changes seen with pneumoperitoneum occur immediately with the creation of the pneumoperitoneum and resolve on exsufflation. However, a study

of laparoscopic Nissen fundoplication in a pig model also showed a significant decrease in cardiac output that remained after the release of the pneumoperitoneum.<sup>42</sup> This study demonstrated a concomitant increase in mediastinal and pleural pressures thought to be due to dissection around the gastroesophageal junction. These parameters have not been studied in infants and children during upper abdominal procedures. However, the cardiopulmonary effects of low pressure pneumoperitoneum have been evaluated. Thirteen children, aged 6 to 36 months, undergoing laparoscopic fundoplication were studied in the 10-degree head-up position by noninvasive thoracic electrical bioimpedance looking at cardiac index, stroke volume, heart rate, mean arterial pressure, and peak inspiratory pressure at an intra-abdominal pressure of 5 mm Hg. The authors concluded that low-pressure pneumoperitoneum with intra-abdominal pressures not greater than 5 mm Hg does not decrease cardiac index in infants and children.<sup>43</sup>

In a study of cardiorespiratory function in 25 children undergoing laparoscopic Nissen fundoplication, 6 children developed postoperative hypoxemia, defined as an oxygen saturation of less than 95%. This desaturation has not been seen after laparoscopic surgery for inguinal hernia repair, leading the authors to conclude that interference with diaphragmatic function due to the surgical dissection may be the cause of the impaired oxygenation. Several of the children in the study had preexisting respiratory disease, presumably secondary to aspiration, which could also account for the desaturations.<sup>44</sup>

In summary, studies of the cardiopulmonary consequences of pneumoperitoneum for laparoscopic surgery have demonstrated a consistent and significant decrease in cardiac index, and an increase in systemic and pulmonary vascular resistance, unless low-pressure pneumoperitoneum is used. The reverse Trendelenburg position results in further reductions in preload and cardiac index. Postoperative diaphragmatic dysfunction may be a result of surgical dissection around the esophageal hiatus. Healthy infants and children without significant co-morbid conditions tolerate the cardiopulmonary effects of pneumoperitoneum well. Infants and children with significant cardiopulmonary disease require advanced planning and may need invasive monitoring during prolonged insufflation. Close monitoring of intra-abdominal pressure to ensure the use of minimally effective intra-abdominal pressure can minimize the adverse cardiopulmonary effects of pneumoperitoneum.

## Anesthesia for Pediatric Thoracoscopy

Video-assisted thoracic surgery in pediatric patients has advantages over open thoracotomy, including reducing postoperative pain, decreasing hospitalization, improving cosmetic results, and decreasing the incidence of chest wall deformity.<sup>45,46</sup> Challenges for the anesthesiologist are numerous, making a thorough knowledge of the physiologic consequences of thoracoscopy and technical requirements in the ventilatory

**Figure 3-3.** There are several methods available for single-lung ventilation in infants and children. The most common method is to use a conventional single-lumen endotracheal tube to intubate a main-stem bronchus (A). Another technique is to position the endotracheal tube in the trachea followed by insertion of a balloon-tipped bronchial blocker that is passed along the endotracheal tube and occludes the ipsilateral main-stem bronchus (B). The position of the bronchial blocker is usually confirmed using fiberoptic bronchoscopy.

management essential. An optimal anesthetic plan considers respiratory derangements due to positioning, lung exclusion, CO<sub>2</sub> insufflation into the pleural cavity, and methods of airway management for each age group in the pediatric population. Anesthesiologists must take into consideration the ventilation-perfusion mismatch that is induced by the lateral decubitus position in the anesthetized patient, single-lung ventilation, and CO<sub>2</sub> insufflation. In addition, much like laparoscopic insufflation, there are major hemodynamic implications during CO<sub>2</sub> insufflation of the chest cavity that compromises preload, stroke volume, cardiac index, and mean arterial pressure.<sup>46</sup>

In a recently published study of 50 pediatric patients undergoing thoracoscopy for a variety of surgical procedures, systolic and diastolic blood pressure was significantly lower and ETco<sub>2</sub> was significantly higher during thoracoscopy. There was a statistically significant increase in ETco<sub>2</sub> during single-lung ventilation compared with two-lung ventilation with intrapleural insufflation. Two-lung ventilation with insufflation was associated with a lower blood pressure than one-lung ventilation. The length of the thoracoscopy statistically significantly increased the ETco<sub>2</sub>.<sup>46</sup> These factors should be considered along with preoperative respiratory or cardiovascular compromise in planning the surgical procedure and anesthetic management. The magnitude of the physiologic changes induced by either one-lung or two-lung ventilation with insufflation is impacted by the patient's age, underlying co-morbid conditions, and the anesthetic agents utilized.

Multiple methods for single-lung ventilation have been described for infants and children. The most common and easiest method is to use a conventional single-lumen endotracheal tube (ETT) to intubate a main-stem bronchus (Fig. 3-3A). Fiberoptic bronchoscopy, in addition to clinical examination, is utilized to confirm proper placement. It is important to avoid obstruction of the right upper lobe bronchus or protrusion into the trachea from overinflation of the cuff

(Fig. 3-4). A disadvantage of this technique is inadequate seal in the main-stem bronchus, causing problems with poor lung collapse on the operative side. Advantages of this technique are its simplicity and availability, because it can be performed in neonates.

Balloon-tipped bronchial blockers can be passed in or along the ETT and their position can be confirmed in the same manner as described earlier

**Figure 3-4.** This photograph shows the anesthesiologist performing fiberoptic bronchoscopy to confirm proper placement of the bronchial blocker, which has been placed into the left main-stem bronchus in this young child.

(see Fig. 3-3B). Complications of this technique include obstruction of the trachea by dislodgement of the blocker balloon proximally, damage or rupture of the airway, and the inability to provide CPAP to the operated lung when needed. An Arndt wire-guided endobronchial blocker is now frequently used in pediatrics. This device utilizes the fiberoptic bronchoscope to guide the blocker into the desired position by attaching the blocker to the bronchoscope with a releasable wire. It is then locked into place proximally to stabilize its position. An additional advantage is its low-pressure and high-volume balloon, which should decrease the risk of mucosal injury.<sup>47</sup>

A Univent tube is a specially designed ETT with a second lumen containing a balloon-tipped bronchial blocker that can be advanced distally into the operative main-stem bronchus. This also requires a fiberoptic bronchoscope for placement. The smallest size available has a 3.5-mm internal diameter.

Double-lumen ETTs (DLTs) are available in right and left sides and consist of a longer bronchial tube fused with a shorter tracheal tube and two cuffs, one on each tube. Left-sided DLTs are used much more commonly than right-sided DLTs owing to the risk of obstructing the right upper lobe bronchus lumen. Limitations of these devices are related to the larger dimensions of the ETT, making its use restricted to patients 8 years and older. Advantages of DLTs are their relative ease of insertion and the ability to suction both lumens and provide oxygenated CPAP to the operative lung. Damage to the airway is possible with these rigid ETTs, as is true with all methods of single-lung ventilation.<sup>46,48</sup>

Complications related to anesthetic management are usually related to mechanical factors, such as airway injury and malposition of the ETTs. Additional problems related to physiologic alterations include hypoxemia and hypercapnia. An unusual surgical complication was reported in which a 3.5-kg infant with a congenital cystic adenomatoid malformation underwent attempted thoracoscopic resection of the lung cyst.<sup>49</sup> During CO<sub>2</sub> insufflation there was a sharp rise in ET<sub>CO</sub><sub>2</sub> accompanied by severe hypoxemia and bradycardia due to occlusion of the ETT by blood. The procedure was immediately converted to an open thoracotomy, and it was discovered that there had been direct insufflation into the cyst and that the cyst communicated directly with the tracheobronchial tree. Another factor to consider is that ET<sub>CO</sub><sub>2</sub> may be inaccurate during thoracoscopy, especially in small infants, because of alteration in dead space and shunt fraction, so there is usually a larger than usual gradient between ET<sub>CO</sub><sub>2</sub> and arterial CO<sub>2</sub>. In this unusual case, the abrupt rise in ET<sub>CO</sub><sub>2</sub> was distinctly abnormal.

Risks associated with hypercarbia, especially in neonates, have been discussed earlier in this chapter. Therefore, it is important to try to maintain a reasonable range of increased CO<sub>2</sub> in neonates undergoing thoracoscopic procedures. The use of the high-frequency oscillating ventilator in neonates undergoing thoracoscopic repair of tracheoesophageal fistula has been described.<sup>50</sup> It is postulated that this ventilation method

may allow better CO<sub>2</sub> elimination while optimizing the visualization for the surgeons. This technique has been used successfully at our institution recently as well and shows promise as a safe anesthetic management approach in these neonates.

## Robotic Surgery

Minimal access surgery, despite its popularity, has some limitations that robot-assisted surgery is attempting to address. Robots can stabilize long instruments without tremor and overcome some of the technical challenges associated with the small workspace and two-dimensional visibility. One type of robot, AESOP (Automatic Endoscopic System for Optimal Positioning, Intuitive Surgical, Inc., Sunnyvale, CA), provides voice control of the telescope that is attached and stabilized by the robotic arm. This device is attached to the operating room table and does not impede access to the patient.<sup>51</sup>

AESOP has been used extensively and does not present any unique anesthetic management challenges. The da Vinci Robot (Intuitive Surgical, Inc., Sunnyvale, CA) is different and presents special challenges and limitations to patient access, which require advance preparation. Recently, a case report of a 2-month-old, 4.1-kg infant undergoing a Kasai procedure utilizing the da Vinci system described the hazards of minimal access.<sup>52</sup> The authors recommended practicing the crisis scenario of removing the robotic equipment and gaining access to the patient rapidly so that an emergency could be handled quickly. In the case of an airway emergency or cardiac arrest, the robotic instruments must be disengaged before backing the cart away from the operating table. This was performed in less than 1 minute in a practice run. Other recommendations were to use a left-sided precordial stethoscope to monitor for inadvertent right main-stem bronchus intubation and to consider fluoroscopy after patient positioning to confirm proper ETT depth. The precordial stethoscope is a low-tech, real-time method to check for left lung breath sounds. Intra-arterial blood pressure monitoring with interval blood gas sampling is also recommended, as well as urine output monitoring, because these procedures increase the setup and operative times currently. It is anticipated that operative times will decrease with experience.

## Anesthetic Management of the Pediatric Congenital Heart Disease Patient Undergoing Noncardiac Surgery

Life expectancy of children with congenital heart disease (CHD) has continued to increase with the advancement of medical and surgical knowledge and expertise. Infants and children with complex congenital heart lesions are presenting more often for management of serious medical problems that may require surgical intervention before and between staged palliative cardiac procedures.

The diversity of anatomic and physiologic abnormalities encountered in children with CHD makes development of a generic anesthetic plan impossible. The main considerations for planning the anesthetic are the degree and type of cardiovascular and pulmonary impairment and the cardiopulmonary effects of the planned surgical procedure.<sup>53,54</sup> Unlike in adults, the estimation of risk in pediatric CHD patients undergoing noncardiac surgery has not been defined. We can, however, use the New York Heart Association (NYHA) functional classification as a guide for the need for further preoperative assessment. The potential deleterious physiologic consequences of anesthetics and surgery, such as laparoscopy, must be carefully examined in relation to the individual child's heart defect and associated hematologic and cardiopulmonary status.

Because cardiopulmonary dynamics are altered abruptly and significantly during procedures such as laparoscopy and thoracoscopy, preoperative assessment of cardiopulmonary reserve is vital. Evaluation for the presence of baseline hypoxemia, abnormalities of cardiac function, pulmonary abnormalities, and history of arrhythmias is essential.

### *Hypoxemia*

Hypoxic children should be evaluated for symptoms of hyperviscosity, such as headache, faintness, depressed mentation, fatigue, and muscle weakness. Preoperative phlebotomy is indicated for patients with a hematocrit greater than 65% and symptomatic hyperviscosity syndrome. Evidence of abnormal hemostasis, particularly prolongation of the prothrombin time or the partial thromboplastin time, occurs in up to 20% of patients with CHD. Reduction of red cell mass by preoperative phlebotomy has been reported to correct these abnormalities in some patients.<sup>54</sup> Prevention of dehydration with the intravenous use of fluids helps to reduce the hematocrit and optimizes preload. Children with hypoxemia due to CHD fall into two categories: (1) those with limited pulmonary blood flow with right-to-left shunting of blood and (2) those with unrestricted pulmonary blood flow with significant mixing of pulmonary and systemic venous blood. Anesthetic management is distinctly different in these two situations.<sup>54</sup>

When pulmonary blood flow is restricted, it is important to maintain adequate hydration and systemic arterial blood pressure to prevent worsening of the right-to-left shunt, which would further decrease pulmonary blood flow. Avoidance of additional increases in resistance to pulmonary blood flow would include careful adjustment of positive-pressure ventilation to prevent severe hypercarbia and high peak inspiratory pressure, both of which can diminish pulmonary blood flow. Unfortunately, even mild hyperventilation may be difficult to achieve during pneumoperitoneum with CO<sub>2</sub> without requiring high peak ventilatory pressures.<sup>54</sup> This may be particularly problematic in children with venous-dependent pulmonary blood flow, such as single ventricle physiology with Glenn or Fontan palliation.

The presence of unrestricted pulmonary blood flow mandates the preservation of ventricular function and the pulmonary to systemic blood flow (Q<sub>p</sub>:Q<sub>s</sub>) ratio at unity.<sup>54</sup> The choice of sevoflurane for induction, and either sevoflurane or isoflurane for maintenance, will minimize the myocardial depressant effect of the volatile anesthetic when kept below 1 MAC (mean alveolar concentration). Inotropic agents may be necessary to restore myocardial function during the anesthetic, especially in neonates.

Another important consideration in chronically hypoxic patients is the development of myocardial fibrosis, reducing ventricular diastolic compliance and contractility. Myocardial cellular changes also occur, such as β-receptor downregulation. The chemoreceptor response to hypoxia is blunted, predisposing these patients to developing profound hypoxia in the postoperative period.<sup>54</sup>

### *Cardiac Failure*

Patients with borderline cardiac function are at risk for intraoperative cardiac failure because of the negative inotropic effects of some anesthetic agents. Additional risks for cardiac failure occur during laparoscopy because of the acute decrease in preload and increase in systemic vascular resistance due to creation of the pneumoperitoneum. A case report by Tobias and Holcomb described the successful anesthetic management of two pediatric patients with dilated cardiomyopathy undergoing laparoscopic cholecystectomy.<sup>55</sup> Their anesthetic and surgical techniques were altered by avoiding anesthetic agents with negative inotropic effects, maintenance of the supine position, increasing ventilation to maintain normocarbia, slow insufflation with a pressure limit of 15 mm Hg, and use of intra-arterial monitoring of blood pressure and blood gases. Preoperative echocardiographic assessment of function and evaluation of exercise tolerance aids in decisions about the need for intraoperative monitoring and anesthetic drug and technique choices. Prophylactic management with inotropic infusions intraoperatively may be advisable.

### *Airway and Pulmonary Abnormalities*

Abnormal airway anatomy is frequently seen in conjunction with CHD.<sup>54</sup> A short trachea is of particular significance in patients undergoing laparoscopic surgery due to the cephalad displacement of the diaphragm during pneumoperitoneum. Intraoperative main-stem bronchus intubation has been seen after insufflation in patients with normal tracheal length, so a high index of suspicion should be maintained, coupled with physical examination to prevent unrecognized main-stem bronchus intubation.<sup>44</sup> Use of a left anterior chest wall precordial stethoscope can be invaluable in the prompt detection of this potentially serious complication. Large and small airway obstruction due to CHD is also not uncommon. Airways can be compressed and/or obstructed by vascular rings, enlarged cardiac chambers, pulmonary artery, aorta, or artificial conduits. Small airway obstruction can

result from bronchiolar smooth muscle hyperplasia in infants with pulmonary hypertension.<sup>54</sup>

Dead space is increased in children with decreased pulmonary blood flow. Positive-pressure ventilation and hypovolemia increase dead space further.<sup>54</sup> Anesthetic management of these children should emphasize maintenance of intravascular volume and ventricular function.

Excessive pulmonary blood flow leads to a progressive increase in pulmonary vascular resistance and airway obstruction. Children who have hypertrophied pulmonary vascular smooth musculature are susceptible to acute life-threatening pulmonary hypertensive episodes. Infants in this category include neonates, infants, and children with large ventricular septal defects or large patent ductus arteriosus. Particularly susceptible infants are those with complete atrioventricular canal and truncus arteriosus. Chronic exposure to excessive pulmonary blood flow results in irreversible pulmonary hypertension and right-to-left shunt. The anesthetic risk to symptomatic patients with this physiology (the Eisenmenger syndrome) appears to be considerable. These patients are usually NYHA functional class III or IV.<sup>54</sup> One case report describing the successful anesthetic management of an adult with Eisenmenger's syndrome presenting for laparoscopic cholecystectomy utilizing a technique consisting of general endotracheal anesthesia with infusion of norepinephrine to maintain systemic vascular resistance. This patient's history was consistent with NYHA functional class II. She had also tolerated a full-term pregnancy and vaginal delivery in the past.<sup>56</sup> Anesthetics that decrease systemic vascular resistance significantly, such as propofol, should be used only with extreme caution in patients with pulmonary hypertension or any cardiac defect in which a decrease in systemic vascular resistance is inadvisable.<sup>18</sup>

Neonates with or without CHD are at risk for reactive pulmonary hypertension due to the immaturity of the pulmonary vascular tree. Hypercarbia, hypoxemia, and stress can all trigger an acute pulmonary hypertensive crisis in this population. Neonates are also at risk for congestive heart failure when challenged with acute volume or pressure loads due to the immaturity of the neonatal myocyte. The Frank-Starling relationship is altered by the noncompliance of the neonatal ventricle so that the heart fails at a much lower pressure and volume. In neonates with CHD, the high risk of precipitating pulmonary hypertension and acute heart failure must be considered when selecting appropriate patients for minimally invasive surgery. In addition, infants with unrepaired CHD such as large ventricular septal defect, large patent ductus arteriosus, complete atrioventricular canal, truncus arteriosus, and single ventricle physiology are at high risk of death in the event of an acute pulmonary hypertensive crisis. The choice of surgical approach should take these factors into account. There is one published study of five infants with palliated hypoplastic left heart syndrome who underwent laparoscopic Nissen fundoplication and gastrostomy after modified Norwood procedures.<sup>57</sup> In the Norwood procedure, the right ventricle functions as the systemic ventricle and pulmonary blood flow is

provided by a Blalock-Taussig shunt. In the modified Norwood procedure, the pulmonary blood flow is provided by a right ventricle to pulmonary artery conduit. All of the patients were monitored with arterial lines and blood gases were checked at regular intervals. Two patients received inotropic support prophylactically, and all five remained hemodynamically stable. Ventilation was meticulously managed to avoid high peak airway pressures and to maintain normocarbia. Pneumoperitoneum was limited to 12 mm Hg. ETCO<sub>2</sub> monitoring correlates poorly with PaCO<sub>2</sub> during peritoneal insufflation so frequent measurement of PaCO<sub>2</sub> was utilized for ventilation management. This is especially true in infants with cyanotic heart disease.<sup>58</sup> Decreases in cardiac index due to the systemic vascular resistance caused by pneumoperitoneum could decrease shunt flow, resulting in desaturation and acidosis. These patients had better preservation of diastolic blood pressure because of the right ventricle to pulmonary conduit modification of the Norwood procedure.<sup>57</sup>

Children who rely on passive venous return to the pulmonary circulation, such as those who have had Glenn or Fontan procedures, require special attention to ventilatory and fluid management during general anesthesia. The cardiac output in this population may be adversely affected by positive-pressure ventilation.

Residual defects in myocardial contractility and the ejection fraction predispose patients to acute heart failure when challenged by abrupt increases in afterload. Cyanotic patients should be considered to be at risk for decompensation when faced with increased afterload because of the known association of myocardial fibrosis with chronic cyanosis.<sup>54</sup>

Infants and children with intracardiac communications are at increased risk for shunting of blood and gas. The risk of gas embolism during laparoscopy is small, but should it occur in the presence of intracardiac communication, gas emboli could gain access to the systemic circulation. This could result in stroke or myocardial ischemia. Utilizing CO<sub>2</sub> as the insufflating gas decreases the likelihood of sustained arterial obstruction by a gas bubble because CO<sub>2</sub> would be absorbed more quickly than air or helium.

Children with repaired heart defects with little or no residual dysfunction tolerate anesthetics well. Subacute bacterial endocarditis prophylaxis recommendations should be utilized as indicated. A preoperative history revealing NYHA functional class I or II in conjunction with a recent echocardiogram demonstrating good function and no other serious concerns is valuable information in assessment of these children.

Recommendations for the anesthetic management of patients with CHD are seen in [Table 3-3](#).

## POSTANESTHESIA CARE

### Pain Management

The incidence of postoperative pain in the pediatric population, although difficult to evaluate objectively, is probably similar to that in the adult population.

**Table 3-3** Recommendations for the Anesthetic Management of Patients with Congenital Heart Disease

1. Preoperative medication with an anxiolytic, such as oral midazolam, should be considered to prevent agitation and increased oxygen consumption.
2. Preoperative intravenous fluids should be considered in patients at risk for hyperviscosity. Children with passive pulmonary blood flow should not be allowed to become dehydrated.
3. Prophylaxis for subacute bacterial endocarditis should be done as recommended by the American Heart Association.
4. Intraoperative monitoring with intra-arterial catheter and central venous pressure would be helpful in guiding fluid management and vasoactive drug therapy. Blood gas analysis can also be used to monitor arterial to end-tidal CO<sub>2</sub> and acid-base status.
5. Intraoperative transesophageal echocardiography could be helpful in aiding the intraoperative diagnosis of heart failure or air embolism in any patient with borderline or reduced cardiac function, intracardiac shunt, or passive pulmonary blood flow.
6. Induction with agents that have less negative inotropic effects, such as etomidate, ketamine, or sevoflurane, seems prudent. The use of an anticholinergic drug to prevent vagal reflexes and bradycardia during peritoneal insufflation is recommended in neonates whose cardiac output is heart rate dependent.
7. Maintenance of anesthesia with isoflurane should have minimal negative inotropic effect and may decrease systemic vascular resistance. A nondepolarizing muscle relaxant is required for optimal abdominal relaxation. Propofol should be used sparingly in any patient with pulmonary hypertension, if at all, because it reduces systemic vascular resistance and can result in sudden hypotension and cardiovascular collapse.
8. For laparoscopic procedures, slow insufflation and maintenance of the supine position are recommended to prevent sudden changes in cardiovascular parameters. It may not be possible to achieve adequate surgical exposure for upper abdominal procedures without some reverse Trendelenburg positioning. When a change in position is necessary, this should be done independently, rather than concurrently with insufflation. Hemodynamics should be allowed to equilibrate after each change before adding another variable.
9. Limiting insufflation pressure to 10-12 mm Hg to minimize cardiopulmonary alterations is recommended.
10. Postoperative analgesia is usually facilitated by the injection of local anesthetic into the small incisions by the surgeon at the end of the procedure. Additional analgesia can be provided by ketorolac and small doses of narcotic in the recovery room. If conversion to an open procedure is required because the patient does not tolerate the decrease in cardiac index and increase in systemic vascular resistance, a regional technique for postoperative analgesia may be considered. A normal coagulation profile is necessary to consider this option. The use of epidural analgesia for upper abdominal incisions has been shown to improve pulmonary function postoperatively and shorten the postoperative hospitalization.

It is reasonable, therefore, to assume that about 75% of children will report significant pain on the first postoperative day.<sup>59</sup> The ineffective treatment of postoperative discomfort in children is most often the result of four factors:

1. Individuals involved in the care of children are working with an evolving knowledge of the mechanisms of pain and its transmission in children. Attitudes toward the management of pain in children have often been biased by several observations made on newborns. It has been known for many years that newborns may cry for relatively short periods after experiencing noxious stimuli and then settle down and sleep without the use of analgesics.<sup>60</sup> In addition, microscopic examination of thalamocortical tracts in the newborn has shown a lack of myelin, leading investigators and clinicians to postulate that the pain perception of neonates is immature and rudimentary.<sup>61</sup> Finally, higher concentrations of endogenous opioids are present in the plasma and cerebrospinal fluid of neonates when compared with those of older children.<sup>62</sup> This type of information has led to the erroneous conclusion that neonates do not have a normal sensation of pain and therefore do not require postoperative pain therapy. Evidence indicates that neonates do experience pain in a manner similar to that of adults. Sophisticated observations of cry patterns, facial expressions, movements, and cardiovascular variables allow reproducible documentation of painful experiences in these smallest of patients.
2. Misconceptions remain regarding the pharmacokinetics of pain medications in children. Clearly, the neonate presents differences from older children and adults that must be taken into account. For instance, neonates appear to have a greater sensitivity to the respiratory depressant effects of narcotics. This may be explained by the fact that relatively fewer  $\alpha_1$  narcotic receptors (mediating analgesia) exist relative to the  $\alpha_2$  receptors (mediating respiratory depression) in neonates when compared with older individuals.<sup>63</sup> Evidence also suggests that for some narcotics the volume of distribution is larger and the elimination half-life is prolonged in premature infants. For example, the elimination half-life of fentanyl is 129 minutes in an adult and 230 minutes in a neonate. As a result, higher levels of narcotics persist in the cerebrospinal fluid of neonates for longer periods. Some have asserted that narcotics should be used in infants younger than 6 months only when observation in an intensive care setting is possible or postoperative ventilation is planned.<sup>64</sup>
3. The management of pain in the pediatric population is hampered by the difficulty that exists in assessing pain. Many children may respond to pain by emotionally withdrawing from their surroundings, and this may be misinterpreted by the medical and nursing staffs as evidence that they have no pain. In addition, when questioned as to their degree of pain, children may not volunteer useful information for fear of painful interventions. To circumvent these difficulties, several

visual and verbal scales have been developed for quantifying painful sensations or describing typical painful behaviors. These have met with varying degrees of success because they are difficult to implement, are time consuming to use, and still rely on patient comprehension and cooperation.

4. Individual biases exist in medical professionals caring for children. These biases run from the belief that pain is a natural consequence of surgery to the beliefs that the risks of respiratory depression and narcotic addiction outweigh the benefits that are associated with aggressive pain management.

The mainstay in pain control remains the use of narcotics. Not only is a bewildering array of narcotics available, but the methods of their administration also are changing. Dose-dependent respiratory depression is common to all narcotics and goes hand in hand with their analgesic properties. Other side effects that vary from drug to drug and patient to patient are somnolence, nausea and vomiting, pruritus, constipation, and urinary retention. Given time, patients develop tolerance to most, if not all, of these side effects while they continue to experience their analgesic properties. The side effects may be treated symptomatically while tolerance is developing, thereby making the patient much more comfortable and manageable. Changing the narcotics will often reduce or eliminate the side effects.

Morphine remains the standard by which most pain therapy is measured. Some pharmacologic differences between morphine and other analgesics must be appreciated to use this narcotic well. Although morphine has roughly the same plasma elimination half-life as other narcotics, its effect and duration of action may have considerable variability because of the drug's low lipid solubility.

Because a poor correlation exists between the plasma concentration of morphine and its desired analgesic effect—a fourfold variation has been measured in the plasma concentration of morphine at which patients medicate themselves for pain—many clinicians believe that morphine is best administered in a patient-controlled device (patient-controlled analgesia [PCA]). As the patient experiences changes in the level of morphine in the central nervous system, he or she is able to administer supplemental doses.

PCA dosing recommendations for morphine include a loading dose ranging from 0.04 to 0.06 mg/kg followed by intermittent PCA doses of 0.01 to 0.03 mg/kg. A lockout interval of 6 to 15 minutes and 0.2 to 0.4 mg/kg every 4 hours is the limit generally used.

When PCA devices are not used, the intermittent administration of morphine to opioid-naïve children should be started at 0.05 to 0.1 mg/kg every 2 to 4 hours. If the treatment of pain is undertaken in a recovery room or intensive care setting, similar doses may be administered every 5 to 10 minutes until the child is comfortable. A background infusion approximately equivalent to one PCA dose per hour may be appropriate for patients with moderate to severe pain.

Patients with a background infusion should be continuously monitored for cardiorespiratory depression by telemetry and pulse oximetry.

Fentanyl is a synthetic narcotic that usually has a relatively short duration of action as a result of rapid distribution into fat and muscle because of its high lipid solubility. With repeated dosing, the duration of action appears to increase.<sup>65</sup> When compared with morphine, fentanyl is about 100 times more potent. (Fentanyl dosages are calculated in micrograms rather than milligrams.) In controlled comparisons with equipotent dosages, morphine is generally found to provide better analgesia than fentanyl but with more side effects such as pruritus, hypotension, nausea, and vomiting.<sup>66-68</sup> Fentanyl may also demonstrate much more rapid tolerance to its analgesic effects than morphine or hydromorphone.

When using fentanyl for procedures, incremental dosing of 0.25 to 0.5  $\mu\text{g}/\text{kg}$  every 5 minutes is safe. All of the respiratory depression from a single dose of fentanyl is evident within 5 minutes because of its rapid equilibration across the blood-brain barrier. The elimination rate of a single dose of fentanyl is reported to be about 1  $\mu\text{g}/\text{kg}/\text{hr}$ .<sup>69</sup> A safe cumulative dose for procedures is 2 to 5  $\mu\text{g}/\text{kg}$ .<sup>70</sup>

Other formulations of fentanyl have clinical applications in pain management. Although not approved for pediatrics at present, transdermal fentanyl, in doses of 25 to 100  $\mu\text{g}/\text{hr}$ , has proved more effective in the treating of chronic pain than some traditional modalities.<sup>71</sup>

Hydromorphone is a well-tolerated alternative to morphine and fentanyl and is associated with less pruritus and sedation than morphine. Moreover, it has a longer duration of action than fentanyl. It is five to seven times more potent than morphine. The dosing schedule for PCA hydromorphone uses a loading dose of 5 to 15  $\mu\text{g}/\text{kg}$ , a lockout of 6 to 15 minutes, supplemental PCA doses of 3 to 5  $\mu\text{g}/\text{kg}$ , and a 4-hour limit of 100  $\mu\text{g}/\text{kg}$ .

As more and more pediatric surgery is being performed on an outpatient basis, significant interest has developed in the role of non-narcotic analgesics for the management of postoperative pain. Many physicians have questioned the efficacy of acetaminophen for significant pain relief, although this may be more a question of the dosage used with recent investigators challenging established dosing recommendations for rectal administration.<sup>72,73</sup> Dosages for analgesia were based on recommendations for fever control (10 to 20 mg/kg), but these doses failed to produce serum levels shown to be effective even in reducing temperature. To achieve adequate serum levels for analgesia, doses of 30 to 40 mg/kg rectally are required. A dose of 30 mg/kg of acetaminophen rectally has proved to have analgesic properties similar to 1 mg/kg of ketorolac.<sup>74</sup>

Ketorolac is an oral and parenteral nonsteroidal anti-inflammatory drug shown to have excellent pain-control characteristics. Dosage recommendations are 0.5 mg/kg intravenously every 6 to 8 hours for 48 hours. Doses greater than 15 mg may yield diminishing analgesic return with increasing side effect profiles. Doses greater than 30 mg are generally not recommended. One of

the drawbacks associated with ketorolac is its inhibition of platelet aggregation, which has been associated with increased bleeding after tonsillectomy.<sup>75</sup> Attention must also be paid to patients with renal impairment, risk for gastric ulcers, and the question of poor union of extensive orthopedic repairs.

Clonidine has gained favor as an adjunct in regional anesthesia. A centrally acting  $\alpha_2$  agonist with a sedative effect, clonidine confers an analgesic benefit. It has been shown to increase the analgesic duration of caudal blocks by as much as 18 hours.<sup>76</sup> Clonidine has also been used effectively in epidural infusions. In adults, clonidine may carry a risk of hypotension, but this side effect is not prominent in children. Moreover, clonidine is not beset by problems of nausea and pruritus. For this reason, it has compared favorably as a substitute for neuraxial opioids, long the standard adjuvant to local anesthetics.

Regional anesthetic techniques used concomitantly with general anesthesia have had a resurgence in both adult and pediatric patients. These techniques include local infiltration of the wound, peripheral nerve blocks, and caudal, epidural, or spinal blocks. Part of the intent of these techniques is to prevent sensitization of the peripheral and central nervous systems, which could result in prolonged or excessive postoperative pain. This approach is often referred to as preemptive analgesia. Whether preemptive analgesia exists in children is still unresolved.<sup>77</sup> Anecdotal reports of improved, prolonged analgesia during the postoperative period when regional anesthetic techniques are used preemptively still await scientific validation.

In selected cases, peripheral nerve blocks appear to be a superior pain control modality. They offer the benefit of absent central side effects (nausea, pruritus, sedation, urinary retention) and can allow for faster recovery. It is increasingly common for these blocks to be performed under ultrasound guidance, which may, in some cases, confer increased accuracy and reduced time consumption.

Whether undergoing an operation on an inpatient or an outpatient basis, infants and children should be afforded maximal pain relief. Recent developments in and understanding of pain-relieving techniques place this goal within the reach of all clinicians caring for children during the postoperative period.

## Recovery and Criteria for Discharge

The recovery period for infants and children may be more crucial than for adult patients. Although the risks of intraoperative problems are similar in adults and children, 3% to 4% of infants and children have major complications in the recovery period, whereas only 0.5% of adults experience these complications. In general, children should be comfortable, awake, stable, off supplemental oxygen, have normal vital signs, and be able to take oral fluids before discharge from outpatient surgery. These variables have been quantified with the Modified Aldrete Score (Table 3-4), which lists the important factors taken into consideration for discharge.

**Table 3-4** Modified Aldrete Score

Variable*	Score
Able to move, voluntarily or on command	
• Four extremities	2
• Two extremities	1
• No extremities	0
Respiration	
• Able to breathe deeply and cough freely	2
• Tachypnea, shallow or limited breathing	1
• Apnea	0
Circulation	
• Blood pressure within 20 mm Hg of preoperative level	2
• Blood pressure within 20-50 mm Hg of preoperative level	1
• Blood pressure $\pm$ 50 mm Hg of preoperative level	0
Consciousness	
• Fully awake	2
• Arousable to voice	1
• Unresponsive	0
Oxygen saturation	
• > 92% on room air	2
• > 90% with oxygen	1
• < 90% with oxygen	0

\*These variables are taken into consideration for discharge from outpatient surgery.

Common impediments to discharge include pain, emergence delirium, nausea, laryngospasm or croup, and hypoxia. Because general anesthesia is nearly universal in children, regional anesthesia is less common than in adults. However, pediatric outpatients are excellent candidates for a host of regional blocks.<sup>78</sup> Some blocks require specialized equipment like a nerve stimulator or ultrasound, but others such as an ilio-inguinal block can be performed by landmarks alone. Local infiltration by the surgeon is encouraged when a neuraxial or peripheral block is not performed.

Emergence delirium is a vexing problem characterized by agitation in a child without apparent physiologic cause. The child is disoriented and often does not recognize his or her own parents. While not intrinsically dangerous, the problem is disturbing to parents and caregivers alike, poses a risk of self-injury, delays discharge, and invariably consumes recovery room resources. It is possible that sevoflurane, with its rapid elimination half-life, is more likely to be associated with emergence delirium.<sup>79</sup> However, other published data show no difference in emergence delirium relative to isoflurane.<sup>80</sup>

Postoperative nausea and vomiting (PONV) is most effectively managed with a combination of steroids (dexamethasone, 0.05-0.5 mg/kg) and serotonin antagonists as first-line therapy.<sup>81</sup> Adequate hydration and avoidance of nitrous oxide, volatile anesthetics (in favor of propofol), and neostigmine all are validated as reducing PONV. Metoclopramide, a commonly prescribed promotility drug, while possibly having a

salutary effect on intraoperative hiccups, bestows little benefit for PONV. Perhaps the most cost-effective perioperative antiemetic is droperidol. Unfortunately, its use has been dramatically curtailed due to a black box warning from the U.S. Food and Drug Administration regarding possible QT prolongation associated with its use. There is much disagreement about the data behind this warning.<sup>82</sup>

Respiratory complications are the most serious of the common problems seen after outpatient surgery. Laryngospasm, while possibly life threatening, is almost always transient and treatable by continuous positive mask pressure with a small dose of propofol (1-2 mg/kg) as an immediate backup. Rescue with succinylcholine is indicated at the first sign of relative bradycardia, which is often audible before it is visualized on an electrocardiogram. Postoperative croup is usually treatable with nebulized racemic epinephrine, and bronchospasm is managed with nebulized  $\beta$  agonists such as albuterol.

### Intraoperative Awareness

Intraoperative awareness is a rare condition in which surgical patients can recall their surroundings or an event and sometimes even pain related to their surgery while they were under general anesthesia. The definition of intraoperative awareness is becoming conscious during a procedure performed under general anesthesia and subsequently having recall of these events. Recall is explicit memory of specific events that took place during the general anesthesia. A Sentinel Event Alert was issued by the Joint Commission (JC) regarding the prevention and management of intraoperative awareness in October 2004. The ASA published a Practice Advisory for Intraoperative Awareness and Brain Functioning Monitoring in April 2006.<sup>83</sup>

The incidence of intraoperative awareness in adults has been reported to be 0.1% to 0.9% in older studies<sup>84</sup> and 0.0068% or 1 per 14,560 patients in a 2007 report of 87,361 patients. Most experts estimate the true incidence in adults to be 0.1% to 0.2%. There is a dearth of literature about intraoperative awareness in infants and children, but there is a 2005 study of 864 children in which there was a reported incidence of 0.8%.<sup>85</sup> Some of these data may be confounded by the memory of entering the operating room after administration of the preoperative sedation or a memory of emergence. Certainly, the likelihood of a clear memory of a painful surgery is a much rarer event than the generic incidence commonly reported. There are multiple adverse effects related to intraoperative awareness including post-traumatic stress disorder in adults and children and medical-legal implications. Therefore, it is important to understand the risk factors, preventive measures that can be taken, and management of the condition when it occurs.

Surgical and anesthetic risk factors for intraoperative awareness include cardiac surgery, cesarean section, trauma surgery, emergency surgery, the use of muscle relaxants with reduced anesthetic dosage, and the use of nitrous oxide/opioid anesthetics. Known

patient risk factors are substance use or abuse, previous intraoperative awareness, a history of difficult intubation or anticipated difficult intubation, and patients with opioid tolerance, such as chronic pain patients on high doses of opioid. Additionally, ASA class 4 or 5 patients and any patient with limited hemodynamic reserve are at risk for intraoperative awareness.

Preventive measures include conventional monitoring, equipment checklists, and verification of proper functioning of intravenous access, infusion pumps, and connections. Benzodiazepine prophylaxis should be selected on a case-by-case basis depending on the patient and surgical risk factors. The common use of volatile anesthetics in pediatrics should decrease the risk of intraoperative awareness. Detection of signs and symptoms of possible awareness intraoperatively may include hypertension, tachycardia, movement, lacrimation, sweating, and decreased lung compliance.

Brain function monitors have been suggested as a method of prevention, and the ASA practice advisory and the JC alert addressed this methodology in their reports. These monitors measure spontaneous electrical activity and convert a single channel of frontal electroencephalograph into an index of hypnotic level. The consensus of the ASA task force found that a specific numerical value may not correlate with a specific anesthetic depth and that the values do not have uniform sensitivity across different anesthetic drugs or types of patients. There is insufficient evidence to recommend the routine use of brain function monitors to either reduce the frequency of intraoperative awareness or monitor the depth of anesthesia. Both the ASA and the JC recommend case-by-case decision by the anesthesiologist for selected patients.<sup>83</sup>

These advisories recommend that the anesthesiologist may consider discussing the risk of intraoperative awareness with patients in substantially increased risk groups preoperatively. The patient can be reassured of the measures that will be taken to prevent intraoperative awareness and that if it occurs it is rarely associated with pain. If intraoperative awareness does occur, the anesthesiologist should discuss the episode with the patient to obtain details and discuss possible reasons for the event. Counseling or other psychological support should be offered.

It is important to remember that intraoperative awareness is a rare occurrence and usually not associated with pain. It is more likely to occur in high-risk surgery because of the need to maintain hemodynamic stability. Parental and patient questions should be referred to the anesthesiologist as soon as possible so that early intervention and counseling can be offered to lessen the resulting trauma.

### SEDATION

Twenty-five years ago, the American Academy of Pediatrics (AAP) asked the Section on Anesthesiology to develop guidelines for monitoring children undergoing sedation by non-anesthesiologists. That year, three children died in sedation disasters in a single

**Table 3-5** Current Definitions of Sedation Levels

<b>Analgesia</b>	Relief of pain without intentionally producing sedation
<b>Minimal sedation/ anxiolysis</b>	A drug-induced state during which the patient responds normally to verbal commands. Ventilatory and cardiovascular functions are unaffected.
<b>Moderate sedation/ analgesia</b>	A drug-induced state during which the patient responds purposefully to verbal commands and/or light touch. Airway and adequate ventilation are maintained without intervention and cardiovascular function is maintained.
<b>Deep sedation/ analgesia</b>	A drug-induced depression of consciousness during which the patient cannot be easily aroused but responds purposefully to noxious stimulation (reflex withdrawal). Assistance may be required to maintain airway and adequate ventilation. Cardiovascular function is usually maintained.
<b>General anesthesia</b>	A drug-induced loss of consciousness during which the patient is not arousable, even by painful stimulation (no reflex withdrawal). Assistance to maintain airway is often required, and positive-pressure ventilation may be required to maintain adequate ventilation. Cardiovascular function may be impaired.

dental office in California. At that time, an analysis of pediatric sedation by non-anesthesiologists revealed a disturbingly high morbidity and mortality rate. In the ensuing years, the AAP, the ASA, the American Academy of Pediatric Dentists (AAPD), and the American College of Emergency Physicians (ACEP) have worked independently and collectively to evaluate the problem, develop guidelines, and institute standardized practices. This has improved the safety of pediatric sedation in practices where these guidelines are followed.

A multidisciplinary review of over 600 adverse drug reports was undertaken and reviewed independently by two pediatric anesthesiologists, one pediatric emergency medicine specialist, and one pediatric critical care specialist, who then debated each case.<sup>86</sup> An epidemiologist/statistician then guided the group through the analysis of these events. The results demonstrated no relationship between adverse outcomes (death/neurologic injury) and route of drug administration (intravenous, nasal, rectal, intramuscular, oral, inhalation [nitrous oxide plus other sedatives]), or drug class. Failure to rescue the patient and inadequate cardiopulmonary resuscitation skills were the major contributing factors. Most of these patients presented with some form of respiratory depression. Other contributory causes were drug overdoses, drug-drug interactions, inadequate monitoring, inadequate recovery, prescription/transcription errors, drug administration without medical supervision, drug administration by a technician, inadequate equipment, and premature discharge from recovery or inadequate recovery procedures.

The major goals of procedural sedation are to provide anxiety relief, pain control, and reasonable movement control.<sup>87,88</sup> Inadequate sedation causes psychological trauma and difficulty completing a high-quality diagnostic or therapeutic procedure and results in excessively high cancellation rates for radiologic procedures.<sup>87,88</sup> In 2002 the AAP, ASA, and the JC all began to use the same sedation terminology, which recognizes the fact that “conscious sedation” is not realistic in children and that children younger than age 6 are considered to be deeply sedated from the beginning of the sedation process. Levels of sedation occur on a continuum, and it is difficult to predict

every patient’s response. For this reason, it is agreed by all groups that the practitioner must be able to rescue the patient from the next deeper level of sedation than the one targeted.<sup>89,90</sup> The current definitions of sedation levels are found in [Table 3-5](#).

The JC mandates standardization for sedation outside the operating room with processes similar to those utilized for monitored anesthesia care delivered by qualified anesthesia providers in the operating room.<sup>89</sup> The JC also requires that sedation practices throughout the hospital be “monitored and evaluated by the Department of Anesthesia.” In response to regulatory guidelines and in recognition of the need to institute a safe, systematic approach to sedation of children, many children’s hospitals have developed dedicated sedation services using experts (anesthesiologists or other highly trained individuals) to perform sedation rather than a variety of providers with a range of training. The benefits of this are many, including optimizing patient safety, reducing sedation failure rates to 0%, and meeting regulatory and administrative requirements.<sup>87,88</sup>

The principles outlined in the *2006 Guidelines for Monitoring and Management of Pediatric Patients During and After Sedation for Diagnostic and Therapeutic Procedures: An Update* are seen in [Table 3-6](#).<sup>91</sup> Appropriate monitoring of patients includes visual observation, pulse oximetry, and measurement of vital signs by an appropriately credentialed health care professional who is not performing the procedure. Capnography (noninvasive measurement of expired CO<sub>2</sub>) is mandated during general anesthesia and is now being encouraged during deep sedation by the JC and the AAP.<sup>92</sup> Several published studies have now demonstrated that the use of nasal or nasal/oral cannulas for continuous CO<sub>2</sub> analysis provides early detection of inadequate ventilation and prompts faster intervention.<sup>93-95</sup> This has been shown to decrease the number of episodes of oxygen desaturation.<sup>95</sup>

Credentialing and privileging practitioners for sedation requires adherence to federal, state, and local laws as well as governing bodies’ requirements for physicians, dentists, and nurses. Medical staff bylaws define credentialing requirements, which are also significantly influenced by the JC recognition that moderate and deep sedation are high-risk activities. Therefore,

**Table 3-6** The 2006 Guidelines for Monitoring and Management of Pediatric Patients during and after Sedation for Diagnostic and Therapeutic Procedures: An Update

- No administration of sedating medication without the safety net of medical supervision
- Pre-sedation evaluation of underlying medical or surgical conditions by the practitioner ordering the medication (JC requirement)
- Appropriate fasting for elective procedures, balancing the depth of sedation and risk for urgent procedures
- Focused airway examination for airway obstruction potential, such as large tonsils or anatomic airway abnormalities
- A clear understanding by the ordering practitioner of the pharmacokinetic and pharmacodynamic effects of the sedative medications, as well as an appreciation of drug interactions
- Appropriate training and skills in airway management to allow rescue of the patient
- Age- and size-appropriate equipment for airway management and venous access
- Appropriate medications and reversal agents
- Sufficient numbers of care providers to carry out the procedure and monitor the patient
- Appropriate monitoring during and after the procedure
- A properly equipped and staffed recovery area
- Recovery to pre-sedation level of consciousness before discharge from medical supervision
- Appropriate discharge instructions

From Coté CJ, Karl HW, Notterman DA, et al: Adverse sedation events in pediatrics: Analysis of medications used for sedations. *Pediatrics* 106: 633-644, 2000.

individuals seeking privileges for procedural sedation must meet threshold criteria.<sup>96</sup> Each practitioner must be a qualified, licensed professional with documented competency-based education, training, and experience in evaluating patients before sedation and performing moderate or deep sedation, including the ability to rescue patients who progress into a deeper-than-desired level of sedation. The individual must possess airway skills capable of managing a compromised airway and maintaining oxygenation and ventilation to qualify for moderate sedation privileges. For deep sedation privileges, the practitioner must be able to rescue the patient from general anesthesia and be able to manage an unstable cardiovascular system in addition to a compromised airway.<sup>96</sup> Each medical facility develops criteria based on these principles. For JC accreditation, the institution must be able to document that its system is safe and effective, with consistent quality improvement activities across the institution. In addition, the institution must be able to document that all

patients sedated by non-anesthesiologists are comparably assessed, monitored, discharged, and have similar sedation outcomes.<sup>89</sup>

## CONCLUSION

Many children who present for surgery are frightened and uncomfortable; it is the anesthesiologist's privilege to help calm and comfort these children. Guiding the child through an operation safely, amnestically, and under conditions amenable to the surgery are goals shared by both the anesthesiologist and surgeon alike. These shared goals are most likely to be met when surgical and anesthesia services communicate openly at the time of surgical scheduling, preoperatively, intraoperatively, and postoperatively. When such an understanding exists, the prospect of a child's operation proceeding safely, efficiently, and with a desired outcome is optimized.

# RENAL IMPAIRMENT

Uri S. Alon, MD • Bradley A. Warady, MD

## BODY FLUID REGULATION

Effective kidney function maintains the normal volume and composition of body fluids. Although there is a wide variation in dietary intake and nonrenal expenditures of water and solute, water and electrolyte balance is maintained by the excretion of urine, with the volume and composition defined by physiologic needs. Fluid balance is accomplished by glomerular ultrafiltration of plasma coupled with modification of the ultrafiltrate by tubular reabsorption and secretion.<sup>1,2</sup> The excreted urine, the modified glomerular filtrate, is the small residuum of the large volume of nonselective ultrafiltrate modified by transport processes operating along the nephron. The glomerular capillaries permit free passage of water and solutes of low molecular weight while restraining formed elements and macromolecules. The glomerular capillary wall functions as a barrier to the filtration of macromolecules based on their size, shape, and charge characteristics. The glomerular filtrate is modified during passage through the tubules by the active and passive transport of certain solutes into and out of the luminal fluid and the permeability characteristics of specific nephron segments. The transport systems in renal epithelial cells serve to maintain global water, salt, and acid-base homeostasis rather than to regulate local cellular processes, such as volume and metabolic substrate uptake, that occur in nonrenal epithelial cells.

An adequate volume of glomerular filtrate is essential for the kidney to regulate water and solute balance effectively. Blood flow to the kidneys accounts for 20% to 30% of cardiac output. Of the total renal plasma flow, 92% passes through the functioning excretory tissue and is known as the effective renal plasma flow. The glomerular filtration rate (GFR) is usually about one fifth of the effective renal plasma flow, giving a filtration fraction of about 0.2.

The rate of ultrafiltration across the glomerular capillaries is determined by the same forces that allow the transmural movement of fluid in other capillary networks.<sup>3</sup> These forces are the transcapillary hydraulic and osmotic pressure gradients and the characteristics

of capillary wall permeability. A renal autoregulatory mechanism enables the kidney to maintain relative constancy of blood flow in the presence of changing systemic arterial and renal perfusion pressures.<sup>1</sup> This intrinsic renal autoregulatory mechanism appears to be mediated in individual nephrons by tubuloglomerular feedback involving the macula densa (a region in the early distal tubule that juxtaposes the glomerulus) and the afferent and efferent arterioles. A decrease in arteriolar resistance in the afferent arteriole, with maintenance of the resistance in the efferent arteriole, sustains glomerular hydraulic pressure despite a decrease in systemic and renal arterial pressures.

Under normal conditions, the reabsorption of water and the reabsorption and secretion of solute during passage of the glomerular filtrate through the nephron are subservient to the maintenance of body fluid, electrolytes, and acid-base homeostasis. In the healthy, nongrowing individual, the intake and the expenditure of water and solute are equal and the hydrogen-ion balance is zero. Renal function may be impaired by systemic or renal disease and by medications such as vasoactive drugs, nonsteroidal anti-inflammatory drugs, diuretics, and antibiotics. Hypoxia and renal hypoperfusion appear to be the events most commonly associated with postoperative renal dysfunction.

## RENAL FUNCTION EVALUATION

The evaluation of kidney function begins with the history, physical examination, and laboratory studies. Persistent oliguria or significant impairment in renal concentrating capacity should be evident from the history. Examination of the urinary sediment may provide evidence of renal disease if proteinuria and/or cellular casts are present. Normal serum concentrations of sodium, potassium, chloride, total CO<sub>2</sub>, calcium, and phosphorus indicate appropriate renal regulation of the concentration of electrolytes in body fluids. The serum creatinine concentration is the usual parameter for GFR. Important limitations and caveats must be observed when using creatinine to estimate GFR.

Urinary creatinine excretion reflects both filtered and secreted creatinine because creatinine is not only filtered by the glomerular capillaries but also secreted by renal tubular cells. As a consequence, creatinine clearance, which is calculated by using serum creatinine concentration and the urinary excretion of creatinine, overestimates true GFR measured by using inulin clearance by 10% to 40%.<sup>4</sup> Serum creatinine concentration and the rate of urinary creatinine excretion are affected by diet. The ingestion of meat, fish, or fowl, which are substances containing preformed creatinine and creatinine precursors, causes an increase in serum creatinine concentration and in urinary creatinine excretion.<sup>5</sup> The overestimation of GFR by creatinine clearance increases as kidney function deteriorates owing to the relative increase in the tubular component of urine creatinine.

During the past 10 years, the serum concentration of cystatin C, a nonglycosylated 13.3-kD basic protein, has been shown to correlate with GFR as well as or better than serum creatinine.<sup>6-9</sup> From about age 12 months and up until age 50 years, normal serum cystatin C concentrations are similar in children and adults (0.70 to 1.38 mg/L). Beginning at about age 50 years, serum cystatin C concentration increases, related to the decline in GFR associated with age. Serum cystatin C concentration is not affected by gender, inflammatory conditions, or diet. Accurate automated systems allow the measurement of cystatin C.<sup>10</sup> At this time, the measurement of cystatin C has not been incorporated into routine clinical practice. However, in the near future, it may become a new tool in the assessment of GFR.

## Urine Volume

The appropriate urine volume in any situation depends on the status of body fluids, fluid intake, extrarenal losses, obligatory renal solute load, and renal concentrating and diluting capacity. Patients with impaired renal concentrating capacity require a larger minimal urinary volume for excretion of the obligatory renal solute load than do those with normal renal concentrating ability. Patients with elevated levels of antidiuretic hormone retain water out of proportion to solute and are prone to hyponatremia. Increased levels of antidiuretic hormone may occur because of physiologic factors such as hypertonicity of body fluids or decrease in the effective circulatory volume (as encountered with low levels of serum albumin or with generalized vasodilatation as in the sepsis syndrome).

Weight Range (kg)	Maintenance Water
2.5-10	100 mL/kg
10-20	1000 mL + 50 mL/kg > 10 kg
20	1500 mL + 20 mL/kg > 20 kg

Recently, some authors have expressed concern that “usual maintenance fluids” (Table 4-1), providing 2 to 3 mEq/L of sodium, potassium, and chloride per 100 calories metabolized, may contribute to the development of hyponatremia in children hospitalized with conditions likely to be associated with antidiuretic hormone excess.<sup>11</sup> The children at risk are those with nonosmotic stimuli for antidiuretic hormone release, such as central nervous system disorders, the postoperative state, pain, stress, nausea, and emesis. It has been proposed in patients prone to develop the syndrome of inappropriate secretion of antidiuretic hormone that isotonic 0.9% normal saline might be a better choice for maintenance fluid therapy.<sup>12</sup>

The urinary volume making the diagnosis of oliguric renal failure likely is based on an estimate of the minimal volume needed to excrete the obligatory renal solute load. The reference base for the calculation of urine volume is per 100 mL of maintenance water, not per kilogram of body weight.<sup>13</sup> The minimal urinary volume for excretion of the obligatory renal solute load is derived by using the following assumptions:

1. Approximately 30 mOsm of obligatory renal solute/100 mL of usual maintenance water is taken as the obligatory renal solute load in children aged 2 months and older.<sup>13</sup>
2. Urinary concentrating capacity increases rapidly during the first year of life and reaches the adult level of 1200 to 1400 mOsm/L at about the second year.<sup>14,15</sup> The maximum urinary concentrating capacity of the term infant from 1 week to 2 months of age is about 800 mOsm/L; from 2 months to 3 years, about 1000 mOsm/L; and beyond that age, about 1200 mOsm/L. Table 4-2 provides an estimate of the minimal urinary volumes that permit excretion of the obligatory renal solute load, assuming an appropriate physiologic response to renal hypoperfusion. The minimal urinary volumes have been calculated by dividing the expected obligatory renal solute load by the

Age	Assumptions		Urinary Volume	
	Renal Solute Load (mOsm/100 cal)	Maximum Urine Concentration (mOsm/kg)	Urine (mL) per 100 mL (per 24 hr)	Maintenance Water (per hr)
1 wk to 2 mo	25 (?)	800	31.3	1.3
2 mo to 2 yr	30 (?)	1000	25.0	1.0
2 yr	30	1200	20.8	1.0

maximal urinary concentrating capacity. Significantly lower urinary volumes are present among patients with oliguric acute renal failure (ARF). Noteworthy is the recent re-characterization of ARF as acute kidney injury (AKI) to better describe the renal dysfunction that has occurred.<sup>16,17</sup>

3. The presence of oliguric renal failure, based on urine volume, can be diagnosed only in the hydrated patient who has adequate blood pressure for renal perfusion and has no urinary tract obstruction. Oliguric AKI is probably not present in a newborn as old as 2 months with a urinary volume equal to or greater than 1.3 mL/hr/100 mL maintenance water or in an older patient with a urinary volume equal to or greater than 1.0 mL/hr/100 mL of maintenance water. Urine output less than these levels requires further evaluation for oliguric AKI.
4. Nonoliguric AKI occurs about as frequently as oliguric AKI. It is diagnosed when an adequately hydrated patient with normal blood pressure and urine volume has elevated serum creatinine and urea nitrogen concentrations. Some of the infants and children with nonoliguric AKI also have decreased serum bicarbonate and calcium concentrations and increased serum potassium and phosphorus concentrations.

### Glomerular Filtration Rate

GFR is the most useful index of renal function because it reflects the volume of plasma ultrafiltrate presented to the renal tubules. Decline in GFR is the principal functional abnormality in both acute and chronic renal failure. Assessment of GFR is important not only for evaluating the patient with respect to kidney function but also for guiding the administration of antibiotics and other drugs. Inulin clearance, which is the accepted standard for measurement of GFR, is too time consuming and inconvenient to be used in the clinical evaluation of most patients. Serum urea nitrogen concentration shows so much variation with dietary intake of nitrogen-containing foods that it is not a satisfactory index of GFR. Serum creatinine concentration and creatinine clearance have become the usual clinical measures for estimation of GFR. However, precautions should be taken when creatinine alone is used for estimation of GFR because of the effect of diet as well as common medications on serum creatinine concentration and excretion rate. Ingestion of a meal containing a large quantity of animal protein increases serum creatinine levels about 0.25 mg/dL in 2 hours and increases creatinine excretion rate about 75% over the next 3- to 4-hour period.<sup>5</sup> Serum creatinine concentrations are increased by ingestion of commonly used medications such as salicylate and trimethoprim.<sup>18,19</sup> These agents compete with creatinine for tubular secretion through a base-secreting pathway. They do not alter GFR but do elevate the serum creatinine concentration.

Because of the difficulties in timed urine collection, several equations have been developed to estimate GFR. The most commonly used is the one developed

by Schwartz<sup>20</sup> and is based on serum creatinine value and the child's height:

$$\text{GFR (mL/min/1.73m}^2\text{)} = \frac{k \times \text{Ht (cm)}}{\text{serum creatinine (mg/dL)}}$$

where k for low birth weight infants is 0.33, full-term infants, 0.45; males 2 to 12 and females 2 to 21 years old, 0.55; and males 13 to 21 years old, 0.70.

However, k value changes with creatinine analysis methodology (see later). Improvement in the precision of this formula can be achieved by formulas containing additional endogenous markers such as urea and cystatin C.<sup>20</sup>

Creatinine is formed by the nonenzymatic dehydration of muscle creatine, at a rate of 50 mg creatinine/kg muscle.<sup>4</sup> The serum creatinine concentration in the neonate reflects the maternal level for the first 3 to 4 days of life and somewhat longer in the premature infant. After this time, the serum creatinine concentration should decrease. From age 2 weeks to 2 years, the value averages about  $0.4 \pm 0.04$  mg/dL ( $35 \pm 3.5$   $\mu\text{M}$ ).<sup>21</sup> The serum creatinine concentration is relatively constant during this period of growth because the increase in endogenous creatinine production, which is directly correlated with muscle mass, is matched by the increase in GFR. During the first 2 years of life, GFR increases from 35 to 45 mL/min/1.73 m<sup>2</sup> to the normal adult range of 90 to 170 mL/min/1.73 m<sup>2</sup>. The normal range for serum creatinine concentration increases from 2 years through puberty, although the GFR remains essentially constant when expressed per unit of surface area. This occurs because growth during childhood is associated with increased muscle mass and, therefore, increased creatinine production, which is greater than the increased GFR per unit of body weight.<sup>21</sup> Table 4-3 shows the mean values and ranges for plasma or serum creatinine levels at different ages.<sup>22</sup> Normative data of serum creatinine may differ from one laboratory to another, based in large part on whether the Jaffe kinetic method or the enzymatic method is used for the creatinine determination, because the latter method provides lower values.<sup>23</sup> At present, most laboratories provide their normative range for age concomitantly with the reported result.

### Fractional Excretion of Substances

Fractional excretions are indexes of renal function that are helpful in evaluating specific clinical conditions. Conceptually, a fractional excretion is the fraction of the filtered substance that is excreted in the urine. Fractional excretions are calculated by using creatinine clearance to estimate GFR and the serum and urine concentrations of the substance studied.

#### Fractional Excretion of Sodium (FENa)

The normal FENa is usually less than 1% but may be elevated with high salt intake, adaptation to chronic renal failure, and diuretic administration.<sup>24</sup> When a decrease in renal perfusion pressure occurs, which is

**Table 4-3** Plasma Creatinine Levels at Different Ages

Age	Height (cm)	True Plasma Creatinine* (mg/dL)	
		Mean	Range ( $\pm 2$ SD)
Fetal cord blood		0.75	0.15-0.99
0-2 wk	50	0.50	0.34-0.66
2-26 wk	60	0.39	0.23-0.55
26 wk-1 yr	70	0.32	0.18-0.46
2 yr	87	0.32	0.20-0.44
4 yr	101	0.37	0.25-0.49
6 yr	114	0.43	0.27-0.59

Adapted from Changler C, Barratt TM: Laboratory evaluation. In Holiday MA (ed): Pediatric Nephrology, 2nd ed. Baltimore, Williams & Wilkins, 1987, pp 282-299.

common in intravascular volume depletion or congestive heart failure, the normal renal response results in a marked increase in the tubular resorption of sodium and water and in the excretion of a small volume of concentrated urine containing a small amount of sodium. This physiologic response to decreased renal perfusion is an FENa less than 1%. The FENa is usually greater than 2% in ischemic AKI (also known as acute tubular necrosis), reflecting the impaired ability of the tubules to reabsorb sodium.

When using FENa to aid in differentiating prerenal azotemia from AKI, it is essential that no recent diuretic therapy has been given. Another caveat is in the patient with a decrease in renal perfusion superimposed on chronic renal failure, in which case the tubules will not be able to preserve sodium in spite of the dehydration. However, with fluid and electrolyte replenishment, kidney function will improve to some extent. The FENa, as well as the other diagnostic indices used to help differentiate prerenal azotemia from ischemic AKI, are not pathognomonic for either disorder. Furthermore, the FENa is often less than 1% in cases of acute kidney injury due to a glomerular disease, in which tubular function remains intact. However, FENa provides helpful information when integrated into the overall clinical evaluation.

### Fractional Excretion of Bicarbonate (FEHCO<sub>3</sub><sup>-</sup>)

Renal tubular acidosis (RTA) describes a group of disorders in which metabolic acidosis occurs as a result of an impairment in the reclamation of filtered HCO<sub>3</sub><sup>-</sup> or as a result of a defect in the renal hydrogen ion excretion, in the absence of a significant reduction in GFR.<sup>25</sup> RTA is considered in the differential diagnosis of the patient with metabolic acidosis, a normal serum anion gap (hyperchloremic metabolic acidosis), and a urinary

pH above 6.0. However, a patient with proximal RTA, due to the decreased reclamation of filtered HCO<sub>3</sub><sup>-</sup>, may have a urinary pH below 6.0 when the plasma HCO<sub>3</sub><sup>-</sup> concentration is below the lowered renal threshold for HCO<sub>3</sub><sup>-</sup> reabsorption. Another exception, with respect to the presence of an elevated urinary pH in RTA, occurs in type IV RTA, a form of distal RTA in which the normal serum anion gap metabolic acidosis is associated with hyperkalemia. Also, under certain conditions, these patients might be able to lower their urine pH (see later).

Besides several genetic disorders such as cystinosis, proximal tubular damage is often seen in children receiving chemotherapy. The diagnosis of a defect in proximal tubular reabsorption of HCO<sub>3</sub><sup>-</sup> is made by showing that the FEHCO<sub>3</sub><sup>-</sup> is greater than 15% when the plasma HCO<sub>3</sub><sup>-</sup> concentration is normalized by sufficient alkalinization. This results in flooding of the distal nephron with HCO<sub>3</sub><sup>-</sup>, so the urine becomes highly alkaline. The FEHCO<sub>3</sub><sup>-</sup> is calculated just as is the FENa, but with serum and urine HCO<sub>3</sub><sup>-</sup> substituted for sodium. A normal individual ingesting a usual diet reabsorbs all the filtered HCO<sub>3</sub><sup>-</sup>, and the FEHCO<sub>3</sub><sup>-</sup> is zero. A urinary pH of 6.2 or less indicates that urinary HCO<sub>3</sub><sup>-</sup> excretion is negligible.

### Urinary Pco<sub>2</sub> or Urine Minus Blood Pco<sub>2</sub>

Classic distal RTA is caused by a defect in the secretion of H<sup>+</sup> by the cells of the distal nephron. It is characterized by hyperchloremic metabolic acidosis, urine with a pH greater than 6.0 at normal as well as at low serum HCO<sub>3</sub><sup>-</sup> concentrations, and an FEHCO<sub>3</sub><sup>-</sup> less than 5% when serum HCO<sub>3</sub><sup>-</sup> is normal.<sup>25,26</sup> Normally, the cells of the distal nephron secrete H<sup>+</sup> into the lumen where, in the presence of filtered HCO<sub>3</sub><sup>-</sup>, carbonic acid (H<sub>2</sub>CO<sub>3</sub>) is formed. Slow dehydration of the H<sub>2</sub>CO<sub>3</sub>

into  $\text{CO}_2 + \text{H}_2\text{O}$  in the medullary collecting ducts, renal pelvis, and urinary bladder results in urinary  $\text{PCO}_2$  greater than 80 mm Hg or urine minus blood (U-B)  $\text{PCO}_2$  greater than 30 mm Hg. Urinary  $\text{PCO}_2$  is evaluated after administering a single dose of sodium bicarbonate ( $\text{NaHCO}_3^-$ ) (2 to 3 mEq/kg) or acetazolamide ( $17 \pm 2$  mg/kg) to flood the distal nephron with  $\text{HCO}_3^-$ .<sup>27</sup> Rather than acetazolamide,  $\text{NaHCO}_3^-$  should be used in a patient with significantly reduced serum  $\text{HCO}_3^-$  levels at the time of the test. Urinary  $\text{PCO}_2$  should be measured only after urinary pH exceeds 7.4 or urinary  $\text{HCO}_3^-$  concentration exceeds 40 mEq/L or both. A defect in distal nephron secretion of  $\text{H}^+$  is diagnosed if U-B  $\text{PCO}_2$  is less than 20 mm Hg or urine  $\text{PCO}_2$  is below 60 mm Hg.

As noted earlier, type IV RTA, a form of distal RTA associated with low urinary pH (<6.0) and hyperkalemia, is a result of decreased  $\text{H}^+$  and  $\text{K}^+$  secretion in the distal tubule and is related to a failure to reabsorb sodium.<sup>25,26</sup> Type IV RTA is probably the most commonly recognized type of RTA in both adults and children. The hyperkalemia inhibits ammonia synthesis, resulting in decreased ammonia to serve as a urinary buffer. Therefore, a low urinary pH occurs despite decreased  $\text{H}^+$  secretion ( $\text{NH}_3 + \text{H}^+ = \text{NH}_4^+$ ). Type IV RTA is physiologically equivalent to aldosterone deficiency, which is one cause of the disorder. In children, it may reflect true hypoaldosteronism but it is much more common as a consequence of renal parenchymal damage, especially that due to obstructive uropathy. In pediatric patients, the physiologic impairment of type IV RTA resolves in a few weeks to months after relief of an obstructive disorder.<sup>2,8</sup>

## MEDICAL ASPECTS OF MANAGING THE CHILD WITH POSTOPERATIVE IMPAIRMENT OF RENAL FUNCTION

### Pathophysiology of Acute Kidney Injury

Acute kidney injury is characterized by an abrupt decrease in kidney function. Because AKI is caused by a decrease in the GFR, the initial clinical manifestations are elevations in serum urea nitrogen and creatinine concentrations and, frequently, reduction in urine output. Among pediatric surgical patients, an impairment in kidney function is most common in those who are undergoing cardiopulmonary procedures.<sup>29,30</sup> In recent years, research has focused on the identification of biomarkers that indicate imminent kidney failure, even before a rise in serum creatinine is noted.<sup>31</sup>

The most important factor in the pathogenesis of postoperative kidney failure is decreased renal perfusion. In the early phase, the reduction in renal blood flow results in a decline in GFR. Intact tubular function results in enhanced resorption of sodium and water. This clinical condition is recognized as prerenal azotemia. Analysis of the patient's urine reveals a high

urinary osmolality of greater than 350 mOsm/kg  $\text{H}_2\text{O}$  and a urine sodium concentration less than 10 mEq/L (20 mEq/L in the neonate).<sup>32</sup> The most useful index of the tubular response to renal hypoperfusion with intact tubular function is FENa. The FENa test is invalid if the patient received diuretics before giving the urine sample. When kidney function is intact in the hypoperfused state, FENa is less than 1% in term infants and children and below 2.5% in premature infants.<sup>33</sup> In most patients with prerenal azotemia, intravascular volume depletion is clinically evident. However, in patients with diminished cardiac output (pump failure), clinical appreciation of reduced renal perfusion can be obscured because body weight and central venous pressure may suggest fluid overload. Similarly, assessment of volume status is difficult in patients with burns, edema, ascites, anasarca, or hypoalbuminemia. The reduced effective intra-arterial volume might be evident from the reduced systemic blood pressure, tachycardia, and prolonged capillary refill time.

Prerenal azotemia can be alleviated by improving renal perfusion either by repleting the intravascular fluid volume or by improving the cardiac output. The improved kidney function is recognized by increased urine output and normalization of serum urea nitrogen and creatinine concentrations. However, if renal hypoperfusion persists for a significant period or if other nephrotoxic factors are present, parenchymal kidney failure can result. Factors that may predispose the patient to AKI include preexisting congenital urinary anomalies or impaired kidney functions, septicemia, hypoxemia, hemolysis, rhabdomyolysis, hyperuricemia, drug toxicity, and use of radiocontrast agents. On rare occasions, abdominal compartmental syndrome causing tense ascites may impair renal perfusion. In that setting, kidney failure may be alleviated by abdominal decompression.<sup>34</sup>

### Medical Management

The child with postoperative oliguria and an elevated serum creatinine concentration should be assessed for possible prerenal azotemia. If the child is found to be hypovolemic, an intravenous fluid challenge of 20 mL/kg of isotonic saline or plasma is commonly infused. In most instances, however, it may be physiologically advantageous to provide a solution in which bicarbonate accounts for 25 to 40 mEq/L of the anions in the fluid bolus (0.5 isotonic NaCl in 5% glucose, to which is added 25 to 40 mEq/L of 1 M  $\text{NaHCO}_3$  and additional NaCl or  $\text{NaHCO}_3$  to bring the solution to isotonicity). If no response is observed and the child is still dehydrated, the dose can be repeated. When the urine output is satisfactory after fluid replenishment, the child should receive appropriate maintenance and replacement fluids and should be monitored. Body weight, urinary volume, and serum concentrations of urea nitrogen, creatinine, and electrolytes also should be monitored.

If urinary output is inadequate after the fluid challenge, an intravenous infusion of furosemide, 1 mg/kg, may be given in a bolus. Patients with kidney

failure may require higher doses, up to 5 mg/kg. If no response occurs after the initial infusion of furosemide, a second, higher dose can be repeated after 1 hour. Some patients may require furosemide every 4 to 8 hours to maintain satisfactory urinary volume. A protocol with constant furosemide infusion has been successfully used in oliguric children after cardiac surgery.<sup>35</sup> Furosemide is infused at 0.1 mg/kg/hr, with the dose increased by 0.1 mg after 2 hours if the urinary volume remains less than 1 mL/kg/hr. The maximum dose is 0.4 mg/kg/hr. At times, urine output can be increased by the use of vasoactive agents such as dopamine. However, their efficacy in otherwise altering the course of AKI is not well established.<sup>36-39</sup> It is of utmost importance to maintain adequate blood pressure and effective renal plasma flow.

Careful monitoring of the patient's fluid and electrolyte status is essential. Those children who fail to respond to furosemide are at risk for fluid overload. Overzealous fluid administration during anesthesia and surgery and for the management of persistent hypoperfusion, along with decreased urinary output, can result in hypervolemia, hypertension, heart failure, and pulmonary edema. In extreme cases, fluid administration must be decreased to the minimum necessary to deliver essential medications. In less severe instances, and in euvolemic patients with impaired kidney function, total fluid intake should equal insensible water loss, urine volume, and any significant extrarenal fluid losses. Urine output must be monitored hourly, and fluid management must be re-evaluated every 4 to 12 hours, as clinically indicated. Valuable information about the patient's overall fluid status can be obtained by carefully monitoring blood pressure, pulse, and body weight. The preoperative values of these parameters help serve as a baseline for postoperative evaluation. Ideally, the patient's hemodynamic status should be assessed continuously by using central venous pressure monitoring. In patients with complicated cardiac problems, a Swan-Ganz catheter that monitors pulmonary wedge pressure should be used.

Fluid overload can lead to hyponatremia. In most cases, because total body sodium remains normal or high, the best way to normalize serum sodium concentration is by restriction of fluid intake and enhancement of urinary volume.<sup>40</sup> In patients with acute symptomatic hyponatremia, careful infusion of NaCl 3% solution (512 mEq Na/L or 0.5 mEq/mL) may be given to correct hyponatremia. Rapid correction at a rate of 1 to 2 mEq/hr over a 2- to 3-hour period, with an increase of serum sodium level by 4 to 6 mEq/L, is usually well tolerated and adequate. Infusion of 6 mL/kg of 3% NaCl increases serum sodium concentration by about 5 mEq/L. Hyponatremia present for more than 24 to 48 hours should not be corrected at a rate more rapid than 0.5 mEq/L/hr.

In children with AKI, hyperkalemia often develops. The early sign of potassium cardiotoxicity is peaked T waves on the electrocardiogram. Higher levels of serum potassium can cause ventricular fibrillation and cardiac asystole. The treatment of hyperkalemia is shown in Table 4-4. Emergency treatment of

**Table 4-4 Treatment of Hyperkalemia**

**Cardiac Protection**

Calcium gluconate, 10%, 0.5-1.0 mL/kg body weight injected intravenously and slowly over 5-10 min, with continuous monitoring of heart rate

**Shift of Potassium into the Intracellular Compartment**

Sodium bicarbonate, 1-2 mEq/kg body weight intravenously over 10-20 min, provided that salt and water overload is not a problem

Glucose, 1g/kg body weight, and insulin, 1 unit per every 4 g of glucose, intravenously over 20-30 min

Stimulants of  $\beta_2$ -adrenergic receptors, such as salbutamol, intravenously or by inhalation

**Elimination of Excess Potassium**

Furosemide 1mg/kg, or higher in the face of decreased GFR

Cation exchange resin, sodium polystyrene sulfonate, 1 g/kg body weight, administered orally or rectally in 20% to 30% sorbitol or 10% glucose, 1 g resin/4 mL. Additional 70% sorbitol syrup may be given if constipation occurs

**Dialysis**

hyperkalemia is indicated when the serum potassium concentration reaches 7.0 mEq/L or when electrocardiographic changes are noted.

In children with AKI, metabolic acidosis rapidly develops. Owing to decreased kidney function, fewer hydrogen ions are excreted. Organic acids accumulate in the body, causing a reduction in the serum  $\text{HCO}_3^-$  concentration. Although a child with uncompromised ventilatory capacity is able to hyperventilate and achieve partial compensation, a child with compromised pulmonary function or a hypercatabolic state is at risk for profound acidosis. Metabolic acidosis is usually treated by administering  $\text{NaHCO}_3^-$ . However, attention should be directed toward the excess sodium load associated with this mode of therapy. Because hypocalcemia develops in many patients with AKI, treatment with alkali should be done with care to protect them from hypocalcemic tetany due to a shift of ionized calcium from free to albumin bound. It is not necessary to correct the metabolic acidosis completely to prevent the untoward effects of acidemia. Increasing the serum  $\text{HCO}_3^-$  concentration to 15 mEq/L is usually satisfactory.<sup>41</sup>

**Dialysis**

The inability to control medically the fluid and electrolyte or acid-base disorders caused by renal failure necessitates the initiation of dialysis therapy. The indications for urgent dialysis are persistent oligoanuria, hyperkalemia, metabolic acidosis, fluid overload, severe electrolyte and mineral disturbances, and uremic syndrome.

The most common indication for postoperative dialysis in a child is hypervolemia caused by repeated attempts at fluid resuscitation, administration of medications, and total parenteral nutrition.<sup>42</sup> Repeated intravenous catheter flushes and endotracheal tube

lavages can add a significant amount of water and solute to the total intake. Fluid overload in the postoperative patient can cause pulmonary edema and hypertension.

### Dialysis Therapy

The three modes of dialysis therapy include hemodialysis (HD), peritoneal dialysis (PD), and continuous renal replacement therapy (CRRT). Although PD has historically been used most often in children, more recent data have revealed an increased use of CRRT in those centers where the expertise and resources are available.<sup>42,43</sup> Recognition of the needs of the patient, the resources of the treating facility, and the advantages and disadvantages of each dialytic technique dictate which modality is best (Table 4-5).<sup>42</sup>

The intrinsic factors that affect the efficacy of PD include peritoneal blood flow, peritoneal vascular permeability, and peritoneal surface area.<sup>44</sup> Although removal of up to 50% of the peritoneal surface area does not seem to interfere with dialysis efficacy,<sup>45</sup>

hypoperfusion of the peritoneal membrane vasculature renders dialysis ineffective.<sup>46</sup> PD is feasible in the postoperative patient even in the presence of peritonitis or immediately after major abdominal procedures.<sup>47-49</sup> However, it is contraindicated in the presence of a diaphragmatic defect. Increased intra-abdominal pressure caused by the intraperitoneal administration of dialysis fluid can cause respiratory embarrassment and contribute to fluid leakage from the sites of surgical incisions and the entrance of the peritoneal catheter. Under such circumstances, the smallest effective dialysis fluid volume is used. It can be gradually increased over time. Common complications associated with PD are peritonitis, exit-site infection, dialysate leakage, catheter obstruction from omentum or fibrin, and abdominal wall hernia. The provision of antibiotics at the time of catheter placement may decrease the risk of peritonitis.<sup>50</sup> The use of fibrin glue at the site of catheter entry into the peritoneum has been associated with a decreased incidence of dialysate leakage during the immediate postoperative period.<sup>51</sup> A rare complication is abdominal organ perforation, seen most commonly

with the use of stiff dialysis catheters.<sup>52</sup> A study in 2000 showed placement of a Tenckhoff catheter to be superior to use of the stiffer Cook catheter (Cook Medical, Bloomington, IN) in terms of complication-free survival.<sup>53</sup> More recently, there is evidence for equal outcomes with the Cook Multipurpose Drainage catheter, a flexible catheter that is placed at the bedside, in contrast to the Tenckhoff catheter, which typically requires surgical placement.<sup>54</sup>

PD is performed with dialysis solutions that contain a 1.5%, 2.5%, or 4.25% glucose concentration. Dialysate with a 1.5% glucose concentration has an osmolality of 350 mOsm/kg H<sub>2</sub>O, which is moderately hypertonic to normal plasma (280 to 295 mOsm/kg H<sub>2</sub>O). With increased glucose concentration, the tonicity of the solution increases, reaching 490 mOsm/kg H<sub>2</sub>O with 4.25% glucose, the highest concentration commercially available. Other factors being equal, the higher the tonicity of the dialysate, the greater the ultrafiltrate (fluid removed from the body). Owing to the rapid movement of water and glucose across the peritoneal membrane, the effect of PD on fluid removal is maximal when short dialysis cycles of 20 to 30 minutes are used. When solutions containing glucose concentrations higher than 1.5% are used, close monitoring of the patient's serum glucose concentration is necessary. If hyperglycemia with a blood glucose concentration of greater than 200 mg/dL develops, it can be controlled by the addition of insulin to the dialysate solution or by intravenous insulin drip. The volume of fluid removed by dialysis in a 24-hour period should generally be limited to 500 mL in the neonate, ranges from 500 to 1000 mL in infants and 1000 to 1500 mL in young children, and should be limited to 3000 mL in children weighing more than 30 kg.<sup>55</sup> The effect of dialysis on the removal of solutes depends mainly on the length of the dwell time of the dialysate within the peritoneal cavity and the molecular weight of the solute. The following are the relative rates of diffusion of common substances: urea > potassium > sodium > creatinine > phosphate > uric acid > calcium > magnesium. Standard dialysate solutions do not contain potassium.<sup>56</sup> Therefore, hyperkalemia may be controlled with a few hours of effective PD.

Hemodialysis has the advantage of more rapid ultrafiltration and solute removal than either PD or CRRT. It is technically more difficult to perform than PD and thus requires particular expertise of the personnel conducting the procedure. Adequate vascular access is the most important requirement, and a variety of temporary pediatric catheters are available.<sup>57</sup> Ideally, placement of the dialysis catheter in the subclavian vein should be discouraged because of the potential development of subclavian stenosis and the subsequent inability to create a dialysis fistula in the ipsilateral arm of those patients who go on to develop end-stage renal disease. The intermittent nature of HD requires that fluid restriction be instituted in the patient who is anuric to help prevent the development of hypervolemia. Fluid removal can also be problematic in the patient who is hypotensive and receiving HD because

of poor patient tolerance and is better accomplished by either PD or CRRT in this clinical setting.

The types of CRRT consist of continuous venovenous hemodialysis (CVVHD), continuous venovenous hemofiltration (CVVH), and continuous venovenous hemodiafiltration (CVVHDF). Although the complexity and cost of CRRT precludes its potential for global utilization, it is now widely practiced in many tertiary pediatric centers because of the safety and efficacy of the procedure in even the sickest patients. The choice of one method of CRRT over another depends on whether one chooses to make use of the diffusive (CVVHD) or convective (CVVH) method or a combination of the two (CVVHDF) properties of the technique. As in HD, a well-functioning vascular access is crucial to the performance of CRRT. Recent data suggest that the optimal access is the one with the largest diameter, preferably located within the internal jugular vein.<sup>58</sup> Likewise, large extracorporeal blood volumes are necessary for the CRRT (and HD) circuit and require the use of blood products in the small patient in whom the circuit volume exceeds 10% of the patient's blood volume. Particular attention must be paid to the possible development of hemofilter-related reactions that might occur with the initiation of therapy.<sup>59,60</sup> The predictability and efficiency of ultrafiltration and solute removal make CRRT an ideal dialytic technique for hemodynamically unstable patients. The capability of removing fluid in a well-controlled, continuous manner also makes adequate nutritional delivery possible. In children at risk for hemorrhage, a protocol using citrate instead of heparin as the anticoagulant has been developed.<sup>61,62</sup> Finally, although it is well recognized that the institution of dialysis is indicated for the control of solute and fluid removal, new information has provided direction regarding the preferred timing of dialysis initiation. Fluid overload itself appears to be a significant risk factor for mortality, and its early and aggressive management with dialysis may prove particularly beneficial.<sup>63</sup>

## ACUTE KIDNEY INJURY IN THE NEONATE

Acute kidney injury occurs in as many as 24% of all patients admitted to the neonatal intensive care unit.<sup>39,64,65</sup> The definition of AKI in a term neonate is most often considered to be a serum creatinine level above 1.5 mg/dL for more than 24 hours in the setting of normal maternal renal function.<sup>66</sup> On occasion, it may be diagnosed in the term infant with a serum creatinine value less than 1.5 mg/dL when it fails to decrease in a normal manner over the initial days/weeks of life.<sup>67-69</sup> The limited availability of cystatin C data from the neonatal population currently precludes its routine use to define AKI.<sup>70,71</sup>

AKI is of the oliguric variety when the elevated serum creatinine concentration is accompanied by a urine output below 1 mL/kg/hr after the initial 24 hours of life and when urine output fails to improve in response to a fluid challenge.<sup>68,72</sup> In contrast, in some neonates,

solute retention develops, as evidenced by an elevated serum creatinine level, with a normal (>1.0 mL/kg/hr) urine flow rate. These neonates are diagnosed as having nonoliguric AKI.<sup>73</sup> The nonoliguric form is particularly common in neonates with AKI secondary to perinatal asphyxia and appears to be associated with a better prognosis than does the oliguric form.<sup>69,73</sup> The diagnosis of nonoliguric AKI can be missed if patients at risk for developing renal insufficiency are monitored solely by the evaluation of urine output without repeated assessments of the serum creatinine concentration.

The causes of AKI traditionally have been divided into three categories: prerenal, intrinsic, and postrenal (Table 4-6). This division, based on the site of the lesion, has important implications because the evaluation, treatment, and prognosis of the three groups can be quite different.

### Prerenal Acute Kidney Injury

Impairment of renal perfusion is the cause of 70% of AKI during the neonatal period.<sup>39,64,65,67-69</sup> Prerenal AKI may occur in any patient with hypoperfusion of an otherwise normal kidney. Although prompt correction of the low perfusion state usually reverses kidney function impairment, delay in fluid resuscitation may result in renal parenchymal damage.

### Intrinsic Acute Kidney Injury

Intrinsic AKI occurs in 6% to 8% of admissions to the neonatal intensive care unit and implies the presence of renal cellular damage associated with impaired kidney function.<sup>67</sup> Intrinsic AKI usually falls into one of the following categories: ischemic (acute tubular necrosis), nephrotoxic (aminoglycoside antibiotics, indomethacin), congenital renal anomalies (autosomal recessive polycystic kidney disease), and vascular lesions (renal artery or vein thrombosis, especially with a solitary kidney).<sup>74</sup>

### Postrenal Acute Kidney Injury

Postrenal AKI results from obstruction of urine flow from both kidneys or from a solitary kidney. The most common causes of postrenal AKI in neonates are posterior urethral valves, bilateral ureteropelvic junction obstruction, and bilateral ureterovesical junction obstruction.<sup>75,76</sup> Although these types of obstructions are characteristically reversible, neonates with long-standing intrauterine obstruction have varying degrees of permanent impairment of renal function.<sup>77,78</sup> This impairment may be due not only to the presence of renal dysplasia but also to cellular damage secondary to AKI.

### Clinical Presentation

Clinical presentation of the neonate with AKI often reflects the condition that has precipitated development of the renal insufficiency. Accordingly, sepsis, shock, dehydration, severe respiratory distress

**Table 4-6**

### Major Causes of Acute Renal Failure in the Newborn

#### Prerenal Failure

- Systemic hypovolemia: fetal hemorrhage, neonatal hemorrhage, septic shock, necrotizing enterocolitis, dehydration
- Renal hypoperfusion: perinatal asphyxia, congestive heart failure, cardiac surgery, cardiopulmonary bypass/extracorporeal membrane oxygenation, respiratory distress syndrome, pharmacologic (tolazoline, captopril, enalapril, indomethacin)

#### Intrinsic Renal Failure

- Acute tubular necrosis
- Congenital malformations: bilateral agenesis, renal dysplasia, polycystic kidney disease
- Infection: congenital (syphilis, toxoplasmosis), pyelonephritis
- Renal vascular: renal artery thrombosis, renal venous thrombosis, disseminated intravascular coagulation
- Nephrotoxins: aminoglycosides, indomethacin, amphotericin B, contrast media, captopril, enalapril, vancomycin
- Intrarenal obstruction: uric acid nephropathy, myoglobinuria, hemoglobinuria

#### Postrenal (Obstructive) Renal Failure

- Congenital malformations: imperforate prepuce, urethral stricture, posterior urethral valves, urethral diverticulum, primary vesicoureteral reflux, ureterocele, megacystis megoureter, Eagle-Barrett syndrome, ureteropelvic junction obstruction, ureterovesical obstruction
- Extrinsic compression: sacrococcygeal teratoma, hematocolpos
- Intrinsic obstruction: renal calculi, fungus balls
- Neurogenic bladder

Adapted from Karlowicz MG, Adelman RD: Acute renal failure in the neonate. *Clin Perinatol* 19:139-158, 1992.

syndrome, and other related conditions may be present. Nonspecific symptoms related to uremia, such as poor feeding, lethargy, emesis, seizures, hypertension, and anemia, also are frequently present.

### Diagnostic Evaluation

Evaluation of the neonate with AKI should include a thorough patient and family history and a physical examination. Suspected prerenal causes of acute oliguria are usually addressed diagnostically and therapeutically by volume expansion, with or without furosemide. If this approach does not result in increased urine output, a more extensive evaluation of kidney function is indicated.

Laboratory studies are an important component of the evaluation and should include the following measures: complete blood cell count and determination of serum concentrations of urea nitrogen, creatinine, electrolytes, uric acid, calcium, glucose, and phosphorus. The serum creatinine value during the first several days of life is a reflection of the maternal value. In term infants, a value of 0.4 to 0.5 mg/dL is expected after the first week of life. In contrast,

the expected value in preterm infants is related to their gestational age, with an initial increase followed by a gradual decrease.<sup>79,80</sup> In all cases, a urinalysis should be obtained to check for the presence of red blood cells, protein, and casts suggestive of intrinsic renal disease.

Urine indices can help distinguish intrinsic renal failure from prerenal azotemia in the oliguric patient.<sup>36-38</sup> As mentioned previously, the index usually found to be most useful is the FENa. This factor is based on the assumption that the renal tubules of the poorly perfused kidney reabsorb sodium avidly, whereas the kidney with intrinsic renal disease and tubular damage is unable to do so. Accordingly, in most cases of neonatal oliguric renal failure secondary to intrinsic disease, the FENa is greater than 2.5% to 3.0%, a value that is different from that of the older child.<sup>39,65,72,81</sup> The FENa should be measured before administering furosemide. In addition, the results should be interpreted with caution in the very premature infant who normally has an even higher (i.e., > 5%) FENa.<sup>66,81,82</sup>

Ultrasonography commonly is the initial imaging study performed.<sup>83</sup> The urinary tract should be evaluated for the presence of one or two kidneys and for their size, shape, and location. Dilation of the collecting system and the size and appearance of the urinary bladder should be evident. A voiding cystourethrogram (VCUG) may also be necessary, specifically when the diagnosis of posterior urethral valves or vesicoureteral reflux is entertained. In most cases, a VCUG is deemed preferable to radionuclide cystography in this setting because of its superior ability to provide reliable anatomic information about the grading of vesicoureteral reflux or the appearance of the urethra.<sup>84</sup> Antegrade pyelography or diuretic renography with either <sup>99m</sup>Tc-dimercaptosuccinic acid (DMSA) or <sup>99m</sup>Tc-mercaptoacetyl triglycine (MAG<sub>3</sub>) as the radiopharmaceutical agent may be needed to evaluate for ureteral obstruction. Finally, radiologic assessment of the differential kidney function may be performed with radioisotope scanning as well.

## Management

The treatment of neonatal AKI should proceed simultaneously with the diagnostic workup. Bladder catheter placement is a good immediate therapy for posterior urethral valves, whereas high surgical drainage may be needed for other obstructive lesions in the neonate. The fluid challenge for the neonate should consist of 20 mL/kg of an isotonic solution containing 25 mEq/L of NaHCO<sub>3</sub><sup>-</sup> infused over a 1- to 2-hour period. In the absence of a prompt diuresis of 2 mL or more of urine per kilogram during 1 to 2 hours, intravenous furosemide at 1 to 3 mg/kg may be helpful. As noted previously, the potential role of low-dose (0.5 to 3.0 µg/kg/min) dopamine continues to be debated.<sup>37,38</sup> The failure to achieve increased urinary output after volume expansion in the neonate with an adequate cardiac output (i.e., renal perfusion) and an unobstructed urinary tract indicates the presence of intrinsic kidney disease and the need to manage oliguric or anuric kidney failure appropriately.

Maintenance of normal fluid balance is of primary concern in the management of the patient with AKI. Daily fluid intake should equal insensible water loss, urine output, and fluid losses from nonrenal sources. In term infants, insensible water losses amount to 30 to 40 mL/kg/day, whereas premature infants may require as much as 50 to 100 mL/kg/day.<sup>82,85</sup> A frequent assessment of the neonate's body weight is essential for fluid management. The electrolyte content of the fluids administered should be guided by frequent laboratory studies. Insensible water losses are electrolyte free and should be replaced by using 5% dextrose in water.

Important systemic disturbances that may arise secondary to AKI include hyperkalemia, hyponatremia, hypertension, hypocalcemia, hyperphosphatemia, and metabolic acidosis. All exogenous sources of potassium should be discontinued in patients with AKI. Despite this restriction, elevated serum potassium levels develop in many neonates and must be treated aggressively owing to the potential for cardiac toxicity.<sup>33,68</sup> Treatment should be initiated by correction of metabolic acidosis with NaHCO<sub>3</sub><sup>-</sup>. One to 2 mEq/kg should be given intravenously over a 10- to 20-minute period, provided that salt and water balance is not problematic. The quantity of NaHCO<sub>3</sub><sup>-</sup> to be prescribed also can be calculated in the following manner: (0.3 × body weight [kg] × base deficit [mM]).<sup>68</sup> Associated hypocalcemia should be treated with the intravenous administration of 10% calcium gluconate at a dose of 0.5 to 1.0 mL/kg injected slowly over a 5- to 15-minute period with continuous monitoring of the heart rate. If a progressive increase in the serum potassium concentration is noted, additional treatment measures may include the use of a sodium-potassium exchange resin (sodium polystyrene sulfonate in 20% to 30% sorbitol, 1 g/kg by enema), with recognition of its frequent ineffectiveness and/or associated complications when used in low birth weight infants.<sup>86</sup> The use of glucose (0.5 to 1.0 g/kg) followed by insulin (0.1 to 0.2 unit regular insulin per gram glucose over a 1-hour period) may be the preferred approach. Either intravenous salbutamol or inhaled albuterol is an additional therapeutic option.<sup>87-89</sup> Dialysis should be considered if these measures prove unsuccessful.<sup>89</sup>

Hyponatremia and systemic hypertension are most often related to overhydration in the infant with oliguria. These problems should be treated initially with fluid restriction or water removal with dialysis, if necessary. The addition of high-dose intravenous furosemide (5 mg/kg) may be beneficial. Serum sodium levels below 125 mEq/L can be associated with seizures, and levels below 120 mEq/L should be corrected rapidly to at least 125 mEq/L by calculating the amount of sodium required in the following manner:

$$\text{Na}^+ \text{ (mEq)} = ([\text{Na}^+] \text{ Desired} - [\text{Na}^+] \text{ Actual}) \times \text{Weight (kg)} \times 0.8$$

When serum sodium levels are less than 120 mEq/L and are associated with symptoms (e.g., seizures), prompt treatment with hypertonic (3%) saline is

indicated. The provision of 10 to 12 mL/kg of 3% saline is generally therapeutic.

The treatment of persistent hypertension may include parenterally administered hydralazine (0.1 to 0.6 mg/kg/dose), labetalol (0.20 to 1.0 mg/kg/dose or 0.4 to 3.0 mg/kg/hr infusion), or enalaprilat (5.0 to 10 µg/kg/dose). Orally administered amlodipine (0.06 to 0.6 mg/kg/day) can be prescribed for the patient who is without symptoms. Treatment of the patient with marked or refractory hypertension can include intravenous sodium nitroprusside (0.5 to 10 µg/kg/min infusion), nicardipine (0.5 to 3 µg/kg/min infusion), or labetalol.<sup>90</sup> Caution should be exercised when initiating therapy with captopril (initial oral dose, 0.01 to 0.05 mg/kg/dose), owing to the profound hypotension that can occur in neonates in association with higher doses.<sup>68,91,92</sup>

In the infant in whom AKI does not fully resolve and becomes chronic renal failure, hyperphosphatemia (serum phosphorus level > 7 mg/dL) necessitates the use of a low phosphorus infant formula and calcium carbonate (50 to 100 mg/kg/day) as a phosphate binder.<sup>93</sup> The use of aluminum hydroxide as a binder is contraindicated, owing to its association with aluminum toxicity in infants and children with renal insufficiency.<sup>94</sup> No experience has been published about the use of newer phosphate-binding agents, such as sevelamer, in the neonatal population.<sup>95-97</sup>

Hypocalcemia, as reflected by a low total serum calcium level, often occurs in AKI in association with hypoalbuminemia. Less commonly, the ionized calcium level is low and the patient is symptomatic. In these cases, intravenous 10% calcium gluconate, 0.5 to 1.0 mL/kg, over a 5-minute period with cardiac monitoring should be given until the ionized calcium level is restored to the normal range.<sup>68</sup> It is important to remember that permanent correction of a low serum calcium level can be achieved only by oral supplementation of calcium and active vitamin D metabolites.

Metabolic acidosis may arise as a result of retention of hydrogen ions and may require  $\text{NaHCO}_3^-$  for correction. The dose of  $\text{NaHCO}_3^-$  to be given can be calculated as follows:

$$\text{NaHCO}_3^- \text{ (mEq)} = (\text{Desired bicarbonate} - \text{Observed bicarbonate}) \times \text{Weight (kg)} \times 0.5$$

This dose may be given orally or added to parenteral fluids and infused during several hours.

Adequate nutrition should be provided, with the goal of 100 to 120 calories and 1 to 2 g of protein/kg/day, provided intravenously or orally. For neonates who can tolerate oral fluids, a formula containing low levels of phosphorus and aluminum, such as Similac PM 60/40 (Abbott Labs, Abbott Park, IL), is recommended. An aggressive approach to nutrition may well contribute to kidney recovery by providing necessary energy at the cellular level.<sup>33</sup>

Although most neonates with AKI can be managed conservatively, occasional patients require PD or CRRT for the treatment of the metabolic complications and fluid overload.<sup>55,98-100</sup> The mortality rate in this group

of patients commonly exceeds 60%. Twenty-three patients who received PD at Children's Mercy Hospital during the neonatal period had a mortality rate of 35% at 1 year.<sup>101</sup> The somewhat lower mortality rate in our center probably reflects the improved outcome of neonates with renal structural abnormalities leading to AKI (17% mortality rate) compared with those infants with multisystem disease. In a report of 12 neonates in whom AKI developed after cardiac surgery and who received CVVH, 7 (59%) of the infants survived and no complications were noted related to the hemofiltration procedure.<sup>102</sup> In another report, on the use of CRRT in 85 children weighing less than 10 kg, 16 weighed less than 3 kg.<sup>100</sup> In these patients, the procedure was well tolerated, other than for the need of pressor support, with survival rates of 25% and 41% for those weighing less than 3 kg and from 3 to 10 kg, respectively. When CRRT is used with infants receiving extracorporeal membrane oxygenation, excessive hemolysis has been documented on occasion.<sup>103</sup>

## OBSTRUCTIVE UROPATHY

Obstructive uropathy in the neonate is the most common renal abnormality diagnosed prenatally and is most often the result of ureteropelvic junction obstruction, posterior urethral valves, or ureterovesical junction obstruction.<sup>75</sup> Obstruction also represents a significant cause of end-stage renal disease in children, accounting for 13% of all cases, and is the underlying cause of end-stage renal disease in nearly 90% of affected boys younger than age 4 years.<sup>104-106</sup> Accordingly, early recognition and treatment of these lesions are desirable because of the adverse effects obstruction can have on kidney function.<sup>40,41,77,78,107</sup> Regardless, after surgical intervention and relief of obstruction, alterations of GFR, renal blood flow, and renal tubular function may occur.<sup>78,107,108</sup> Specifically, injury to the renal tubule may result in an impaired capacity to reabsorb sodium, to concentrate urine, and to secrete potassium and hydrogen, all of which may have profound clinical implications. The resorption of other solutes, such as magnesium, calcium, and phosphorus, may also be affected.<sup>78,108</sup>

The ability of the renal tubule to reabsorb salt and water after relief of the obstruction typically depends on whether the obstruction is unilateral or bilateral. In unilateral obstruction, the proximal tubules of the juxtamedullary nephrons are unable to reabsorb salt and water maximally, whereas the fractional reabsorption of salt and water is increased in the superficial nephrons.<sup>108</sup> However, the amount of sodium excreted by the previously obstructed kidney is not different from that of the contralateral kidney, because tubuloglomerular balance is maintained. In contrast, relief of bilateral obstruction or, on occasion, unilateral obstruction in neonates results in a postobstructive diuresis characterized by a marked elevation in the absolute amount of sodium and water lost.<sup>109</sup> In part, these changes are a result of an osmotic diuresis

secondary to retained solutes, such as urea.<sup>109,110</sup> Some contribution may also occur from atrial natriuretic factor, the plasma level of which is elevated during obstruction, as well as from enhanced synthesis of prostaglandins.<sup>108,111</sup> Decreased renal medullary tonicity and decreased hydraulic water permeability of the collecting duct in response to antidiuretic hormone, the latter a result of reduced aquaporin channels, contribute to the impaired concentrating ability of the kidney.<sup>35,107,112</sup>

The clinical conditions associated with prolonged salt wasting are severe volume contraction and circulatory impairment. Conditions associated with the concentrating abnormalities are secondary nephrogenic diabetes insipidus and hypernatremic dehydration. Accordingly, management must ensure the provision of adequate amounts of fluid and salt. Sodium intake should be monitored by serum and urine electrolyte determinations. Fluid intake should equal insensible losses, urine output, and nonrenal losses and should be guided by frequent assessments of body weight.

Ureteral obstruction also can result in the impairment of hydrogen and potassium secretion and the syndrome of hyperkalemic, hyperchloremic metabolic acidosis, or type IV RTA.<sup>113-115</sup> This clinical situation appears to be the result of the impaired turnover of the sodium-potassium pump or a decreased responsiveness of the distal renal tubule to the actions of aldosterone. In a portion of the patients with this presentation, the FENa is normal and the FEK is inappropriately low, relative to the elevated serum level. Treatment is directed toward correcting the underlying obstructive abnormality with surgery as well as providing  $\text{NaHCO}_3^-$  to alleviate the metabolic acidosis and hyperkalemia.

Finally, the outcome of obstructive uropathy in the neonate in terms of preservation of GFR is, in part, related to how promptly surgical intervention and relief of obstruction take place. In these patients, the serum creatinine value obtained at age 12 months has been shown to be predictive of long-term kidney function.<sup>40,41,78,107</sup>

# COAGULOPATHIES AND SICKLE CELL DISEASE

Kathleen A. Neville, MD, MS • Brian M. Wicklund, MD, CM, MPH • Gerald M. Woods, MD

The pediatric surgeon will encounter patients with various hematologic disorders, including children with hemophilia and sickle cell disease (SCD), who represent the largest populations that have been followed by hematologists for an extended period. We discuss these two conditions because of the unique surgical challenges that these patients provide to the pediatric surgeon, pediatric hematologist, and other physicians involved.

## BIOCHEMISTRY AND PHYSIOLOGY OF HEMOSTASIS

The hemostatic system functions to arrest bleeding from injured blood vessels and to prevent the loss of blood from intact vessels. It also maintains a delicate balance that prevents unwanted clots from forming and dissolves blood clots that previously formed. This system, which is comprised of both thrombotic and thrombolytic proteins, platelets, and cells lining blood vessels, maintains hemostasis. Pathologic defects in this regulatory system result in either bleeding or thrombosis when too little or too much clot is formed or when dissolution of a clot is not properly regulated.

Obtaining a complete patient and family history is essential to effectively anticipate hemostatic disorders. Preoperative preparations can be made only if a good history is taken so that medications that interfere with coagulation or platelet function can be discontinued. Laboratory studies help identify and characterize the problems that are uncovered by the history. However, consideration and workup of potential genetic bleeding and platelet disorders largely depends on a meticulous bleeding history for both the patient and family members and on a detailed physical examination.

Three distinct structures are involved in the process of hemostasis: blood vessels, platelets, and circulating hemostatic proteins. Together, these components form the coagulation system, the naturally occurring

anticoagulation system, and the fibrinolytic system. Coagulation must act rapidly to stop the loss of blood from an injured vessel, but the clot that is formed must remain localized so that it does not interfere with the passage of blood through the intact circulation. The anticoagulation system prevents the extension of the clot beyond the site of injury. The fibrinolytic system removes excess hemostatic material that has been released into the circulation and slowly lyses the clot once it is no longer needed.

The stimulus that initially causes clot formation occurs as a consequence of disruption of endothelial cells. This leads to exposure of collagen and subendothelial tissues. The hemostatic response to tissue injury consists of four stages. First, vasoconstriction by the contraction of smooth muscle in the injured vessel wall reduces blood flow. Second, platelets adhere to the exposed endothelium, aggregate, and release their granular contents. This activity stimulates further vasoconstriction and recruits more platelets. This action results in “primary hemostasis” that occludes the gap in the blood vessel and stops blood loss through the vessel. Third, the extrinsic and intrinsic coagulation systems are activated to form fibrin, which stabilizes the platelets and prevents disaggregation. Fourth, fibrinolysis results from the release of plasminogen activators from the injured vessel wall. These activators limit the coagulation process. Once healing has taken place, they begin dissolution of formed clot so that vascular patency can be restored.<sup>1</sup>

## Endothelial Cells

Endothelial cells line the lumen of all blood vessels. They maintain the integrity of the blood vessel and prevent extravasation of blood into the surrounding tissue.<sup>1</sup> When the vessel is intact, it provides a thromboresistant surface that prevents the activation of the coagulation system. Passive thromboresistance is provided by endothelial proteoglycans, primarily

endogenous heparin sulfate. Heparin is an anticoagulant compound that acts as a co-factor in converting antithrombin to a potent inhibitor of activated clotting factors. Active thromboresistance is achieved through several mechanisms, including the synthesis and release of prostacyclin (PGI<sub>2</sub>), a potent vasodilator and an inhibitor of platelet adhesion and aggregation.<sup>1,2</sup>

When the endothelium is injured, tissue factor (thromboplastin) is produced and rapidly promotes local thrombin formation.<sup>3</sup> Tissue factor binds factor VII and converts it to factor VIIa (Fig. 5-1). The production of factor VIIa is the first step in activation of the extrinsic coagulation pathway, which begins the activation of the common pathway. It also activates factor IX, which is the major activator of the common pathway, resulting in the formation of fibrin.<sup>4</sup> The contribution that these processes make to the control of bleeding depends on the size of the interrupted vessel. Capillaries seal with little dependence on the hemostatic system, but arterioles and venules require the presence of platelets to form an occluding plug. In arteries and veins, hemostasis depends on both vascular contraction and clot formation around an occluding primary hemostatic plug.<sup>5</sup>

## Platelets

In the resting state, platelets circulate as disk-shaped, anuclear cells that have been released from megakaryocytes in the bone marrow. They are 2 to 3 μm in size and remain in circulation for approximately 10 days unless they participate in coagulation reactions or are removed by the spleen. Normal blood contains 150,000 to 400,000 platelets per microliter.<sup>5</sup> In the resting state, platelets do not bind to intact endothelium.

## Platelet Adhesion

Once platelets bind to injured tissue and are activated, their discoid shape changes. They spread on the subendothelial connective tissue and degranulate. Degranulation occurs when platelets internally contract and extrude storage granule contents into the open canalicular system. Dense granules release serotonin, adenosine diphosphate (ADP), calcium, and adenosine triphosphate (ATP). Alpha granules release factor V, fibrinogen, von Willebrand factor (FVIII:vWF), fibronectin, platelet factor 4, β-thromboglobulin, and platelet-derived growth factor.<sup>6,7</sup> Lysosomal vesicles also

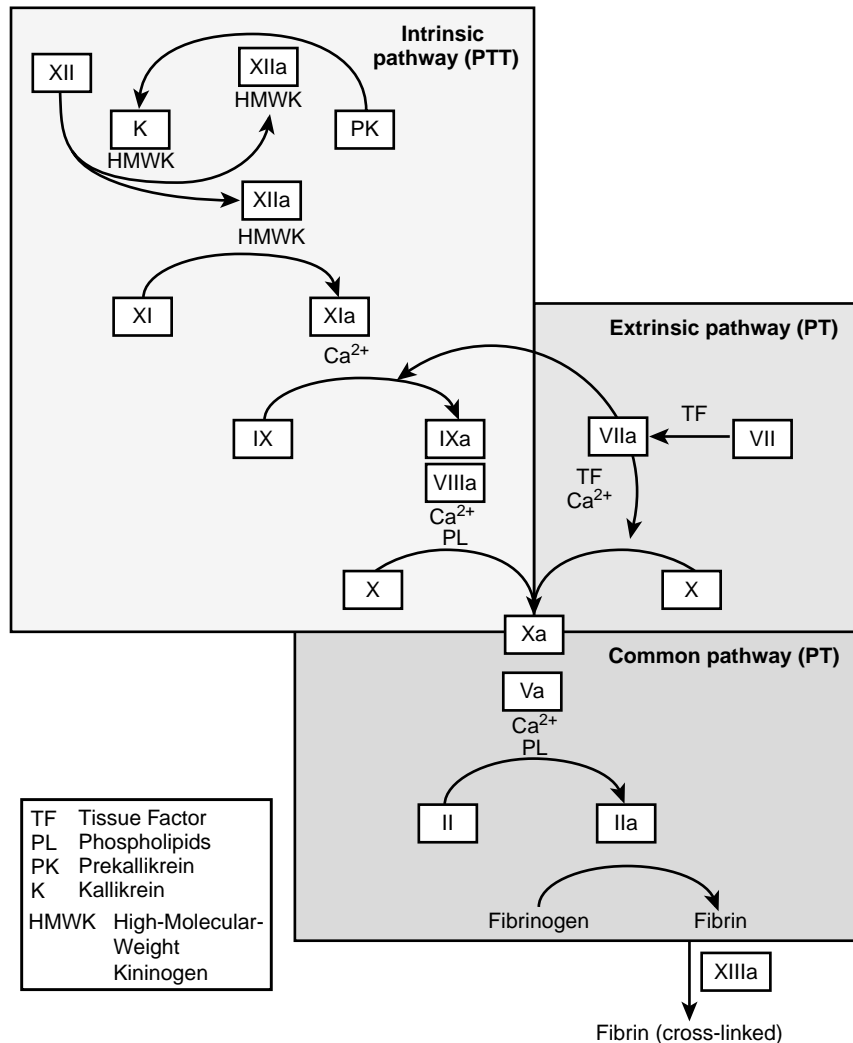

Figure 5-1. The coagulation cascade.

are present within platelets. The material released from the granules recruits and aggregates more platelets from the circulation onto the already adherent platelets.<sup>7</sup>

When a vessel is disrupted, platelet adhesion occurs through the binding of collagen and vWF (found in the subendothelium) to the platelet membrane. For platelet adhesion to occur, platelets must express specific glycoprotein Ib receptors on their surface to bind the vWF complex. If this specific glycoprotein is missing, platelets are unable to adhere to areas of injury.<sup>8</sup> Platelets in Bernard-Soulier syndrome lack glycoprotein Ib and are unable to adhere and form the initial hemostatic plug.<sup>9</sup> If the vWF is defective or deficient in amount, platelets do not adhere to sites of vascular injury. The result is von Willebrand's disease, of which several specific types and subtypes have been defined.<sup>10-12</sup> If an operation is performed on a patient with either Bernard-Soulier syndrome or von Willebrand's disease without the transfusion of normal amounts and types of platelets or vWF, respectively, serious bleeding can result because of the inability to form an initial hemostatic platelet plug. Very high concentrations of PGI<sub>2</sub> also can inhibit platelet adhesion to exposed subendothelium.<sup>5</sup>

After platelet adhesion has occurred, in addition to degranulation and an increased local concentration of ADP, small amounts of thrombin are formed, and platelet membrane phospholipase is activated to generate thromboxane A<sub>2</sub>. Thromboxane A<sub>2</sub> and serotonin released from the dense granules stimulate vasoconstriction and induce the exposure of membrane receptors for fibrinogen (glycoproteins IIb/IIIa). Fibrinogen binding to stimulated platelets then induces aggregation.<sup>7</sup>

## Platelet Aggregation

Aggregation is a complex reaction that involves platelet granule release, cleavage of membrane phospholipids by phospholipases A<sub>2</sub> and C, alterations in intracellular cyclic adenosine monophosphate (cAMP) levels, mobilization of intracellular calcium, and the expression of fibrinogen receptors on the platelet surface. If fibrinogen receptors (glycoproteins IIb and IIIa) or fibrinogen are missing, platelets do not aggregate.<sup>13</sup> Glanzmann's thrombasthenia is a deficiency of glycoproteins IIb and IIIa in which platelets adhere normally but do not aggregate. These patients have a serious, life-long bleeding disorder.<sup>6</sup>

After aggregation, platelets function to enhance thrombin formation. The platelet membrane provides specific binding sites for factors Xa and V. The result is an efficient site for the assembly of the prothrombinase complex, which converts prothrombin into thrombin.<sup>7</sup> Thrombin formation results in the formation of a stable hemostatic plug of adherent platelets surrounded by a network of fibrin strands.

## Generation of Thrombin

Tissue injury induces activation of the plasma-based coagulation system, resulting in the generation of thrombin from prothrombin. Thrombin is the enzyme

responsible for transforming liquid blood into a fibrin gel. The initial activation of factor VII by tissue factor results in the production of thrombin by the extrinsic system. Tissue factor is released after injury to the endothelial cells but is not expressed on the surface of the cells.

The majority of thrombin production results from the activation of the intrinsic coagulation system, not the extrinsic system. Exposed subendothelium converts factor XII to factor XIIa and thereby activates the intrinsic pathway, although it is interesting to note that deficits in factor XII do not cause a bleeding disorder. Activation of factors XI and IX follows, and activated factor IX in combination with factor VIII, calcium, and platelet phospholipid activates factor X. Activated factor VII, complexed with tissue factor, activates factor IX. Factor Xa with factor V then cleaves prothrombin into the active molecule thrombin, which can convert fibrinogen into fibrin.<sup>4,14</sup>

## Formation of Fibrin

When thrombin acts on fibrinogen, fibrin monomers result after the proteolytic release of fibrinopeptides A and B. The monomeric fibrin then polymerizes into a gel.<sup>4,14</sup> With additional stabilization of the fibrin gel provided by factor XIII, fibrin surrounds and stabilizes the platelet plug. This process makes the multimeric fibrin more resistant to plasmin digestion and completes the formation and stabilization of the blood clot.<sup>15</sup>

Several regulatory proteins serve to localize thrombin formation to the surface of the blood vessel. Endothelial cells have receptors for protein C, an anticoagulant protein. Protein C from the plasma binds to these receptors. Protein S is a co-factor for the activation of protein C. Thrombomodulin is an endothelial surface protein that acts in combination with thrombin to activate the bound protein C. Activated protein C then degrades factors Va and VIIIa, which inhibit thrombin formation.<sup>16</sup>

Heparin-like anticoagulant molecules are present on endothelial cells. They act in combination with antithrombin III to inhibit factors XIIa, XIa, IXa, and Xa and thrombin. Inhibition of these factors prevents the spread of clot to uninjured adjacent vessels and the blockage of large vessels by excessive clot formation.<sup>14,16</sup> Endothelial cells, as mentioned previously, produce PGI<sub>2</sub>, a potent vasodilator and inhibitor of platelet aggregation and adhesion.

## Fibrinolysis

The regulatory process that dissolves fibrin and preserves vessel patency is called fibrinolysis. Circulating plasminogen is converted into plasmin by tissue plasminogen activators. These activators are released from the vessel walls at the site of blood clotting. They bind to the fibrin clot and convert plasminogen to plasmin. Plasmin enzymatically degrades fibrin, fibrinogen, and other plasma proteins, and this process results in the dissolution of formed clot.<sup>14,16</sup>

## CLINICAL EVALUATION

Currently, no screening test to evaluate hemostasis is completely reliable in the preoperative evaluation of patients. A careful history, including a full family history, is still the best means of uncovering mild bleeding problems, including von Willebrand's disease or qualitative platelet abnormalities.<sup>17</sup> These disorders may easily escape standard laboratory screening procedures, such as prothrombin time (PT), activated partial thromboplastin time (aPTT), platelet count, and bleeding time. aPTT screening yields many false-positive results caused by both analytical problems and detection of clinically insignificant disorders. In addition, a normal aPTT may lead to a false sense of safety because it does not exclude all serious bleeding disorders. Therefore, it is imperative to identify patients at risk who need laboratory evaluation by obtaining a thorough history. Because no method can reliably predict all bleeding complications, postoperative monitoring remains mandatory for all patients.<sup>18</sup> Likewise, patients with mild disorders who have not previously undergone surgical procedures may have no history of bleeding problems and might be identified preoperatively only if screening tests are performed.<sup>17</sup> It is important to consider the history as the most important component of a diagnostic strategy and to investigate thoroughly any story of unusual bleeding, even if the screening tests are normal.<sup>19</sup> Conversely, studies examining the utility of a screening preoperative PT and aPTT in patients undergoing tonsillectomy and adenoidectomy concluded that routine screening with a PT and aPTT for all patients regardless of history cannot be recommended.<sup>18,20</sup> In obtaining a history from the patient and parents, positive answers to the questions posed in Table 5-1 indicate the need for further evaluation.<sup>17,21-23</sup>

If there is a history of abnormal bleeding, the following points must be established. The type of bleeding (i.e., petechiae, purpura, ecchymosis, and single or generalized bleeding sites) can give an indication of the underlying defect. Petechiae and purpura are most frequently associated with platelet abnormalities, either of function or of numbers. Von Willebrand's disease is most frequently associated with mucosal bleeding, including epistaxis, whereas hemophilia is most often associated with bleeding into joints or soft tissue ecchymosis, or both. Bleeding when the umbilical cord separates is most often associated with a deficiency in factor XIII, as is unexplained bleeding of the central nervous system.<sup>15,24</sup> A single bleeding site, such as repetitive epistaxis from the same nostril, is frequently indicative of a localized, anatomic problem and not a system-wide coagulation defect.

The course or pattern of the bleeding (i.e., spontaneous or after trauma) and its frequency, duration of problems, and severity can provide clues to whether a bleeding disorder is present. A family history of bleeding is important to define, and the pattern of inheritance (i.e., X-linked or autosomal; recessive or dominant) can help narrow the differential diagnosis (e.g., hemophilia A and B are X-linked recessive diseases, whereas von Willebrand's disease is autosomal dominant).

**Table 5-1**

### Questions to Ask about Potential Bleeding Problems

1. Is there any history of easy bruising, bleeding problems, or an established bleeding disorder in the patient or any family members?
2. Has excessive bleeding occurred after any previous surgical procedure or dental work? Have the parents or any siblings had excessive bleeding after any surgical or dental procedures, specifically tonsillectomy or adenoidectomy?
3. Have frequent nosebleeds occurred, and has nasal packing or cautery been needed? Has bleeding without trauma occurred into any joint or muscle?
4. Does excessive bleeding or bruising occur after aspirin ingestion?
5. Does significant gingival bleeding occur after tooth brushing?
6. Has there been any significant postpartum hemorrhage?
7. Has the patient been taking any medication that might affect platelets or the coagulation system?
8. If the patient is male and was circumcised, were any problems noted with prolonged oozing after the circumcision?
9. If the patient is a child, do the parents remember any bleeding problems when the umbilical cord separated?
10. If the patient is menstruating, does she have profuse menstruation?
11. Has the patient ever received any transfusions of blood or blood products? If so, what was the reason for the transfusion?

Any previous or current drug therapy must be fully documented, and a search is made for any over-the-counter medications that the patient might be taking but does not consider "medicine" and has therefore not mentioned. Aspirin, ibuprofen, cough medications containing guaifenesin, and antihistamines can lead to platelet dysfunction or uncover a previously undiagnosed bleeding disorder such as von Willebrand's disease.<sup>25,26</sup> The presence of other medical problems including renal failure with uremia, hepatic failure, malignancies, gastrointestinal malabsorption, vascular malformations, cardiac anomalies with or without repair, and autoimmune disorders is essential to elicit because these may have associated coagulopathies.

The physical examination is used to help narrow the differential diagnosis and guide the laboratory investigation of hemostatic disorders. Certain physical findings may be associated with specific coagulation abnormalities, whereas others may be indicative of underlying systemic disease with an associated coagulopathy. Petechiae and purpuric bleeding occur with platelet and vascular abnormalities. Mucocutaneous bleeding suggests a platelet disorder and includes petechiae, ecchymoses, epistaxis, and genitourinary and gastrointestinal bleeding. Bleeding into potential spaces such as joints, fascial planes, and the retroperitoneum is instead suggestive of a coagulation factor deficiency. Bleeding from multiple sites in an ill patient can be seen with disseminated intravascular coagulation (DIC) or thrombotic thrombocytopenic purpura (TTP). Hemophilia patients often have palpable purpura and deep muscle bleeding that is painful but may be difficult to

detect. Findings compatible with a collagen disorder include the body habitus of Marfan syndrome; blue sclerae; skeletal deformities; hyperextensible joints and skin; and nodular, spider-like, or pinpoint telangiectasia. Other signs may be indicative of systemic disease. For example, hepatosplenomegaly and lymphadenopathy may suggest an underlying malignancy, whereas jaundice and hepatomegaly may be indicative of hepatic dysfunction.

## LABORATORY EVALUATION

When the bleeding history and/or family history suggest the possibility of a bleeding disorder, or if it is impossible to obtain a history due to family or social circumstances, it is customary to proceed with a series of laboratory investigations to look for a possible bleeding diagnosis. Generally, screening tests are performed first and can include a blood cell count, PT, and aPTT (Fig. 5-2).<sup>19</sup> Additional tests can be done to measure fibrinogen levels, assess the thrombin time, screen for inhibitors of specific coagulation factors, measure specific factor levels, and test for platelet function and von Willebrand's disease.<sup>19,27</sup> Patients also can be evaluated for evidence of DIC by using multiple assays to test for the presence of various fibrinopeptides and products from the breakdown of fibrin or fibrinogen.

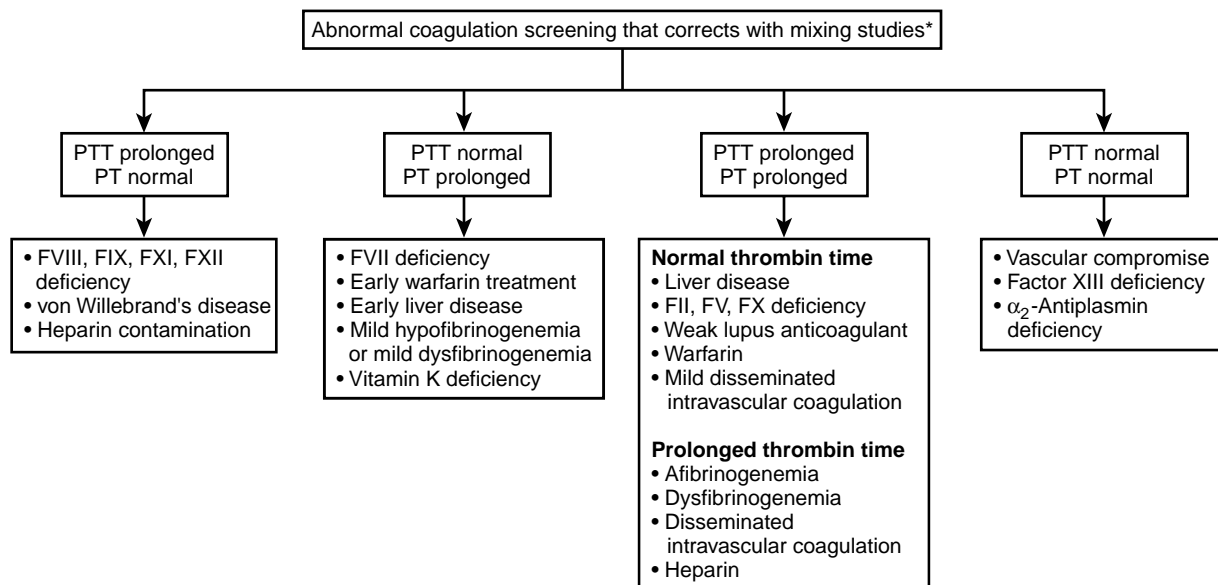

### Platelet Count

The platelet count measures the adequacy of platelet numbers to provide initial hemostasis. Thrombocytopenia (a platelet count of  $< 150,000/\mu\text{L}$ ) is one of

the most common problems that occur in hospitalized patients. As stated previously, typical manifestations include bruising, menorrhagia, and gastrointestinal or urinary tract bleeding. The risk of bleeding is inversely proportional to the platelet count. When the platelet count is less than  $50,000/\mu\text{L}$ , minor bleeding occurs easily and the risk of major bleeding increases. Counts between  $20,000$  and  $50,000/\mu\text{L}$  predispose to bleeding with trauma, even minor trauma; with counts less than  $20,000/\mu\text{L}$ , spontaneous bleeding may occur; with counts less than  $5,000/\mu\text{L}$ , severe spontaneous bleeding is more likely. However, patients with counts less than  $10,000/\mu\text{L}$  may be asymptomatic for years.<sup>28</sup> Surgical bleeding does not usually occur until the platelet count is less than  $50,000$  platelets/ $\mu\text{L}$ .<sup>29</sup> A platelet count of less than  $50,000/\mu\text{L}$  is considered a cutoff criterion for transfusions, and the prophylactic use of platelet transfusion is indicated for any invasive procedure. Patients with thrombocytopenia and significant bleeding should also receive transfusion of platelets.<sup>29</sup>

### Bleeding Time and the PFA-100 Analyzer

The bleeding time is defined as the length of time required for a standardized incision to stop oozing blood that can be absorbed onto filter paper. A variety of procedures have been used, but all have variable sensitivity and have been difficult to reproduce accurately, leading many centers to drop the bleeding time from the list of approved laboratory tests.<sup>30</sup> The PFA-100 Analyzer (Siemens Healthcare Diagnostics, Deerfield, IL) is now widely used as a replacement for the

\*Repeating an abnormal coagulation screening with a mixture of 1 part patient plasma and 1 part normal plasma ("mixing studies") will normalize the test if a factor deficiency is present, but the screening test will remain abnormal if an anticoagulant is present. These anticoagulants rarely are a cause of thromboembolic disease and even more rarely cause bleeding.

**Figure 5-2.** Screening tests for abnormal coagulation.

bleeding time. It creates an in-vitro high shear stress condition that results in the activation of platelet-dependent and vWF-dependent attachment and aggregation of platelets to a collagen-ADP or collagen-epinephrine surface. In most cases, the PFA-100 closure time is superior to the bleeding time in the detection of von Willebrand's disease, aspirin effect, or platelet dysfunction.<sup>30</sup> However, test results can be influenced by the sample's hematocrit. Although the PFA-100 does not detect all platelet dysfunctions or cases of von Willebrand's disease, when used in conjunction with a standardized questionnaire, it will likely detect impaired hemostasis in most cases.<sup>30,31</sup>

## Prothrombin Time

The PT is a measure of the function of the extrinsic and common coagulation pathways. It represents the time (in seconds) for the patient's plasma to clot after the addition of calcium and thromboplastin (an activator of the extrinsic pathway).<sup>32,33</sup> Isolated prolongation of the PT is seen most commonly in patients who are deficient in vitamin K due to previous antibiotic treatment. It also occurs with factor VII deficiency, mild hypofibrinogenemia, dysfibrinogenemia, and warfarin treatment. The PT may also be prolonged when significant liver dysfunction occurs.<sup>32,33</sup>

## Partial Thromboplastin Time

The aPTT measures the function of the intrinsic and common coagulation pathways. The aPTT represents the time (in seconds) for the patient's plasma to clot after the addition of phospholipid, calcium and an intrinsic pathway activator. The aPTT detects deficiencies in factors XII, XI, IX, and VIII and in the common pathway, but mild factor deficiencies may be missed. The aPTT also is used to monitor anticoagulation with heparin.<sup>32,33</sup>

Several inherited disorders of coagulation are not detected by the preceding tests. Results from standard hemostatic screening tests such as the aPTT and international normalized ratio (INR) assessments are normal in factor XIII (FXIII) deficiency. Therefore, assessment of clot stability is the most common screening test used for FXIII deficiency with a quantitative assay required to confirm the diagnosis of FXIII deficiency.<sup>34</sup> Von Willebrand's disease patients may have normal or prolonged aPTTs, and patients with a deficiency in  $\alpha_2$ -antiplasmin have a normal aPTT. Both the PT and aPTT are prolonged in patients with deficiencies of factors X and V, prothrombin, and fibrinogen and in patients with DIC or severe liver disease.<sup>32,33</sup>

## Fibrinogen

The standard method for fibrinogen determination measures clottable fibrinogen by using a kinetic assay. Normal levels of fibrinogen are 150 to 350 mg/dL. Because fibrinogen is the substrate for the final reaction in the formation of a clot, and all plasma-based

screening tests depend on the formation of a clot as the end point of the reaction, fibrinogen levels below 80 mg/dL prolong the PT, aPTT, and thrombin time and therefore make the results uninterpretable. Large amounts of fibrin degradation products interfere with the formation of fibrin and cause an artificially low level of measured fibrinogen. Partially clotted samples also cause a low level of fibrinogen to be assayed. An immunologic-based assay for fibrinogen is used to measure both clottable and nonclottable fibrinogen. This test is most often used in identifying patients with a dysfibrinogenemia in whom the functional level of fibrinogen is low and the immunologic level is normal.<sup>33,35</sup>

## Inhibitor Screening Tests

Repeating the PT or aPTT by using a 1:1 mix of patient plasma with normal plasma is a useful procedure for investigating a prolonged PT or aPTT. Normal plasma has, by definition, 100% levels of all factors. When mixed with an equal volume of patient plasma, a minimum of 50% of any given factor is present, which should normalize the PT or aPTT. Correction of the clotting time suggests the presence of a factor deficiency, whereas lack of normalization suggests the presence of an inhibitor that interferes with either thrombin or fibrin formation.<sup>32,33</sup>

Two types of acquired inhibitors prolong the aPTT. One blocks or inactivates one of the intrinsic factors, whereas the other is a lupus-like inhibitor that interferes with phospholipid-based clotting reactions. The first type of inhibitor occurs in 10% to 15% of hemophilia A patients and can occur spontaneously, but it is extremely rare in nonhemophilic children.<sup>36</sup> The lupus-like inhibitor is associated not with bleeding problems but rather with an increased risk of thrombotic problems in adults. Lupus-like inhibitors are mentioned because they commonly cause prolongations of the aPTT.<sup>37</sup> Specific investigation of either of these situations should be referred to a coagulation reference laboratory.

## Platelet Function Studies

Platelet function studies measure in-vitro platelet aggregation. In this procedure, platelet-rich plasma is incubated with an agonist and then changes in the amount of light transmitted through the platelet suspension are recorded. Agonists used to induce platelet aggregation include collagen, epinephrine, ADP, thrombin, and ristocetin. Three distinct phases are seen in the reaction. The first is an initial change in the shape of the platelets, leading to a temporary decrease in light transmission. Next is the first wave of aggregation, which is a reversible platelet-platelet interaction. With additional stimulation, the final phase—the second wave of aggregation—occurs and produces irreversible platelet aggregation. The second wave of aggregation is due to the release reaction of the platelet granules and thromboxane A<sub>2</sub> synthesis. The release reaction is extinguished by aspirin

and is absent in patients with an inherited storage pool defect, congenital deficiency in thromboxane A<sub>2</sub> synthesis, or cyclooxygenase deficiency.<sup>7</sup> The PFA-100 has become the test of choice to replace the bleeding time and is used to screen for a variety of disorders, but full characterization of platelet function requires traditional platelet aggregation studies in a specialized laboratory.

### Specific Factor Assays

Specific factor assays are available for all known coagulation, fibrinolysis, and anticoagulation factors to quantify their levels in plasma. These tests are not indicated unless a screening test result is abnormal. The only exception involves the patient with a history that is suggestive of von Willebrand's disease, factor XIII deficiency, or dysfibrinogenemia. In these cases, the aPTT may not be sensitive enough to detect the disorder. Further testing may be justified by clinical suspicion based on the patient's history.<sup>32,33</sup> For von Willebrand's disease, the workup consists of measuring factor VIII levels, vWF antigen levels, ristocetin cofactor activity, and ristocetin-induced platelet aggregation. Analysis of the distribution of vWF multimers can be useful to the hematologist in identifying the specific type of von Willebrand's disease.<sup>10-12</sup>

### Tests for Disseminated Intravascular Coagulation

The tests that are available in most hospital laboratories for identification of DIC are semiquantitative fibrin or fibrinogen degradation product assays, which involve a slide agglutination procedure or a D-dimer assay. An increased amount of these degradation products suggests that either plasmin has circulated to lyse fibrin and fibrinogen or the patient's hepatic function is insufficient to clear the small amounts of regularly produced degradation products. The D-dimer test is a slide agglutination procedure that tests for the presence of two D subunits of fibrin that are cross-linked by factor XIII. This test provides specific evidence that plasmin has digested fibrin clot and not fibrinogen. It is positive in patients with DIC, in patients with resolving large intravascular clots, and in patients with hepatic insufficiency. Specific assays to demonstrate the presence of soluble fibrin monomer complexes or fibrinopeptides produced by the conversion of prothrombin to thrombin also are useful in some situations and available in specialized laboratories.<sup>33,38</sup>

## HEMOPHILIA A AND B

Hemophilia A and B are X-linked recessive bleeding disorders caused by decreased levels of functional procoagulant factors VIII and IX, respectively. Approximately 80% of all hemophilia patients have factor VIII deficiency, which is classic hemophilia. The remaining 20% have factor IX deficiency, which is called Christmas disease. These are rare disorders,

with a prevalence of only 13.4/100,000 males.<sup>39</sup> Until 1964, the treatment of hemophilia was limited by volume restrictions imposed by the use of whole blood or fresh frozen plasma. At that time, the factor VIII-rich fraction of fresh frozen plasma called cryoprecipitate was discovered.<sup>40</sup> Specific lyophilized factor VIII concentrates have since been developed, as have prothrombin-complex concentrates containing factors II, VII, IX, and X. Also, concentrates containing only factor IX for the treatment of hemophilia B patients and factor VIII/vWF concentrates for the treatment of von Willebrand's disease have been developed.<sup>41,42</sup> The lyophilized factor concentrates have allowed storage of the clotting factor using standard refrigeration and have permitted the outpatient treatment of bleeding episodes plus the development of home self-infusion programs.<sup>43</sup> This treatment, combined with the development of comprehensive hemophilia treatment centers, has produced a remarkable change in the outlook for these patients who previously developed significant joint deformities in their teens to 20s and were frequently wheelchair bound in adult life. Home therapy has decreased the damage caused by hemarthroses, with hemophiliac children born since the mid 1970s having far fewer joint deformities than do older hemophiliacs. These factor concentrates have allowed surgical procedures to be performed with much less risk, even to the point that orthopedic procedures can be readily accomplished.<sup>44</sup> Moreover, the comprehensive hemophilia treatment system has shown a 40% reduction in mortality for hemophilia patients.<sup>45</sup>

Viral infections transmitted by cryoprecipitate and factor concentrates were the major problem faced by hemophilia patients in the late 1970s to mid 1980s. Approximately 60% of all hemophilia patients became human immunodeficiency virus (HIV) positive in the 1980s, but there have not been any HIV infections from clotting factor concentrates since 1987.<sup>46</sup> Hepatitis C is the other major viral infection that was transmitted by plasma-derived factor concentrates used to treat hemophilia. Estimates from the mid 1980s are that more than 90% of multiply transfused hemophiliacs were positive for non-A, non-B hepatitis and that more than 95% had been infected with hepatitis B.<sup>47</sup> A different study shows that 75% of HIV-negative hemophiliacs, treated with earlier plasma-derived factor concentrates, have evidence of hepatitis C infection.<sup>48</sup> Again, no documented cases of hepatitis C transmission by clotting factor concentrates after 1987 are known.<sup>46</sup> Since 1993, recombinant produced factor VIII concentrates have been available. At present, only recombinant factor VIII and IX concentrates are used for the treatment of patients with newly diagnosed hemophilia A and B.<sup>49</sup>

Hemophilia patients are classified into three categories based on their level of circulating procoagulant. Those with factor levels below 1% are severe hemophiliacs, have a high risk of bleeding, and usually require replacement therapy two to four times per month.<sup>39,50</sup> Bleeding occurs in areas subject to minor trauma. Hemarthroses, hematomas, and ecchymoses

are common. Recurrent hemarthroses can cause pseudotumors of the bone, whereas hematomas can cause compression damage to tissue or nerves and even ischemic compartment syndromes. Bleeding episodes in severe hemophiliacs can be irregularly spaced, with periods of recurrent hemarthrosis requiring frequent replacement doses of factor concentrate, interspersed with periods during which little or no concentrate is used.<sup>39</sup> In moderate hemophiliacs, who have procoagulant levels of 1% to 5%, spontaneous hemorrhage occurs infrequently but relatively minor trauma can cause bleeding into joints or soft tissues.

Mild hemophiliacs, with levels greater than 5%, rarely have bleeding problems and typically have problems only with major trauma or surgical procedures.<sup>36,39</sup> Some mild hemophilias may not be diagnosed until late childhood or adulthood. Therefore, a history may not be present to alert the pediatric surgeon to the risk of bleeding. Moreover, because one third of all cases of hemophilia are caused by new mutations, there may not be a family history to arouse suspicion of a bleeding problem.<sup>36</sup> Preoperative laboratory testing may provide the only point at which mild hemophilia is diagnosed.

The indications for surgical intervention in hemophiliacs are the same as those for patients with a normal clotting system, but they most frequently center on areas of damage secondary to bleeding episodes. In 1985, the results of a review of 350 consecutive operations performed at the Orthopedic Hospital in Los Angeles were published.<sup>51</sup> Because the study represented patients from before the start of home therapy and comprehensive care, the group was expected to have significant orthopedic problems secondary to multiple hemarthroses. Of the 350 procedures reviewed, 312 were characterized as serious and 38 of lesser intensity; 318 operations were on hemophiliacs with moderate and severe hemophilia and 30 on patients with mild hemophilia. As expected, musculoskeletal procedures made up two thirds of all operations on moderate and severe hemophiliacs and half of all operations on mild hemophiliacs. One death occurred in a child with a massive intracranial hemorrhage who did not survive an emergency craniotomy.<sup>51</sup> Bleeding problems during operation were not observed, but 23% of all serious operations were complicated by postoperative hemorrhages. Only operations on the knee had significantly more postoperative hemorrhages (40%). Operations on other joints and soft tissue areas had similar rates of complications (15%). Most of the postoperative hemorrhages occurred with plasma factor levels greater than 30%, which is the minimum level that is considered hemostatic. The authors also noted that the incidence of postoperative hemorrhage decreased after postoperative day 11, although other studies have found that vigorous physical therapy may cause postoperative hemorrhage and have therefore recommended the continuation of factor replacement throughout the period of physical therapy.<sup>51,52</sup>

The management of the hemophilic patient requires close cooperation among surgeons, hematologists, and personnel in the hemophilia center, the coagulation

laboratory, and the pharmacy or blood bank. Careful preoperative planning is essential to the success of the procedure, and an adequate supply of clotting factor concentrate must be available to cover the patient's needs before the patient is admitted. The patient also must be screened for the presence of an inhibitor to either factor VIII or IX during the 2 to 4 weeks before the operation. If an inhibitor is present, management of the patient becomes much more complex and depends on the strength of the inhibitor. A low-titer inhibitor may be overcome with increased doses of human clotting factor, but high-titer inhibitors may require the use of activated prothrombin complex concentrate (FEIBA) or recombinant activated factor VII (NovoSeven) to "bypass" the effect of the antibody against either factor VIII or IX. These patients have been desensitized with daily doses of human factor concentrate over a period of months to years, restoring their response to regular infusions of factor VIII or IX.<sup>44,53,54</sup>

At our institution, the hemophilia patient is seen in the hematology clinic on the morning of the scheduled operation. After a bolus dose of factor (usually 50 units/kg of factor VIII in hemophilia A patients), a continuous infusion of 4 to 8 units/kg/hr of factor VIII (for the hemophilia A patient) is started to maintain a factor level greater than 80% for the next 1 to 2 days.<sup>55</sup> The factor level is checked immediately before the operation and is the final screen for the presence of an inhibitor. The infusion is maintained throughout the procedure and is then reduced on the second or third postoperative day to allow the plasma levels to decrease to 50%. Replacement is continued for a full 10 to 14 days after the operation. Daily measurement of factor levels is necessary to ensure maintenance of appropriate levels. For neurosurgical or orthopedic procedures, much longer periods of factor coverage—even 4 to 6 weeks—are needed, especially if significant physical therapy is planned.<sup>39,44</sup>

Many hemophiliacs do their own factor infusions at home and are supported by home care pharmacies. With the advent of home nursing services, patients are being discharged home with prolonged periods of factor coverage. Hemophilia center personnel must be closely involved in the planning of these discharges to ensure that sufficient clotting factor is available at home and that close follow-up is maintained during periods of scheduled home therapy. Hemophilia patients should not receive any compounds that contain aspirin or ibuprofen. Any minor procedures that would require factor correction should be combined with the major procedure, if possible, to save on the use of factor concentrate.

Previously, the hemophilia B patient undergoing a surgical procedure had specific problems because of the thrombogenic risk inherent in the use of older factor IX concentrates. Since the advent of newer, more purified factor IX concentrates, surgical procedures in hemophilia B patients have been performed without excess thrombotic problems. Now, with high purity plasma-derived and recombinant-produced factor IX concentrates, there are no excess thrombosis risks.<sup>56,57</sup>

## CLOTTING FACTOR DOSING

Factor VIII is dosed differently from factor IX, based on their half-lives. Factor VIII has an 8- to 12-hour half-life, and the infusion of 1 unit of factor per kilogram of body weight increases the plasma level by 2%. If a severe hemophilia A patient weighs 50 kg, an infusion of 25 units/kg, or 1250 units, of factor VIII will raise his factor level to 50%. Factor IX has a half-life of 24 hours and must be infused in larger amounts than factor VIII to raise the plasma level. Infusion of 1 unit/kg of factor IX will raise the plasma level only by 1%. Continuous infusion of highly purified factor IX, as well as factor VIII, has been shown to prevent excessive peaks and troughs of factor levels, is simpler to manage, and decreases the cost by decreasing the overall amount of factor used. It has not shown to cause any problems with excess thrombosis.<sup>58</sup> Recombinant factor IX has a marked variability in dose response to infusions, and individual recovery studies may be needed before it is used for surgical hemostasis. Often, a 20% increase in dose is needed to give the same factor levels as obtained by use of plasma-derived factor IX.<sup>59</sup>

## NEONATAL HEMOSTASIS

The newborn's coagulation system is not fully mature until 6 months after birth. The lower levels of procoagulant, fibrinolytic, and anticoagulant proteins in neonatal patients complicate both surgical procedures and the care of sick and preterm infants. Platelet counts are within the usual adult normal ranges of 150,000 to 450,000/mL in healthy term and preterm infants. These platelets have a lower function than those of adults, but they function properly in hemostasis and produce a normal bleeding time.<sup>59</sup> Circulating coagulation factors do not cross the placenta, and infants with inherited deficiencies of clotting factors, fibrinolytic proteins, or natural anticoagulants may initially be seen in the neonatal period. Levels of fibrinogen, factor V, factor VIII, and vWF are within the adult normal range at birth.<sup>60</sup> All other procoagulants are at reduced levels, depending on gestational age. Vitamin K-dependent factors may become further depressed in infants who are breast fed and not given vitamin K at birth.<sup>59</sup>

Of more concern are the low levels of anticoagulant and fibrinolytic proteins. Very low levels of protein C have been associated with purpura fulminans in newborns. In sick infants, levels of antithrombin III and plasminogen may be inadequate to deal with increased levels of clot-promoting activity in the blood. Sick infants with indwelling catheters are at significant risk of thrombotic complications.<sup>61</sup>

## DISSEMINATED INTRAVASCULAR COAGULATION

DIC is the inappropriate activation of both thrombin and fibrin. It may follow sepsis, hypotension, hypoxemia, trauma, malignancy, burns, and extracorporeal

circulation. Hemorrhage due to the depletion of clotting factors as well as thrombosis due to the excess formation of clot are seen, and the end-organ damage caused by ischemia and impairment of blood flow causes irreversible disease and death.<sup>62</sup>

Acute DIC is associated with the consumption of factors II, V, VIII, X, and XIII, as well as fibrinogen, antithrombin III, plasminogen, and platelets. Review of the peripheral smear usually shows a microangiopathic hemolytic anemia. The PT and aPTT may both be prolonged, and the fibrinogen level may be initially elevated as an acute-phase reactant but ultimately decreases as the DIC worsens. The presence of D-dimers indicates the circulation of plasmin digested fibrin and may indicate the presence of DIC, but it may also be elevated due to thrombus or hepatic dysfunction. Antithrombin III levels may be low, and the use of antithrombin III concentrates in septic shock may play a role in the future treatment of DIC. However, adult studies have not shown any improvement in mortality for patients with septicemia treated with antithrombin III.<sup>63</sup> At present, the major therapy for DIC is correction of the underlying disorder, with fresh frozen plasma and platelet transfusions as indicated to support hemostasis. Low-dose heparin infusions have been used to stop the ongoing consumption of clotting factors before starting replacement therapy but have not been shown to appreciably improve the outcome.<sup>62,64</sup>

## MANAGEMENT OF QUANTITATIVE AND QUALITATIVE PLATELET DISORDERS

Thrombocytopenias are caused by either inadequate production of platelets by the bone marrow or by increased destruction or sequestration of the platelets in the circulation. The history and physical examination may be suggestive of a diagnosis that can be confirmed by laboratory testing. Medication use, a family history of blood disorders, a history of recent viral infection, short stature, absent thumbs or radii, or a congenital malformation may indicate a defect in platelet production. The destruction may be immunologic, as in immune thrombocytopenic purpura; mechanical, as in septicemia; or drug induced, as in patients with sensitivity to heparin or cimetidine. Establishing the cause of the thrombocytopenia determines the therapy needed to restore the platelet count in preparing the patient for operation. A bone marrow aspirate or biopsy, or both, can establish the number and morphology of the megakaryocytes and also rule out malignancy. The clinical response to therapeutic modalities, such as a platelet transfusion, also can be an important test and can help direct further investigations to define the diagnosis. In patients with immune-based platelet consumptions such as immune thrombocytopenic purpura, usually no response is found to platelet transfusion. Moreover, only a very short response may be seen in patients with other causes of increased consumption. Management of the patient is then aimed

at reducing the consumption and should involve consultation with a hematologist about the use of corticosteroids, the use of intravenous immunoglobulin or anti-D immunoglobulin (WinRho), the discontinuation of medications, and other treatment modalities.<sup>65</sup>

If the thrombocytopenia is caused by a lack of production of platelets, due to either aplastic anemia, malignancy, or chemotherapy, transfusion with platelet concentrate to increase the platelet count above a minimum of 50,000/ $\mu$ L will allow minor surgical procedures to be performed safely. Most surgeons and anesthesiologists prefer the platelet count to be greater than 100,000/ $\mu$ L before undertaking major surgery. Continued monitoring of platelet counts is vital because further transfusions may be needed to keep the platelet count above 50,000/ $\mu$ L for 3 to 5 days after operations.<sup>66</sup>

Qualitative platelet defects can be caused by rare congenital defects such as Bernard-Soulier syndrome, Glanzmann's thrombasthenia, or platelet storage pool disease. Alternatively, they can be caused by drug ingestions such as an aspirin-induced cyclooxygenase deficiency. In these situations, transfusion of normal donor platelets provides adequate hemostasis for the surgical procedure. Discontinuation of all aspirin-containing products 1 week before operation permits correction of the cyclooxygenase deficiency as new platelets are produced.<sup>6,67</sup>

## DISORDERS OF THROMBIN GENERATION AND FIBRIN FORMATION

Patients with rare deficiencies of other clotting factors, such as factors XI, X, VII, V, prothrombin, and fibrinogen, can have clinical bleeding depending on the level of deficiency. Most of these disorders are inherited in an autosomal recessive manner and can therefore affect both male and female patients. Replacement therapy with fresh frozen plasma or, in certain situations, with prothrombin complex concentrates corrects the deficiency and should be conducted under the direction of a hematologist.<sup>44,68</sup>

Vitamin K deficiency, both in the neonatal period and due to malabsorption, can cause deficiencies of factors II, VII, IX, and X. Treatment with 1 to 2 mg of intravenous vitamin K may begin to correct the deficiencies within 4 to 6 hours. However, if a surgical procedure is contemplated, fresh frozen plasma (15 mL/kg) should be given with the vitamin K, and prothrombin times monitored for correction of the coagulopathy before the operation. Laboratory monitoring should be maintained during the postoperative period to ensure continuation of the appropriate factor levels. Repeated doses of fresh frozen plasma and vitamin K may be needed.<sup>5</sup>

Patients with factor XIII deficiency usually are initially seen with delayed bleeding from the umbilical cord, rebleeding from wounds that have stopped bleeding, intracranial hemorrhage, and poor wound healing. These problems may be treated with relatively small amounts of fresh frozen plasma (5 to 10 mL/kg).

Because factor XIII has a half-life of 6 days, this treatment is usually needed only once to stop bleeding or at the time of operation.<sup>15,44</sup> Patients with dysfibrinogenemia or afibrinogenemia may be treated with fresh frozen plasma or cryoprecipitate.<sup>44</sup>

## FIBRINOLYTIC AND THROMBOTIC DISORDERS

Failure to control excess fibrinolysis can result in a bleeding disorder, and deficiencies of the naturally occurring anticoagulants may result in excess clot formation. A severe hemorrhagic disorder due to a deficiency of  $\alpha_2$ -antiplasmin has responded to treatment with aminocaproic acid or tranexamic acid, both antifibrinolytic agents.<sup>36</sup> Congenital antithrombin III, protein S, and protein C deficiencies are associated with recurrent thrombosis and are usually controlled with oral anticoagulants.<sup>36</sup> Factor V Leiden, prothrombin G20210A, and other activated protein C-resistance gene mutations will cause or add additional risk for thrombotic tendency in proportion to their homozygous or heterozygous states.<sup>69-71</sup> Operation requires discontinuation of the anticoagulation, and the patients will require replacement therapy during the procedure and in the postoperative healing period until anticoagulation can be restarted. Depending on the deficiency, antithrombin III concentrates or fresh frozen plasma can be used for replacement therapy, which should be conducted under the guidance of a hematologist with ready access to a full coagulation laboratory.

## RECOMBINANT ACTIVATED FACTOR VII

Recombinant activated factor VII (rFVIIa) was developed for the treatment of bleeding in patients with hemophilia A or B who had inhibitors and was approved by the U.S. Food and Drug Administration (FDA) for this indication in 1999.<sup>72-74</sup> Good hemostasis with few side effects was seen in patients with intracranial hemorrhage, post-laparotomy and postpartum hemorrhage, and hemorrhage into the gluteal muscles (as a complication after cholecystectomy) and for surgical prophylaxis for major and minor procedures.<sup>75-77</sup> Home treatment programs for some patients who are hemophiliacs with inhibitors now use rFVIIa as front-line therapy for bleeding.<sup>78</sup> Children have a more rapid rate of clearance (elimination mean half-life, 1.32 hours in children vs. 2.74 hours in adults).<sup>79</sup> They also seem to have fewer side effects with this treatment.<sup>74,80</sup> Although various dosages and schedules have been studied, initial recommended therapy in hemophilia A or B with inhibitors is 90 mg/kg intravenously every 2 hours until the bleeding is controlled.<sup>81</sup>

The off-label use of rFVIIa has been reported in therapy-resistant severe bleeding from other conditions such as congenital factor VII deficiency, chronic liver disease, and inherited platelet disorders.<sup>82-84</sup>

Successes in patients without a known bleeding disorder who have trauma or postoperative hemorrhage also are described.<sup>80,82,85,86</sup> These reports should be interpreted with caution, because rFVIIa is currently not the standard of care in any of these off-label uses and exceptional circumstances impelled its use. It is highly recommended that rFVIIa be administered under the supervision of a physician experienced in its use who can anticipate the risks and respond to the complications, particularly risks of thrombosis, which are reported in 1% to 3% of patients.<sup>72,87,88</sup> rFVIIa shows great promise in the emergency treatment of uncontrolled hemorrhage for many situations and is becoming the standard of care for the treatment of intracranial hemorrhage.<sup>89</sup>

## SICKLE CELL DISEASE

### General Principles

Sickle cell disease (SCD) is the most common disorder identified by neonatal blood screening, with approximately 2000 affected infants born in the United States each year. Overall, the incidence of SCD exceeds that of most other serious genetic disorders, including cystic fibrosis and hemophilia.<sup>90,91</sup> SCD is caused by a genetic mutation that results in an amino acid change in the  $\beta$ -globin and the production of sickle hemoglobin (Hb S) instead of normal hemoglobin (Hb A). The sickle cell gene, in combination with any other abnormal  $\beta$ -globin gene, results in SCD. There are many types of SCD. The most common include sickle cell anemia (Hb SS), the sickle  $\beta$ -thalassemias (Hb S $\beta^0$  and Hb S $\beta^+$ ), hemoglobin SC disease (Hb SC) and sickle cell/hereditary persistence of fetal hemoglobin (S/HPFH). Sickle cell anemia is the most common and, in general, the most severe form of SCD. Sickle  $\beta^0$ -thalassemia patients have clinical manifestations similar to those in patients with Hb SS disease. Sickle-C disease is the second most common form of SCD and generally has a more benign clinical course than does Hb SS or sickle  $\beta^0$ -thalassemia. Sickle  $\beta^+$ -thalassemia and S/HPFH patients also generally have a more benign clinical course. Patients with Hb SS disease and sickle  $\beta^0$ -thalassemia generally have lower hemoglobin levels and present a greater risk under general anesthesia than do patients with Hb SC disease and sickle  $\beta^+$ -thalassemia. Patients with S/HPFH may actually have hemoglobin levels that approach or are normal.

The red cell membrane is abnormal in patients with SCD, and the red cell life span is shortened by hemolysis. Intermittent episodes of vascular occlusion cause tissue ischemia, which results in acute and chronic organ dysfunction.<sup>92</sup> Consequently, patients with SCD require special considerations to prevent perioperative complications.

Because of the nature of the complications of SCD, people with this disorder are more likely to undergo surgery than the general population during their lifetime.<sup>93</sup> According to one study, the most common procedures were cholecystectomy; ear, nose, and throat

procedures; orthopedic procedures; splenectomy; or herniorrhaphy.<sup>94</sup> Cholecystectomy, splenectomy, and orthopedic procedures are often required to treat complications of SCD.

Children with SCD can require surgical evaluation and treatment either because of complications of their SCD or unrelated processes. Moreover, symptoms associated with vaso-occlusive episodes, such as abdominal pain and bone pain with fever, may be difficult to distinguish from other pathologic processes, such as cholecystitis and osteomyelitis.

The differential diagnosis for acute abdominal pain in a patient with SCD includes uncomplicated sickle cell acute pain episode ("crisis"), cholelithiasis, appendicitis, pancreatitis, ulcer, constipation, pneumonia, pericarditis, and splenic sequestration. Whereas 50% of painful episodes include abdominal pain, they are usually associated with pain in the chest, back, and joints. However, whereas previous episodes of pain that are similar in character suggest an acute painful episode, and this population may have the usual problems that can present as abdominal pain, the incidence of gallstones with cholecystitis, peptic ulcer disease, and pyelonephritis is increased. Complications such as splenic or hepatic sequestration are almost unique problems in patients with this disease. Abdominal pain as a solitary symptom, especially when accompanied by fever, leukocytosis, and localized abdominal tenderness, is suggestive of pathology other than that which occurs with a sickle cell acute painful episode. A study that reviewed the presentation and management of acute abdominal conditions in adults with SCD suggested that a surgical condition is more likely if the pain does not resemble previous painful episodes and if no precipitating event is found.<sup>95</sup> Acute painful episodes were relieved within 48 hours with hydration and oxygen in 97% of patients, whereas no patient with a surgical disease achieved pain relief over the same period with these modalities. The leukocyte count and serum bilirubin were not helpful in establishing the correct diagnosis.

Vaso-occlusive episodes can also produce bone pain and fever, symptoms that are difficult to differentiate from those of osteomyelitis. The majority of bone pain in SCD is due to vaso-occlusion, but osteomyelitis secondary to *Salmonella* species or *Staphylococcus aureus* is not infrequent.<sup>96,97</sup> The presence of an immature white blood cell count or elevation of the sedimentation rate, C-reactive protein, or leukocyte alkaline phosphatase is suggestive of a bone infection and may be an indication for aspiration of the bone lesion. Radiographic studies including simple plain films, bone scan, or magnetic resonance imaging are generally less helpful but may be useful in arriving at the proper diagnosis when positive and combined with the appropriate clinical findings.<sup>97</sup>

### Preoperative Assessment and Management

An optimal surgical outcome requires careful preoperative, intraoperative, and postoperative management by a team consisting of a surgeon, anesthesiologist,

and hematologist. Potential sickle cell–related complications include acute chest syndrome, pain episodes, hyperhemolytic crisis, aplastic crisis, alloimmunization with delayed transfusion reactions, and infections. The outcome of children with SCD requiring a surgical procedure is improved by careful attention to the cardiorespiratory, hemodynamic, hydration, infectious, neurologic, and nutritional status of the child.<sup>93,98-100</sup> If possible, procedures should be performed when the child is in his or her usual state of health with regard to the SCD. Attention should be directed toward chronic manifestations of disease because predictors of a poor postoperative outcome include increased age, recent exacerbations of the disease, and preexisting infection and pregnancy.<sup>101</sup> Particular attention should be directed toward any recent history of acute chest syndrome, pneumonia, wheezing, and alloimmunization. Special efforts must be made to avoid perioperative hypoxia, hypothermia, acidosis, and dehydration because any of these events can result in serious morbidity.

Many centers perform preoperative transfusions with the aim of reducing the complications of surgery and anesthesia.<sup>102</sup> The largest study to examine the role of transfusion in the preoperative management of sickle cell anemia was a randomized study that compared exchange transfusion (with a goal of achieving an Hb value of > 10 g/dL and Hb S value of < 30%) versus simple transfusion (to achieve an Hb value of > 10 g/dL).<sup>94,102</sup> This study concluded that not only was simple transfusion as effective as exchange transfusion in preventing perioperative complications but it also provided a significantly lower rate of transfusion-related complications.<sup>94</sup> The question of which procedures are safe to perform in children with SCD without preoperative transfusion remains controversial because there is a lack of randomized controlled trials to answer this question. However, simple transfusion to increase the Hb level to 10 g/dL for major procedures and blood replacement for both profound anemia of less than 5 g/dL and intraoperative hemorrhage appear appropriate.<sup>103</sup> Several studies suggest that minor procedures can possibly be safely undertaken without transfusion.<sup>93,102,104</sup> Alloimmunization can be minimized by giving antigen-matched blood (matched for K, C, E, S, Fy, and Jk antigens).<sup>100</sup> Regardless of transfusion status, strong multidisciplinary collaboration is vital throughout the perioperative period.

### Intraoperative Management

Anesthetic considerations are based more on the type of surgical procedure planned than on the presence of SCD because no single anesthetic technique has been shown to be the gold standard. However, regional anesthetic techniques may allow for opioid sparing in the postoperative period.<sup>101</sup> The goals of anesthetic management are to avoid factors that predispose the patient to sickling (e.g., hypoxemia, hypothermia, dehydration, and acidosis). Careful monitoring for hypoxia, hypothermia, acidosis, and dehydration is essential. Monitoring should include arterial blood

gases, digital oxygen saturation, end-tidal carbon dioxide, temperature, electrocardiogram, blood pressure, and urine output.<sup>101,105</sup>

### Postoperative Management

As with the preoperative and intraoperative periods, it is essential to prevent hypothermia, hypoxia, and hypotension throughout the postoperative period. Before extubation, the patient should be awake and oxygenating well. Once extubated, the patient must be carefully monitored with a digital oxygen saturation monitor and the pulmonary status critically assessed on a continuing basis. Continuous pulse oximetry should be provided in the early postoperative period. Assessment of fluid status should continue until the patient has resumed adequate oral intake and is able to maintain hydration without intravenous supplementation. All patients should receive incentive spirometry, as well as adequate hydration and oxygenation.

Appropriate levels of analgesia (preferably by a continuous intravenous line and patient-controlled analgesia, if appropriate) should be provided so the patient is comfortable enough to cooperate with ambulation and maintain pulmonary toilet without oversedation. Experienced respiratory therapists should administer a vigorous program for pulmonary toilet. The patient must be monitored closely for the occurrence of pulmonary edema or atelectasis that can progress to acute chest syndrome.<sup>106</sup>

## SPECIFIC SURGICAL CONDITIONS

### Adenotonsillectomy

Adenotonsillectomy is a fairly common procedure in children with SCD. Adenotonsillary hypertrophy, which may be associated with early functional hyposplenism and obstructive sleep apnea secondary to enlarged adenoids, occurs somewhat frequently.<sup>93,107,108</sup> As with other types of surgery, preoperative transfusions should be performed before surgery.<sup>109</sup> Clinicians should be aware that postoperative complications may be greater if obstructive sleep apnea is present and that a younger age may influence the likelihood of postoperative complications.<sup>93,110</sup>

### Cholelithiasis and Cholecystectomy

Abdominal operations such as cholecystectomy and splenectomy are the most frequent type of surgery performed in patients with SCD.<sup>93,103</sup> At present, no clear consensus exists regarding the appropriate therapy for SCD children who have cholelithiasis. The reported prevalence of cholelithiasis varies from 4% to 55%.<sup>111,112</sup> This wide variation is dependent on the ages of the study population and the diagnostic modalities used.<sup>113</sup> We routinely screen symptomatic children with ultrasonography and laboratory studies (e.g., total and direct bilirubin, serum glutamic-oxaloacetic transaminase, serum glutamate-pyruvate

transaminase, alkaline phosphatase, and  $\gamma$ -glutamyl-transpeptidase). It is our practice to screen all SCD children for gallstones by **no later than age 12 years**.

A child with SCD and symptomatic cholelithiasis should undergo cholecystectomy after appropriate preoperative preparation to avoid the increased morbidity of an emergency operation on an unprepared patient.<sup>113-118</sup> If indicated, intraoperative cholangiography can be performed to assess for common duct stones.<sup>119</sup>

The utility of laparoscopic cholecystectomy in SCD was first reported in 1990.<sup>120</sup> Since that time, laparoscopic cholecystectomy has been performed with increasing frequency in children with SCD.<sup>113,121-124</sup> The advantages of laparoscopic cholecystectomy over open cholecystectomy are decreased pain, earlier feeding, earlier discharge, earlier return to school, and improved cosmesis. The presence of common duct stones at times complicates the laparoscopic approach and may require conversion to an open operation for removal. At present, the role of extracorporeal shock wave lithotripsy as a palliative therapeutic modality is uncertain.

### Splenic Sequestration and Splenectomy

Before the advent of routine newborn screening for hemoglobinopathies, acute splenic sequestration was the second most common cause of mortality in children younger than age 5 years with sickle cell anemia.<sup>125</sup> Splenic sequestration classically was first seen with the acute onset of pallor and listlessness, a precipitate decrease in hemoglobin, thrombocytopenia, and massive splenomegaly.<sup>126</sup> It now appears that parental education along with earlier recognition and immediate treatment with volume support (including red blood cell transfusions) has resulted in significantly decreased mortality for this condition. It is rare for an otherwise uncomplicated patient with Hb SS disease who is older than 6 years of age to develop an acute splenic sequestration syndrome. However, patients with Hb SC and sickle  $\beta^+$ -thalassemia disease can experience splenic sequestration at an older age.<sup>127</sup>

The management of the SCD child with splenic sequestration is a clinical dilemma. The rate of recurrent splenic sequestration is high and greatly influences subsequent management, which may be divided into observation only, chronic transfusion, and splenectomy. Indications for these approaches are not clearly defined.<sup>100</sup> The benefit of splenectomy must be balanced with the increased risk of overwhelming bacterial sepsis in the younger asplenic SCD patient.<sup>100,128</sup> Partial splenectomy<sup>129,130</sup> and especially laparoscopic splenectomy<sup>131</sup> are being performed more commonly as the number of experienced practitioners grows.

---

### CONCLUSION

Children with SCD may require various surgical procedures for which the principles outlined in this chapter should be utilized. As a consequence of their disease, school-aged and adolescent patients are at higher risk for other medical complications that may require surgical intervention. For example, patients with priapism that is refractory to medical management may require operative management.<sup>132</sup> The physician should make sure the operating and anesthesia teams are aware of the diagnosis of sickle cell syndrome and the need for special attention. In patients with Hb SS and Hb S $\beta^0$ -thalassemia, simple transfusion to a hemoglobin level of 10 g/dL should be performed before all but the lowest-risk procedures. Alloimmunization should be minimized by giving antigen-matched blood (matched K, C, E, S, Fy, and Jk antigens). Patients with sickle cell disease, regardless of genotype, should all receive careful attention, with preoperative monitoring of intake and output, hematocrit, peripheral perfusion, and oxygenation status. Intraoperative monitoring of blood pressure, cardiac rhythm and rate, and oxygenation should be conducted for all surgical procedures. Postoperative care should include meticulous attention to hydration, oxygen administration with careful monitoring, and respiratory therapy.<sup>100</sup>

# EXTRACORPOREAL MEMBRANE OXYGENATION

Jason S. Frischer, MD • Charles J. H. Stolar, MD

Extracorporeal membrane oxygenation (ECMO) is a lifesaving technology that employs partial heart/lung bypass for extended periods. It is not a therapeutic modality but rather a supportive tool that provides sufficient gas exchange and perfusion for patients with acute, *reversible* cardiac or respiratory failure. This affords the patient's cardiopulmonary system a time to "rest," at which point the patient is spared the deleterious effects of high airway pressure, high  $\text{FiO}_2$ , traumatic mechanical ventilation, and perfusion impairment. Since the early anecdotal reports of neonatal and pediatric ECMO, the Extracorporeal Life Support Organization (ELSO) has registered approximately 35,000 neonatal and pediatric patients treated with ECMO for a variety of cardiopulmonary disorders. The number of centers providing extracorporeal support and reporting to ELSO continues to increase along with the total number of cases.<sup>1</sup>

## HISTORY

The initial effort to develop extracorporeal bypass was first led by cardiac surgeons. Their goal was to repair intracardiac lesions under direct visualization and, therefore, they needed to arrest the heart, divert and oxygenate the blood, and perfuse the patient so that repair could be performed. The first cardiopulmonary bypass circuits used in the operating room involved direct cross circulation between the patient and another subject (usually the patient's mother or father) acting as both the pump and the oxygenator.<sup>2</sup>

The first attempts at establishing cardiopulmonary bypass by complete artificial circuitry and oxygenation were constructed with disk-and-bubble oxygenators and were limited because of hemolysis encountered by direct mixing of oxygen and blood. The discovery of heparin and the development of semipermeable membranes (silicone rubber) capable of supporting

gas exchange by diffusion were major advancements toward the development of ECMO.<sup>3</sup> During the 1960s and early 1970s, the silicone membrane was configured into a number of oxygenator models by a number of investigators.<sup>4-7</sup>

In 1972, the first successful use of prolonged cardiopulmonary bypass was reported.<sup>8</sup> The patient sustained a ruptured aorta following a motorcycle accident. Venoarterial extracorporeal bypass support was maintained for 3 days. A multicenter prospective randomized trial sponsored by the National Heart, Lung, and Blood Institute (a branch of the National Institutes of Health) studied the efficacy of ECMO for adult respiratory distress syndrome. In 1979, they concluded that the use of ECMO had no advantage over that of conventional mechanical ventilation in this study, and the trial was stopped early.<sup>9</sup> However, Bartlett and colleagues<sup>10</sup> noted that all of the patients in the study had irreversible pulmonary fibrosis before the initiation of ECMO. In 1976, they reported the first series of infants treated with long-term ECMO, with a significant number of survivors. Six (43%) of 14 patients with respiratory distress syndrome survived. Many of these patients were premature and weighed less than 2 kg. Also, 22 patients with meconium aspiration syndrome had a 70% survival. These neonates tended to be larger.

Since then, despite study design issues, three randomized controlled trials and a number of retrospective published reports have reported the efficacy of ECMO versus conventional mechanical ventilation.<sup>11-18</sup> Other centers started to employ ECMO. By 1996, 113 centers were maintaining ECMO programs registered with ELSO.<sup>1</sup> Over the next 2 decades, improvements in technology, a better understanding of the pathophysiology of pulmonary failure, and a greater experience in using ECMO have contributed to improved outcomes for infants with respiratory failure. In 2003, the University of Michigan reported an association between ECMO volume and an observed reduction

in neonatal mortality seen in that state between 1980 through 1999.<sup>19</sup>

ELSO, formed in 1989, is a collaboration of physicians and scientists with an interest in ECMO. The organization provides the medical community with guidelines, training manuals and courses, and a forum in which these individuals can meet and discuss the future of extracorporeal life support. The group also provides a registry to investigators for the collection of data from almost all centers that maintain an ECMO program throughout the world. This database provides valuable information for analysis of this lifesaving biotechnology.<sup>20,21</sup>

## CLINICAL APPLICATIONS

Neonates are the patients who benefit most from ECMO. Cardiopulmonary failure in this population secondary to meconium aspiration syndrome, congenital diaphragmatic hernia (CDH), persistent pulmonary hypertension of the newborn (PPHN), and congenital cardiac disease are the most common pathophysiologic processes requiring ECMO. For the pediatric population, the most common disorders treated with ECMO are viral and bacterial pneumonia, acute respiratory failure (non-acute respiratory distress syndrome [ARDS]), ARDS, sepsis, and cardiac disease. The experience with cardiac ECMO has been increasing over the past decade. Treatment of patients who are unweanable from bypass after cardiac surgery and as a bridge to heart transplantation in patients with postsurgical or end-stage ventricular failure are areas in which ECMO use is increasing.<sup>1,22,23</sup> Some less frequently used indications for ECMO include respiratory failure secondary to smoke inhalation,<sup>24</sup> severe asthma,<sup>25</sup> rewarming of hypercoagulopathic/hypothermic trauma patients,<sup>26</sup> and maintenance of an organ donor pending liver allograft harvest and transplantation.<sup>27</sup>

## PATHOPHYSIOLOGY OF NEWBORN PULMONARY HYPERTENSION

Pulmonary vascular resistance (PVR) is the hallmark and driving force of fetal circulation. Normal fetal circulation is characterized by PVR that exceeds systemic pressures, resulting in higher right-sided heart pressures and, therefore, preferential right-to-left blood flow. The fetal umbilical vein carries oxygenated blood from the placenta to the inferior vena cava via the ductus venosus. Because of the high PVR, the majority of the blood that reaches the right atrium from the inferior vena cava is directed to the left atrium through the foramen ovale. The superior vena cava delivers deoxygenated blood to the right atrium that is preferentially directed to the right ventricle and pulmonary artery. This blood then takes the path of least resistance and shunts from the main pulmonary artery directly to the descending aorta via the ductus arteriosus, bypassing the pulmonary vascular bed and the left side of the heart. Therefore, as a consequence of these anatomic

right-to-left shunts, the lungs are almost completely bypassed by the fetal circulation.

At birth, with the infant's initial breath, the alveoli distend and begin to fill with air. This is paralleled by relaxation of the muscular arterioles of the pulmonary circulation and the expansion of the pulmonary vascular bed. This causes a rapid drop in PVR to below systemic levels. This activity causes the left atrial pressure to become higher than the right atrial pressure, leading to closure of the foramen ovale, resulting in all venous blood flowing from the right atrium to the right ventricle and into the pulmonary artery. The ductus arteriosus also closes at this time. Therefore, all fetal right-to-left circulation ceases, completing separation of the pulmonary and systemic circulations. Anatomic closure of these structures takes several days to weeks. Thus, maintaining the pressure gradient of systemic pressure greater than the pulmonary circulation is vital to sustaining normal circulation.

Failure of the transition from fetal circulation to newborn circulation is described as PPHN or persistent fetal circulation.<sup>28</sup> Clinically, PPHN is characterized by hypoxemia out of proportion to pulmonary parenchymal or anatomic disease. Normally, in fetal and term neonates, the pulmonary arterioles are muscular only as far as the terminal bronchioles. In hypoxic fetuses and infants, the proliferation of smooth muscle on the arterioles may extend far beyond the terminal bronchioles, resulting in thickened and more reactive vessels. In response to hypoxic conditions, these vessels undergo significant self-perpetuating vasoconstriction. Although sometimes idiopathic, PPHN can occur secondary to a number of disease processes, such as meconium aspiration syndrome, CDH, polycythemia, and sepsis.

Treatment for PPHN is directed at decreasing right-to-left shunts and increasing pulmonary blood flow. Previously, most patients were treated with hyperventilation, induction of alkalosis, neuromuscular blockade, and sedation. Unfortunately, these therapies have not reduced morbidity, mortality, or the need for ECMO in the neonatal population. ECMO allows for the interruption of the hypoxia-induced negative cycle of increased smooth muscle tone and vasoconstriction. ECMO provides richly oxygenated blood and allows the pulmonary blood pressure to return to normal subsystemic values without the iatrogenic complications encumbered by overly aggressive "conventional" therapy. Recently, data recommending gentle ventilation and the use of inhaled nitric oxide for these children have been reported. Hyperventilation and neuromuscular blockade were not part of the treatment strategy.<sup>29</sup> The infants were allowed to breathe spontaneously. This strategy has decreased morbidity, mortality, and the need of ECMO.

## PATIENT SELECTION CRITERIA

The selection of patients as potential ECMO candidates continues to remain controversial. The selection criteria are based on data from multiple institutions,

**Table 6-1** Recommended Pre-ECMO Studies

Head ultrasonography
Cardiac echocardiography
Chest radiography
Complete blood cell count, with platelets
Type and crossmatch of blood
Electrolytes, calcium
Coagulation studies (prothrombin time, partial thromboplastin time, fibrinogen, fibrin degradation products)
Serial arterial blood gas analysis

patient safety, and mechanical limitations related to the equipment. The risk of performing an invasive procedure that requires heparinization of a critically ill child must be weighed against the estimated mortality of the patient with conventional therapy alone. A predictive mortality of greater than 80% after exhausting all conventional therapies is the criterion most institutions follow to select patients for ECMO. Obviously, these criteria are subjective and will vary between facilities, based on local clinical experience and available technologies. All ECMO centers must develop their own criteria and continually evaluate their patient selection based on ongoing outcomes data.

Recommended pre-ECMO studies are listed in [Table 6-1](#). Indications for neonatal, cardiac, and pediatric ECMO all have their own modifiers. The definition of “conventional therapy” also is anything but consistent in any category. Nevertheless, ECMO is indicated when (1) there is a reversible disease process, (2) the ventilator treatment is causing more harm than good, and (3) tissue oxygenation requirements are not being met. A discussion of generally accepted selection criteria for using neonatal ECMO follows.

### Reversible Cardiopulmonary Disorders

The underlying principle of ECMO relies on the premise that the patient has a reversible disease process that can be corrected with either therapy (including the possibility of organ transplantation) or “rest” and that this reversal will occur in a relatively short period of time. Prolonged exposure to high-pressure mechanical ventilation with high concentrations of oxygen can have a traumatic effect on the newborn’s lungs and frequently leads to the development of bronchopulmonary dysplasia (BPD).<sup>30</sup> It has been suggested that BPD can result from high levels of ventilatory support for as little as 4 days or less.<sup>31</sup> The pulmonary dysfunction that follows barotrauma and oxygen toxicity associated with mechanical ventilation typically requires weeks to months to resolve. Therefore, patients who have been ventilated for a long time and in whom lung injury has developed are not amenable to a short course of therapy with ECMO. Most ECMO centers will not accept patients who have had more than 10 to 14 days of mechanical ventilation as candidates for ECMO, owing to the high probability of established, irreversible pulmonary dysfunction.

Echocardiography should be performed on every patient being considered for ECMO to determine cardiac anatomy and function. Treatable conditions such as total anomalous pulmonary venous return and transposition of the great vessels, which may masquerade initially as pulmonary failure, can be surgically corrected but may require ECMO resuscitation initially. Infants with correctable cardiac disease should be considered on an individual basis. ECMO also provides an excellent bridge to cardiac transplantation. ECMO as a bridge to lung transplantation is controversial because the time to receive a lung donor generally far exceeds the period of time one can be maintained on bypass.

### Coexisting Anomalies

Every effort should be made to establish a clear diagnosis before the initiation of ECMO. Infants with anomalies incompatible with life do not benefit from ECMO. ECMO is not a resource that is intended to delay an inevitable death. Many lethal pulmonary conditions such as overwhelming pulmonary hypoplasia, congenital alveolar proteinosis, and alveolar capillary dysplasia may present as reversible conditions but are considered lethal.<sup>32</sup>

### Gestational Age

The gestational age of an ECMO patient should be at least 34 to 35 weeks. In the early experience with ECMO, significant morbidity and mortality related to intracranial hemorrhage (ICH) was associated with premature infants (<34 weeks’ gestation).<sup>33</sup> Despite modification of the ECMO technique over the past 2 decades, premature infants continue to be at risk for ICH. In preterm infants, ependymal cells within the brain are not fully developed, thus making these infants susceptible to hemorrhage. Systemic heparinization necessary to maintain a thrombus-free circuit adds to the risk of hemorrhagic complications.

### Birth Weight

Technical considerations and limitation of cannula size restrict ECMO candidates to infants weighing at least 2000 g. The smallest single-lumen ECMO cannula is 8 French, and flow through a tube is proportional to the fourth power of the radius. Small veins permit only small cannulas, resulting in flow that will be reduced by a power of 4. Neonates who weigh less than 2 kg provide technical challenges in cannulation and in maintaining adequate blood flow through the small catheters.

### Bleeding Complications

Infants with ongoing, uncontrollable bleeding or an uncorrectable bleeding diathesis pose a relative contraindication to ECMO.<sup>20</sup> Any correctable coagulopathy should be corrected before initiating ECMO because the need for continuous systemic heparinization adds an unacceptable risk of bleeding.

## Intracranial Hemorrhage

Candidates for ECMO should not, as a rule, have had an ICH. A preexisting ICH may be exacerbated by the use of heparin and the unavoidable alterations in cerebral blood flow while receiving ECMO. Patients with small interventricular hemorrhages (grade I) or small intraparenchymal hemorrhage can be successfully treated on ECMO by maintaining a lower than optimal activated clotting time in the range of 180 to 200 seconds. These patients should be closely observed for extension of the intracranial bleeding. Patients posing a particularly high risk for ICH are those with a previous ICH, cerebral infarct, prematurity, coagulopathy, ischemic central nervous system injury, or sepsis. Consideration of these patients for ECMO should be individualized.<sup>32</sup>

## Failure of Medical Management

ECMO candidates are expected to have a reversible cardiopulmonary disease process, with a predictive mortality of greater than 80% to 90% with all available modalities short of ECMO. Because different institutions have varying technical capabilities, opinions, and expertise, “optimal” medical management is a subjective term that varies widely. Vasoconstrictive agents, inotropic agents, pulmonary vascular smooth muscle relaxants, sedatives, and analgesics are all pharmacologic agents that are part of the medical management. Ventilatory management usually begins with conventional support but may also include the administration of surfactant, nitric oxide, inverse inspiration/expiration (I:E) ratios, or high-frequency ventilation. Ventilator and respiratory care strategies that incur significant barotrauma and other morbidity should be rigorously avoided.

ECMO use has been obviated in patients who otherwise meet ECMO criteria because of recent innovations in medical management. These innovations include the use of permissive hypercapnia with spontaneous ventilation, avoidance of muscle paralysis, and the avoidance of chest tubes. In 1978, the Children’s Hospital of New York reported a nontraditional approach to the management of patients with PPHN, which has been successfully extended to infants with CDH.<sup>34</sup> Hyperventilation, hyperoxia, and muscle relaxants were not used, and permissive hypercapnia in conjunction with spontaneous ventilation was emphasized. Low-pressure ventilator settings were used and persistent  $Paco_2$  of 50 to 80 mm Hg and a  $PaO_2$  of 40 mm Hg were allowed. With careful attention to maintaining a *preductal* oxygen saturation greater than 90% or  $PaO_2$  of 60 mm Hg or greater, 15 infants who met ECMO criteria with PPHN and in severe respiratory failure were initially treated with this approach and survived without ECMO.

## Risk Assessment

Because of the invasive nature of ECMO, and the potentially life-threatening complications, investigators have worked to develop an objective set of criteria

to predict which infants have an 80% mortality without ECMO. The two most commonly used measurements for neonatal respiratory failure are the alveolar-arterial oxygen gradient ( $[A-a]DO_2$ ) and the oxygenation index (OI), which are calculated as follows:

$$(A-a)DO_2 = (Patm - 47)(FIO_2) - [(Paco_2)/0.8] - Pao_2$$

where  $Patm$  is the atmospheric pressure and  $FIO_2$  is the inspired concentration of oxygen.

$$OI = \frac{MAP \times FIO_2 \times 100}{Pao_2}$$

where MAP is the mean airway pressure.

Although criteria for ECMO varies from institution and by diagnosis, it is generally accepted that, in the setting of optimal management, an  $(A-a)DO_2$  greater than 625 mm Hg for more than 4 hours, or an  $(A-a)DO_2$  greater than 600 mm Hg for more than 12 hours, or an OI of greater than 40 establishes both a relatively sensitive and specific predictor of mortality. Other criteria used by many institutions include a *preductal*  $PaO_2$  less than 35 to 50 mm Hg for 2 to 12 hours or a pH of less than 7.25 for at least 2 hours with intractable hypotension. These are sustained values measured over a period of time and are not accurate predictors of mortality.<sup>14,20,35-37</sup> Patients with CDH are in their own category, and criteria for this situation are discussed later in this chapter.

Older infants and children do not have as well-defined criteria for high mortality risk. The ventilation index is determined by the following:

$$\frac{\text{Respiratory rate} \times Paco_2 \times \text{Peak inspiratory pressure}}{1000}$$

The combination of a ventilation index greater than 40 and an OI more than 40 correlates with a 77% mortality. A mortality of 81% is associated with an  $(A-a)DO_2$  greater than 580 mm Hg and a peak inspiratory pressure of 40 cm  $H_2O$ . Indications for support in patients with cardiac pathology are based on clinical signs such as hypotension despite the administration of inotropes or volume resuscitation, oliguria (urine output < 0.5 mL/kg/hr), and decreased peripheral perfusion.

## Congenital Diaphragmatic Hernia

Of most interest to surgeons are neonates with abdominal viscera in the thoracic cavity due to a CDH. These patients are plagued with pulmonary hypertension and have pulmonary hypoplasia both on the ipsilateral and contralateral lungs with regard to the hernia. Often, pulmonary insufficiency ensues and a vicious cycle of hypoxia, hypercarbia, and acidosis quickly ravages the child’s well-being. This process must be interrupted by medical management, which has vastly improved over the past 2 decades with the use of permissive hypercapnia/spontaneous respiration, pharmacologic therapy, and delayed elective repair.

High-frequency oscillation may have its major role in forestalling respiratory failure when used as a “front end” strategy rather than as a “rescue therapy.”<sup>38</sup> Surfactant plays no more than an anecdotal role. Nitric oxide is an important vasodilator in the treatment of pulmonary hypertension in these patients. Other pulmonary vasculature vasodilators such as epoprostenol, sildenafil, and iloprost are starting to demonstrate a significant efficacy in this patient population. The primary indicator for ECMO in the patient with CDH is when tissue oxygen requirements are not being met, as evidenced by progressive metabolic acidosis, mixed venous oxygen desaturation, and multiple organ failure. The other indicator is mounting iatrogenic pulmonary injury.

Permissive hypercapnia with spontaneous respiration is initiated with intermittent mandatory ventilation (IMV), 30 to 40 breaths per minute, equal I/E time, inspiratory gas flow of 5 to 7 L/min, peak inspiratory pressure (PIP) of 20 to 22 cm H<sub>2</sub>O, and positive end-expiratory pressure (PEEP) of 5 cm H<sub>2</sub>O. The FIO<sub>2</sub> is selected to maintain preductal SaO<sub>2</sub> greater than 90%. If this mode is not sufficient, as demonstrated by severe paradoxical chest movement, severe retractions, tachypnea, inadequate or labile oxygenation (preductal O<sub>2</sub> saturations < 80%), or PaCO<sub>2</sub> greater than 60 mm Hg, then a new mode of ventilation is needed.

High-frequency ventilation would be the next mode of therapy to be considered. It is delivered by setting the ventilator to IMV mode with a rate of 100, inspiratory time of 0.3, an inspiratory gas flow of 10 to 12 L, a PIP of 20, and a PEEP of 0 (due to auto-PEEP). The PIP is adjusted as needed based on chest excursion, with attempts to maintain PIP at less than 25 mm Hg.

High-frequency oscillation can be instituted if the high-frequency ventilation is refractory to improving the hypoxia and hypercarbia using the same parameters as just mentioned, but improvement may be no more than temporary. The goal is to maintain preductal oxygen saturations between 90% and 95%. Spontaneous breathing is preserved by rigorously avoiding muscle relaxants. Sedation is used only as needed. Meticulous attention to maintaining a clear airway and the well-being of the infant is obvious but critical.<sup>39,40</sup>

Before ECMO is initiated for an infant with CDH, the infant must first demonstrate some evidence of adequate lung parenchyma. Some programs use radiographic parameters to determine adequate lung volumes. The lung-to-head ratio (LHR) is measured by prenatal ultrasonography.<sup>41</sup> It is defined as the product of the orthogonal diameters of the right lung divided by the head circumference. Severe pulmonary hypoplasia is considered when the LHR is less than 1.0 and intermediate hypoplasia lies between 1.0 and 1.4.<sup>42</sup> The LHR is operator dependent and can only be obtained in a narrow gestational window and therefore leads to poor reproducibility across different centers.

In the past decade there has been a great advance in fetal magnetic resonance imaging (MRI), and this technology has recently been applied to CDH. Studies

are starting to demonstrate that a percentage of the predicted lung volume (PPLV) can accurately predict disease severity in CDH. A group of investigators in Boston published a report that stated that a value less than 15 is associated with significantly higher risks, meaning prolonged support and/or death in this population.<sup>43</sup>

Many centers believe the best method to evaluate pulmonary hypoplasia and predict outcome is to evaluate the patient clinically. This is assessed by having a recorded best PaCO<sub>2</sub> less than 50 mm Hg and a preductal oxygen saturation greater than 90% for a sustained period of at least 1 hour at any time in their clinical course. With these criteria, successful ECMO should yield an overall survival rate of 75% or better. If patients with lethal anomalies, overwhelming pulmonary hypoplasia, or neurologic complications are not included, survival can approach 85%.<sup>39,40,44</sup>

## Extracorporeal Cardiopulmonary Resuscitation

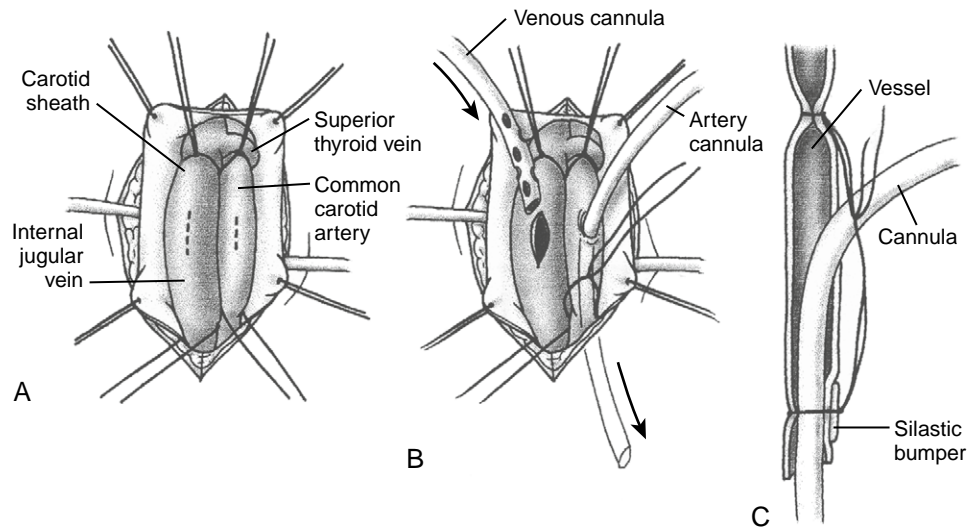

Studies demonstrate that 1% to 4% of pediatric intensive care unit admissions have a cardiac arrest. Survival to discharge for a patient who had an arrest in the pediatric intensive care unit ranges from 14% to 42%. The ELSO data demonstrate that approximately 73% of extracorporeal cardiopulmonary resuscitation (ECPR) was used for patients with primary cardiac disease. Overall survival to discharge in this population reached 38%. The American Heart Association recommends ECPR for in-hospital cardiac arrest refractory to initial resuscitation, secondary to a process that is reversible or amenable to heart transplantation. Conventional CPR must have failed, no more than several minutes should have elapsed, and ECMO must be readily available. ECPR is at its infancy, and this method of acute resuscitation needs to be explored further. Future research needs to analyze which patients will benefit the most with as little morbidity as possible.<sup>45</sup>

## Second Course of ECMO

Approximately 3% of patients that are treated with ECMO will require a second course. The survival rates for patients in this cohort are comparable to the first course. Negative prognostic indicators for second-course ECMO patients include renal compromise patients, higher number of first-course complications, age older than 3 years old, or a prolonged second course.<sup>46</sup>

## METHODS OF EXTRACORPOREAL SUPPORT

The goal of ECMO support is to provide an alternate means for oxygen delivery. Three different extracorporeal configurations are used clinically: venoarterial (VA), venovenous (VV), and double-lumen single cannula venovenous (DLVV) bypass. The inception of ECMO and its early days were characterized by VA

**Figure 6-1.** Details of the cannulation procedure. **A**, The carotid sheath is exposed, the sternocleidomastoid muscle is retracted laterally, and the common carotid artery and the internal jugular vein are dissected free. **B**, The patient is anticoagulated after the vessels are dissected and ligated cephalad. The arterial cannula is passed into the junction of the innominate artery and the aorta. The venous catheter is passed into the right atrium. **C**, A polymeric silicone (Silastic) bumper is used to facilitate ligation of the cannulas. The two ligatures on each vessel are then tied together.

ECMO because it offered the ability to replace both cardiac and pulmonary function. Venous blood is drained from the right atrium through the right internal jugular vein, and oxygenated blood is returned via the right common carotid artery to the aorta.

There are potential disadvantages with VA ECMO. A major artery must be cannulated and sacrificed. The risk of gas and particulate emboli into the systemic circulation is substantial, pulmonary perfusion is reduced, and decreased preload and increased afterload may reduce cardiac output, resulting in nonpulsatile flow. Finally, the coronary arteries are perfused by left ventricular blood, which is relatively hypoxic.

VV and DLVV avoid these disadvantages and provide pulmonary support but do not provide cardiac support. VV bypass is established by drainage from the right atrium via the right internal jugular vein with reinfusion into a femoral vein. DLVV is accomplished by means of a double-lumen catheter inserted into the right atrium via the right internal jugular vein. A major limitation of VV or DLVV ECMO is that a fraction of the infused, oxygenated blood reenters the pump and, at high flows, may limit oxygen delivery (recirculation). A limitation specific to DLVV is catheter size, which confines use of this method of support to larger neonates, infants, and smaller pediatric patients. VV and DLVV bypass have become the preferred method of extracorporeal support for all appropriate patients who do not require cardiac support.<sup>20</sup>

## Cannulation

Cannulation can be performed in the neonatal or pediatric intensive care unit under adequate sedation and intravenous anesthesia, with proper monitoring. The infant is positioned supine with the head at the foot of the bed and the head and neck hyperextended over a

shoulder roll and turned to the left. Local anesthesia is administered over the proposed incision site. A transverse cervical incision is made along the anterior border of the sternomastoid muscle, one fingerbreadth above the right clavicle. The platysma muscle is divided, and dissection is carried down with the sternomastoid muscle retracted to expose the carotid sheath. The sheath is opened, and the internal jugular vein, common carotid artery, and vagus nerve are identified (Fig. 6-1A). The vein is exposed first and encircled with proximal and distal ligatures. Occasionally it is necessary to ligate the inferior thyroid vein. The common carotid artery lies medial and posterior, contains no branches, and is mobilized in a similar fashion. The vagus nerve should be identified and protected from injury.

If time permits, an activated clotting time (ACT) should be checked before heparinization. The patient is then systemically heparinized with 50 to 100 U/kg of heparin, which is allowed to circulate for 2 to 3 minutes, which should produce an ACT of more than 300 seconds. The arterial cannula (usually 10 Fr for newborns) is measured so that the tip will lie at the junction of the brachiocephalic artery and the aorta (2.5 to 3 cm or approximately one third the distance between the sternal notch and the xiphoid). The venous cannula (12-14 Fr for neonates) is measured so that its tip lies in the distal right atrium (6 to 8 cm or approximately half the distance between the suprasternal notch and the xiphoid process). The arterial cannula is usually inserted first with VA bypass. The carotid artery is ligated cephalad. Proximal control is obtained, and a transverse arteriotomy is made near the cephalad ligature (see Fig. 6-1B). To help prevent intimal dissection, stay sutures (of fine Prolene) are placed around the arteriotomy and used for retraction when placing the arterial cannula. The saline-filled cannula is inserted to its premeasured position and

secured in the vessel with two silk ligatures (2-0 or 3-0). A small piece of vessel loop (bumper) may be placed under the ligatures on the anterior aspect of the carotid to protect the vessel from injury during decannulation (see Fig. 6-1C).

In preparation for the venous cannulation, the patient is given succinylcholine to prevent spontaneous respiration. The proximal jugular vein is then ligated cephalad to the site selected for the venotomy. Gentle traction on this ligature helps during the venous catheter insertion. A venotomy is made close to the ligature. The saline-filled venous catheter is passed to the level of the right atrium and secured in a manner similar to that used for the arterial catheter. Any bubbles are removed from the cannulas as they are connected to the ECMO circuit. Bypass is initiated. The cannulas are then secured to the skin above the incision. The incision is closed in layers, ensuring that hemostasis is meticulous.

For VV and DLVV bypass, the procedure is exactly as just described, including dissection of the artery, which is surrounded with a vessel loop to facilitate conversion to VA ECMO should that become necessary. The venous catheter tip should be in the mid-right atrium (5 cm in the neonate) with the arterial portion of the DLVV catheter oriented medially (pointed toward the ear) to direct the oxygenated blood flow toward the tricuspid valve.

The cannula positions for VA ECMO are confirmed by chest radiograph and transthoracic echocardiogram. The venous catheter should be located in the inferior aspect of the right atrium, and the arterial catheter at the ostium of the innominate artery and the aorta. With a double-lumen venous catheter, the tip should be in the mid-right atrium with return oxygenated blood flow toward the tricuspid valve.<sup>47</sup>

A challenging situation can arise when one attempts to cannulate a newborn with a right-sided CDH. Anatomic distortion can lead to cannulation of the azygos vein, which will then fail to provide adequate ECMO support. This can usually be detected by poor pump function and echocardiography, which will not be able to demonstrate the cannula in the superior vena cava or right atrium. In this situation, attempting cannula manipulation is often wrought with failure, and one should consider other avenues for venous drainage, including central cannulation.<sup>48</sup>

The small pediatric population (ages 2-12 years of age) presents a difficult and controversial scenario with regard to cannulation. Some centers continue to perform arterial cannulation via the carotid artery. The long-term outcome is unknown in this population after sacrificing the artery. Due to this concern, some centers will cannulate these patients via femoral access. The arterial cannula is large and often either partially or completely obstructs antegrade flow. This has the potential morbidity of distal limb ischemia, which can lead to sensory or motor deficits, tissue loss, or even limb loss. One potential way to avoid this morbidity is to provide antegrade flow via a percutaneously placed distal perfusion catheter (Fig. 6-2).<sup>49</sup>

**Figure 6-2.** This infant has been cannulated for ECMO using the femoral artery and vein. To prevent possible distal limb ischemia, antegrade flow has been provided via a percutaneously placed distal perfusion catheter.

## ECMO Circuit

Venous blood is drained from the infant by gravity through the cannula that is in the right atrium via the right internal jugular vein into a small reservoir or bladder (Fig. 6-3). An in-line oxymetric probe is located between the venous-return cannula and the bladder. This continuously monitors blood pH, PaO<sub>2</sub>, PCO<sub>2</sub>, and O<sub>2</sub> saturation. The monitor provides the information equivalent to the mixed venous blood gas (excluding any recirculation in VV or DLVV ECMO) and is extremely useful in monitoring the patient's status. The bladder is a 30- to 50-mL reservoir that acts as a safety valve. In the event that venous drainage does not keep up with arterial flow from the pump, the bladder volume will be depleted, sounding an alarm and automatically shutting off the pump. The blood flow through the circuit ceases to prevent gas bubbles forming from solution or drawing air into the circuit. Hypovolemia is one of the most common causes of decreased venous inflow into the circuit, but kinking and occlusion of the venous line should be suspected first. Raising the height of the patient's bed can improve venous drainage by gravity. An algorithm for managing pump failure due to inadequate venous return is shown in Figure 6-4.

A displacement roller pump pushes blood through the membrane oxygenator. The roller pumps are designed with microprocessors that allow for calculation of the blood flow based on roller-head speed and tubing diameter of the circuit. The pumps are connected to continuous pressure monitoring throughout the circuit and are servoregulated if pressures within the circuit exceed preset parameters. Another safety device, the bubble detector (not depicted in Fig. 6-3), is interposed between the pump and the membrane oxygenator that halts perfusion to the patient if air is detected within the circuit. The oxygenator consists of a long, two-compartment chamber composed of a spiral-wound silicone membrane and a polycarbonate

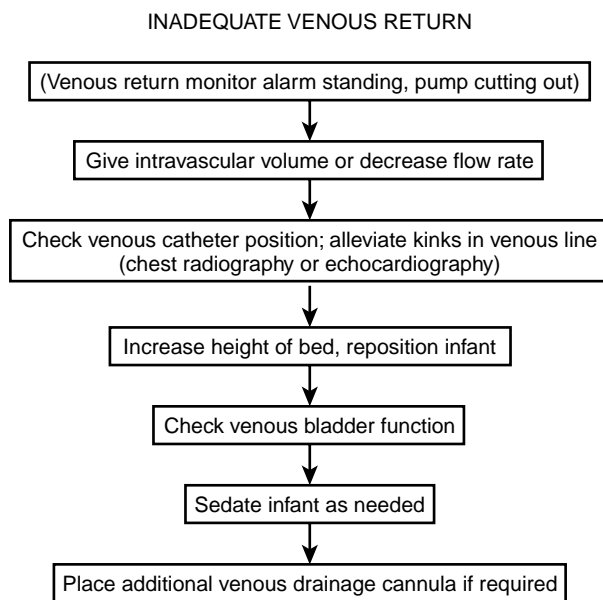

**Figure 6-3.** Diagram of venoarterial extracorporeal membrane oxygenation circuit.

core, with blood flow in one direction and oxygen flow in the opposite direction. Oxygen diffuses through the membrane into the blood circuit, and carbon dioxide and water vapor diffuse from blood into the sweep gas. The size (surface area) of the oxygenator is based on the patient's size. Another oxymetric probe is located in the arterial return line distal to the oxygenator to

provide information about the blood returning to the patient. The blood emerges from the upper end of the oxygenator and passes through the countercurrent heat exchanger and returns at body temperature to the aortic arch via the right common carotid artery.

## PATIENT MANAGEMENT ON ECMO

Once the cannulas are connected to the circuit, bypass is initiated, and the flow is slowly increased to 100 to 150 mL/kg/min. Continuous in-line monitoring of the (pre-pump)  $\bar{S}\bar{V}O_2$  and arterial (post-pump)  $PaO_2$  as well as pulse oximetry is vital. The goal of VA ECMO is to maintain an  $\bar{S}\bar{V}O_2$  of 37 to 40 mm Hg and saturation of 65% to 70%. VV ECMO is more difficult to monitor because of recirculation, which may produce a falsely elevated  $\bar{S}\bar{V}O_2$ . Inadequate oxygenation and perfusion are indicated by metabolic acidosis, oliguria, hypotension, elevated liver function test results, and seizures. Arterial blood gases should be monitored closely, with  $PaO_2$  and  $Paco_2$  maintained at as close to normal levels as possible. The oxygen level of the blood returning to the patient should be maintained fully saturated. To increase a patient's oxygen level on ECMO, one can either increase the ECMO flow rate ( $\sim$  cardiac output) or the hemoglobin must be increased to maintain hemoglobin at 15 g/dL ( $\sim$  oxygen content).  $CO_2$  elimination is extremely efficient with the membrane, and it is important to adjust the sweep (gas mixing) to maintain a  $Paco_2$  in the range of 40 to 45 mm Hg. This is important, especially during weaning, because a low  $Paco_2$  inhibits the infant's spontaneous respiratory drive. Vigilant monitoring allows timely adjustments. In addition to continuous blood gas monitoring, the arterial blood gas

**Figure 6-4.** Suggested algorithm for the management of inadequate venous return during extracorporeal membrane oxygenation. (Adapted from DeBerry BB, Lynch J, Chung DH, Zwischenberger JB: Emergencies during ECLS and their management. In Van Meurs K, Lally KP, Peek G, Zwischenberger JB (eds): ECMO: Extracorporeal Cardiopulmonary Support in Critical Care, 3rd ed. Ann Arbor, MI, Extracorporeal Life Support Organization, 2005, pp 133-156.)

**Table 6-2** General Studies Obtained during ECMO

Laboratory Study	General Frequency and Comments
Chest radiography	Daily
Cranial ultrasonography	Only for neonates, the first 3 days and then as needed
Activated clotting time	Every 1 hr, more often if outside of parameters
Preoxygenator blood gas	Every 4 hr
Postoxygenator blood gas	Every 4 hr
Patient blood gas	Every 6 hr
Glucose monitoring test	Every 4 hr
Complete blood cell count with platelets	Every 6 hr; include a differential daily
Chem-7	Every 6 hr, including magnesium, calcium, and phosphorus daily
Fibrinogen	Daily and after infusion of cryoprecipitate and fresh frozen plasma; may also include prothrombin time and D-dimer

is directly measured every 4 hours. As soon as these parameters are met, all vasoactive drugs are weaned and ventilator levels are adjusted to “rest” settings. Gastrointestinal prophylaxis ( $H_2$  antagonists or proton pump inhibitors) is initiated, and mild sedation and analgesia are provided, usually with fentanyl and midazolam. Paralyzing agents are avoided. Ampicillin and either gentamicin or cefotaxime are administered for antimicrobial prophylaxis. Routine blood, urine, and tracheal cultures should be obtained.<sup>20,47</sup> A daily chest radiograph is performed. Opacification or “white out” is often noted during the early ECMO course. The reasons for this are multifactorial and include decreased ventilatory pressures (both PIP and PEEP), reperfusion of the injured lung, and exposure of the blood to a foreign surface, causing an inflammatory response with the release of cytokines. A list of typical diagnostic tests is shown in Table 6-2.

Heparin is administered (30-60 mg/kg/hr) throughout the ECMO course to preserve a thrombus-free circuit. ACTs should be monitored hourly and maintained at 180 to 220 seconds. A complete blood cell count should be obtained every 6 hours and coagulation profiles obtained daily. To prevent a coagulopathy, platelets are transfused to maintain a platelet count greater than 100,000/mm<sup>3</sup>. The use of fibrinogen and other clotting factors is controversial. The hematocrit should remain above 40% by using red blood cell transfusions so that oxygen delivery is maximized.<sup>20</sup>

Volume management of patients on ECMO is extremely important and very difficult. It is imperative that all inputs and outputs be diligently recorded and electrolytes monitored every 6 hours. All fluid losses should be replaced and electrolyte abnormalities corrected. All patients should receive maintenance fluids as well as adequate nutrition by using parenteral hyperalimentation. The first 48 to 72 hours of

ECMO typically involve fluid extravasation into the soft tissues. The patient becomes edematous and often requires volume replacement (crystalloid, colloid, or blood products) to maintain adequate intravascular and bypass flows, appropriate hemodynamics, and urine output greater than 1 mL/kg/hr. By the third day of bypass, diuresis of the excess extracellular fluid begins and can be facilitated with the use of diuretics and, if necessary, an in-line hemofilter.<sup>20,47</sup>

## Operative Procedure on ECMO

Surgical procedures, such as CDH repair, may be performed while the child remains on bypass, but one must account for the need for continued postoperative anticoagulation. Hemorrhagic complications are a frequent morbidity associated with this situation, and these complications increase mortality. To try to avoid these problems before the procedure, the platelet count should be greater than 150,000/mm<sup>3</sup>, the ACT can be reduced to 180 to 200 seconds, and ECMO flow is increased to full support. Moreover, it is imperative that meticulous hemostasis is obtained throughout the operation. The fibrinolysis inhibitor aminocaproic acid (100 mg/kg) is administered just prior to incision, followed by a continuous infusion (30 mg/kg/hr) until evidence of bleeding ceases.<sup>20,47</sup>

## Weaning and Decannulation

As the patient improves, less blood flow is required to pass through the ECMO circuit and the flow may be weaned at a rate of 10 to 20 mL/hr as long as the patient maintains good oxygenation and perfusion. The most important guide to VA ECMO weaning is the  $S\bar{V}O_2$ . For VV ECMO, it is the  $SaO_2$ . Flows should be decreased to 30 to 50 mL/kg/min, and the ACT should be at a higher level (200-220 seconds) to prevent thrombosis. Moderate conventional ventilator settings are used, but higher settings can be used if the patient needs to be weaned from ECMO urgently. If the child tolerates the low flow, all medications and fluids should be switched to vascular access on the patient and the cannulas may be clamped, with the circuit bypassing the patient via the bridge. If the possibility remains that the child may need to be placed back on bypass, then the cannulas should be flushed with heparin (2 U/mL). The patient is then observed for 2 to 4 hours. If this is tolerated, decannulation can be accomplished.

Decannulation is performed in a near-identical manner as cannulation. This should be executed under sterile conditions with the patient in the Trendelenburg position and with the use of a muscle relaxant to prevent air aspiration into the vein. Ventilator settings should be increased with the use of the muscle relaxant. The venous catheter is typically removed first to allow for better exposure, and the vessel is ligated. Repair of the carotid artery is controversial. Short-term results demonstrate acceptable patency rates and an equivalent short-term neurodevelopmental outcome when compared with children undergoing carotid

artery ligation.<sup>50,51</sup> However, long-term follow-up of ECMO survivors is necessary to determine whether carotid artery repair is important. The incision should be irrigated and closed over a small drain, which is removed 24 hours later.<sup>20,47</sup>

## COMPLICATIONS

### Mechanical Complications

#### *Membrane Failure*

Failure of the membrane oxygenator is demonstrated by a decrease in oxygenation or retention of CO<sub>2</sub>. The cause of such complications include either fibrin clot formation or water condensation, both of which diminish the membrane's ability to transfer oxygen and CO<sub>2</sub>. An incidence of oxygenator failure or clot in the oxygenator is reported in 21.6% of respiratory ECMO runs in the neonatal and pediatric population.<sup>1</sup> This is potentially a serious complication and deserves due attention. The membrane should not be subject to high pressures, which should be continuously monitored. Pressure limits are specific for different manufacturers of membranes and for the size of the membrane. Signs of clot formation within the membrane can be detected by direct visualization of the top or bottom of the membrane, but the extent of the clot cannot be determined. The progressive consumption of coagulation factors, such as platelets and fibrinogen, also indicates that the membrane may be progressively building clot, and the need to change the oxygenator should be considered. Another sign of impending membrane failure is the formation of water vapor exiting the exhaust port of the oxygenator, along with rising CO<sub>2</sub> levels. The oxygenator can easily be exchanged without coming off bypass if the circuit was built with a double-diamond tubing arrangement with dual connectors both before and after the membrane. Such an arrangement allows parallel placement of a new oxygenator without having to come off bypass.

#### *Raceway Tubing Rupture*

Tubing rupture has become a much less frequent event with the introduction of Super Tygon (Norton Performance Plastics, Inc., Akron, OH) tubing. Extra tubing between the bladder and the oxygen membrane should be part of the initial circuit construction so that it can be used to rotate or "walk the raceway" tubing within the roller pump. This should be performed every 5 to 7 days and requires coming off pump for a matter of seconds. The tubing should be inspected repeatedly and all connections secured properly and replaced if defective. When a raceway rupture does occur, the pump must be turned off immediately, and the patient must be ventilated and perfused by conventional methods (increased ventilator pressures and oxygen, and CPR performed, if necessary). The raceway tubing should be replaced and the flow recalibrated.

### *Accidental Decannulation*

Securing the cannulas properly and taping the tubing in place to the bed with some motion of the patient's head still possible will help prevent accidental decannulation. Unexpected decannulation is a surgical emergency, and immediate pressure should be applied to the cannula site along with discontinuation of bypass. Conventional ventilator settings should be increased simultaneously. The neck incision must be immediately re-explored to prevent further hemorrhage and the cannulas replaced if continued bypass is needed.

### Patient Complications

#### *Air Embolism*

The ECMO circuit has several potential sources for entry of air. The initial cannulation procedure can be a source of air embolism. Thus, all visible air bubbles should be removed by using heparinized saline. Other entry points throughout the circuit include all of the connectors, the stopcocks, and the membrane oxygenator. Therefore, the circuit must be continually inspected. Air on the arterial side requires the patient to be taken off bypass immediately. The air should be aspirated from a port and the blood recirculated through the bridge until all air has been removed. Air on the venous side is not as urgent a problem, and the air can often be "walked" into the bladder where it can be aspirated without coming off bypass.

In the event that an air embolism reaches the patient, he or she should be immediately taken off ECMO and conventional ventilator settings adjusted to best meet the child's needs. The patient should be placed in the Trendelenburg position to prevent air from entering the cerebral circulation. Next, an attempt should be made to aspirate any accessible air out of the arterial cannula. If air enters the coronary circulation, inotropic support may be necessary. Before reinstating ECMO, identifying and repairing the cause of the embolus is essential. Prevention of air embolism is vital. When setting up the circuit, all air must be removed and all connections made tight and thoroughly inspected before initiating bypass.

#### *Neurologic Complications*

For respiratory ECMO in neonates and pediatric patients, neurologic complications have an overall incidence of 26.3%.<sup>1</sup> ICH, infarct, and seizure carry significant mortality when encountered in ECMO patients. Frequent neurologic examinations should be performed and the use of paralytic agents avoided. The examination should include evaluation of alertness and interaction, spontaneous movements, eye findings, the presence of seizures, fullness of the fontanelles, tone, and reflexes. Cranial ultrasonography should be performed on all neonates before initiating ECMO to identify those patients in whom significant ICH already exists. A retrospective analysis revealed that birth weight and gestational age were the most

significant correlating factors with ICH for neonates on ECMO.<sup>33</sup> Once the patient goes on ECMO, ultrasonography is repeated during the first 3 days when indicated by clinical condition. If the examination reveals a new moderate (grade II) hemorrhage or an expanding ICH, ECMO is usually discontinued and reversal of anticoagulation is advisable.

In the event that an ICH is suspected or detected on cranial ultrasonography and deemed to be small in size, it is reasonable to maintain a low ACT (180-200 seconds) with a platelet count greater than 125,000 to 150,000/mm<sup>3</sup>. Serial head ultrasound imaging should be performed to monitor the progression of the hemorrhage.<sup>20</sup>

### *Cannula Site or Bleeding at Other Sites*

The ECMO registry reports an 8.4% incidence of cannulation site bleeding and a 13% incidence of other surgical site bleeding.<sup>1</sup> Contact of blood with the foreign surface of the circuit activates the coagulation cascade. The number of platelets and their function are also affected. In conjunction with anticoagulation, the risk of bleeding while undergoing an operation on ECMO is considerable. To reduce this risk, meticulous hemostasis should be maintained during the procedure and before closure. If necessary, the surgeon should employ topical hemostatic agents. Lowering the ACT parameters to 180 to 200 seconds and maintaining a platelet count of at least 125,000/mm<sup>3</sup> can assist in obtaining hemostasis. If bleeding from the cannula incision is greater than 10 mL/hr for 2 hours despite conservative treatment strategies, it should be explored.<sup>20</sup>

Bleeding into the site of previous surgical interventions occurs frequently and must be handled aggressively. Constant monitoring for bleeding by observing a decreasing hematocrit, an increasing heart rate, a decline in the blood pressure, or an inadequate venous return are signs of hemorrhage. Treatment includes replenishing lost blood products, including coagulation factors, if necessary. ACT parameters should be decreased to 180 to 200 seconds and platelet count maintained at least greater than 125,000/mm<sup>3</sup>. The use of agents that inhibit fibrinolysis, such as aminocaproic acid, also can help prevent bleeding. The use of recombinant activated factor VII (NovoSeven, Novo Nordisk, Inc., Princeton, NJ) has been described in the management of bleeding unresponsive to conventional methods. This is an off-label use of this agent, and thrombosis is a significant morbidity that has been described.<sup>52</sup> Often, one must evacuate the hematoma and explore for surgical bleeding, if necessary, as is the case in the postcardiac surgery patient left with an open chest and central cannulation. If bleeding is not quickly controlled, decannulation and removing the obligatory anticoagulation must be strongly considered.

### *Coagulation Abnormalities*

ECMO patients have a coagulopathy secondary to consumption by the circuit. The treatment for this coagulopathy is removal of the source, and a circuit

change is a logical approach. Disseminated intravascular coagulation (DIC) occurs in approximately 2.4% of ECMO cases.<sup>1</sup> DIC is characterized by the consumption of plasma clotting factors and platelets, resulting in deposition of fibrin thrombi in the microvasculature. Once the factor levels and platelet count decrease below certain levels, bleeding will occur. Sepsis, acidosis, hypoxia, and hypotension are the most common causes, which is why ECMO patients are at risk for developing DIC. The most common cause of coagulopathy is consumption of clotting factors by the circuit and only seldom is it due to sepsis or DIC.

### *Patent Ductus Arteriosus*

The dramatic decrease in pulmonary hypertension seen usually in the first 48 hours of an ECMO run causes dramatic changes in the neonate's circulation. A left-to-right shunt through the patent ductus arteriosus (PDA) develops and causes less-efficient oxygenation, pulmonary edema, and poor peripheral perfusion. As a rule, the PDA closes spontaneously with the use of fluid restriction and diuresis. The use of indomethacin should be avoided because of its effects on platelet function. Rarely is PDA ligation required or indicated while on ECMO.

### *Renal Failure*

Oliguria is common in ECMO patients and is often seen during the first 24 to 48 hours. The capillary leak that is seen after placing a child on ECMO may cause decreased renal perfusion, or it may be due to the nonpulsatile nature of blood flow that occurs with VA ECMO. Once the patient is considered to be adequately volume resuscitated, and fluid shifts have stabilized, the use of furosemide (1 to 2 mg/kg) can be used to improve urine output. If the creatinine level continues to rise, then renal ultrasonography is recommended. The use of continuous hemofiltration, which is easily added in-line to the ECMO circuit, is another mechanism to assist in managing the fluid shifts, hyperkalemia, and azotemia. Hemofiltration removes plasma water and dissolved solutes while retaining proteins and cellular components of the intravascular space.<sup>20,53</sup>

### *Hypertension*

The reported incidence of hypertension on ECMO varies from 28% to as high as 92%.<sup>54</sup> According to the ELSO registry, 13.1% of respiratory ECMO patients require pharmacologic intervention. One group reported that detectable ICH occurred in 44% of their hypertensive patients and clinically significant ICH developed in 27%.<sup>55</sup> The patient should initially be assessed for reversible causes of hypertension, such as pain, hypercarbia, and hypoxia. Embolic renal infarction is another important cause of hypertension. Medical management includes the use of hydralazine, nitroglycerin, and captopril.

## Infection

The incidence of nosocomial infections during ECMO has been reported as high as 30%. Associated risk factors include the duration of the ECMO run, the length of hospitalization, and surgical procedures performed before the initiation of ECMO or during the run.<sup>56</sup> The ELSO registry data from July 2008 states an 8.5% culture-proven infection rate in ECMO neonates and pediatric patients.<sup>1</sup> This is remarkably low, considering the large surface area of the circuit, the duration of bypass, and the frequency of access to the circuit. Fungal infections carry a significantly higher hospital mortality rate, and the onset of sepsis carries a higher morbidity and mortality rate in neonates, as would be expected.<sup>57,58</sup> Because of the large volume of blood products often transfused into ECMO patients, the risk of developing a bloodborne infectious disease is significant. One study reported that approximately 8% of a group of children who were treated with ECMO as neonates were seropositive for antibodies to hepatitis C virus.<sup>59</sup> With more stringent screening techniques, this number has probably decreased since its initial publication.

## RESULTS

ECMO is a prime example of the evolution from an experimental technique to a commonly used therapeutic approach. The ELSO registry has accumulated data since the early 1980s from all registered centers throughout the world, allowing analysis of this management. The number of registered centers continues to rise, as does the number of ECMO cases. In 1992, over 1500 ECMO cannulations for neonatal respiratory disease were performed. In 2007, only 808 cases were reported. In contrast, the number of cardiac cases has steadily increased over the past 20 years with the exception of 2007. The decline in case volume is likely due to improvements in ventilation management strategies and the addition of new agents to our armamentarium for respiratory failure (inhaled nitric oxide, smooth muscle relaxants, and high-frequency oscillation).<sup>1,20</sup>

Overall survival to discharge for neonates and pediatric patients is 64.9% for all diagnoses.<sup>1</sup> Higher survival rates are seen in neonates with respiratory diseases (76%) versus pediatric patients with respiratory failure (55%), but the pediatric population (45%) fairs better than neonates (38%) with cardiac failure as the reason for ECMO (Table 6-3).<sup>1</sup> According to the 2007 ELSO Registry data, newborns with meconium aspiration syndrome who require ECMO have the best survival rate at 94%, whereas ECMO survival for infants with CDH is 51% (Table 6-4).<sup>1</sup>

The pediatric population of ECMO patients represents a diverse group with regard to patient age as well as diagnoses. Almost an equal number of respiratory cases (3854) and cardiac cases (4181) have been reported. This is in stark contrast to the neonatal population in which there is an almost 7:1 ratio of a primary

**Table 6-3** ECMO Cases by Patient Group (ELSO Registry, 1980-2007)

Indication	No. Cases	Survival to Discharge (%)
Neonatal respiratory failure	22,429	76
Neonatal cardiac failure	3,416	38
Pediatric respiratory failure	3,854	55
Pediatric cardiac failure	4,181	45

ELSO, Extracorporeal Life Support Organization.<sup>1</sup>

respiratory to a primary cardiac diagnosis.<sup>1</sup> A higher complication rate exists with the pediatric patients, reflecting the longer duration of bypass required for reversal of the respiratory failure.

## Feeding and Growth Sequelae

Approximately one third of ECMO-treated infants have feeding problems.<sup>60-62</sup> The possible causes for the poor feeding are numerous and include interference from tachypnea, generalized central nervous system depression, poor hunger drive, soreness in the neck from the surgical procedure, manipulation or compression of the vagus nerve during the cannulation, sore throat from prolonged intubation, and poor oral-motor coordination.<sup>63,64</sup> Newborns with CDH have a higher incidence of feeding difficulties as compared to those with meconium aspiration syndrome. CDH children often have foregut dysmotility, which leads to significant gastroesophageal reflux, delayed gastric emptying, and obvious feeding difficulties. Respiratory compromise and chronic lung disease add to the problem.<sup>63-65</sup>

Normal growth is most commonly reported in ECMO-treated patients, yet these children are more likely to experience problems with growth than are normal controls. Head circumference below the fifth percentile occurs in 10% of ECMO-treated children.<sup>66</sup> Growth problems are most commonly associated with ECMO children who had CDH or residual lung disease.<sup>64</sup>

**Table 6-4** Neonatal Respiratory ECMO Cases (ELSO Registry, 1980-2007)

Indication	No. Cases	Survival to Discharge (%)
Meconium aspiration syndrome	7,354	94
Respiratory distress syndrome	1,461	84
PPHN/PFC	3,630	78
Sepsis	2,561	75
Congenital diaphragmatic hernia	5,582	51

ELSO, Extracorporeal Life Support Organization<sup>1</sup>; PPHN, persistent pulmonary hypertension of the newborn; PFC, persistent fetal circulation.

## Respiratory Sequelae

Respiratory morbidity is more likely to be iatrogenic than a consequence of congenital lung disease. Nevertheless, approximately 15% of infants require supplemental oxygen at 4 weeks of age in some series. At age 5 years, ECMO children were twice as likely to have reported cases of pneumonia as compared with controls (25% vs. 13%). These children with pneumonia are more likely to require hospitalization, and the pneumonia occurs at a younger age (half of the pneumonias were diagnosed before 1 year of life).<sup>67,68</sup> CDH infants have been found to have severe lung disease after ECMO and often require supplemental oxygen at the time of discharge.<sup>64,68-71</sup>

## Neurodevelopmental Sequelae

Probably the most serious post-ECMO morbidity is neuromotor handicap. The total rate of handicap from 540 patients at 12 institutions is 6%, with a range from 2% to 18%.<sup>66,72-84</sup> Nine percent of ECMO survivors have significant developmental delay, ranging from none to 21%. This is comparable to other critically ill, non-ECMO-treated neonates.<sup>85</sup> A single center study using multivariate analysis identified ventilator time as the only independent predictor of

motor problems at age 1 in CDH patients.<sup>86</sup> Auditory defects are reported in more than one fourth of ECMO neonates at discharge.<sup>87</sup> The deficits are detected by brain-stem auditory evoked response (BAER) testing, are considered mild to moderate, and generally resolve over time. The cause of the auditory defects also may be iatrogenic, caused by induced alkalosis, diuretics, or gentamicin ototoxicity. As a result, all patients should have a hearing screening at the time of neonatal intensive care unit discharge. Visual deficits are uncommon in ECMO neonates who weigh more than 2 kg.<sup>88</sup>

Seizures are widely reported among ECMO neonates, ranging from 20% to 70%.<sup>89-92</sup> However, by age 5 years, only 2% had a diagnosis of epilepsy. Seizures in the neonatal population are associated with neurologic disease and poorer outcomes, including cerebral palsy and epilepsy.<sup>93</sup> Severe nonambulatory cerebral palsy has an incidence of less than 5% and is usually accompanied by significant developmental delay.<sup>66,72,77</sup> Milder cases of cerebral palsy are seen in up to 20% of ECMO survivors. Overall, ECMO-treated neonates function within the normal range and the rate of handicap appears to be stable across studies with an average of 11%, ranging from 2% to 18%.<sup>66,72,74-84</sup> Again, this morbidity reflects how desperately ill these children are and is not a direct effect of ECMO.

# MECHANICAL VENTILATION IN PEDIATRIC SURGICAL DISEASE

Samir Gadepalli, MD • Ronald B. Hirschl, MD

Amazingly, ventilation via tracheal cannulation was performed as early as 1543 when Vesalius demonstrated the ability to maintain the beating heart in animals with open chests.<sup>1</sup> This technique was first applied to humans in 1780, but there was little progress in positive-pressure ventilation until the development of the Fell-O'Dwyer apparatus. This device provided translaryngeal ventilation using bellows and was first used in 1887 (Fig. 7-1).<sup>2,3</sup> The Drinker-Shaw iron lung, which allowed piston-pump cyclic ventilation of a metal cylinder and associated negative-pressure ventilation, became available in 1928 and was followed by a simplified version built by Emerson in 1931.<sup>4</sup> Such machines were the mainstays in the ventilation of victims of poliomyelitis in the 1930s through the 1950s.

In the 1920s, the technique of tracheal intubation was refined by Magill and Rowbotham.<sup>5,6</sup> In World War II, the Bennett valve, which allowed cyclic application of high pressure, was devised to allow pilots to tolerate high-altitude bombing missions.<sup>7</sup> Concomitantly, the use of translaryngeal intubation and mechanical ventilation became common in the operating room as well as in the treatment of respiratory insufficiency. However, application of mechanical ventilation to newborns, both in the operating room and in the intensive care unit, lagged behind that for children and adults.

The use of positive-pressure mechanical ventilation in the management of respiratory distress syndrome (RDS) was described in 1962.<sup>8</sup> It was the unfortunate death of Patrick Bouvier Kennedy at 32 weeks of gestation in 1963 that resulted in additional National Institutes of Health (NIH) funding for research in the management of newborns with respiratory failure.<sup>9</sup> The discovery of surfactant deficiency as the etiology of RDS in 1959, the ability to provide positive-pressure ventilation in newborns with respiratory insufficiency in 1965, and demonstration of the effectiveness of continuous positive airway pressure in enhancing lung volume and ventilation in patients with RDS in 1971

set the stage for the development of continuous-flow ventilators specifically designed for neonates.<sup>10-12</sup> The development of neonatal intensive care units, hyperalimentation, and neonatal invasive and noninvasive monitoring enhanced the care of newborns with respiratory failure and increased survival in preterm newborns from 50% in the early 1970s to more than 90% today.<sup>13</sup>

**Figure 7-1.** The Fell-O'Dwyer apparatus that was first used to perform positive-pressure ventilation in newborns. (Reprinted from Matas R: Intralaryngeal insufflation. *JAMA* 34:1468-1473, 1900.)

## PHYSIOLOGY OF GAS EXCHANGE DURING MECHANICAL VENTILATION

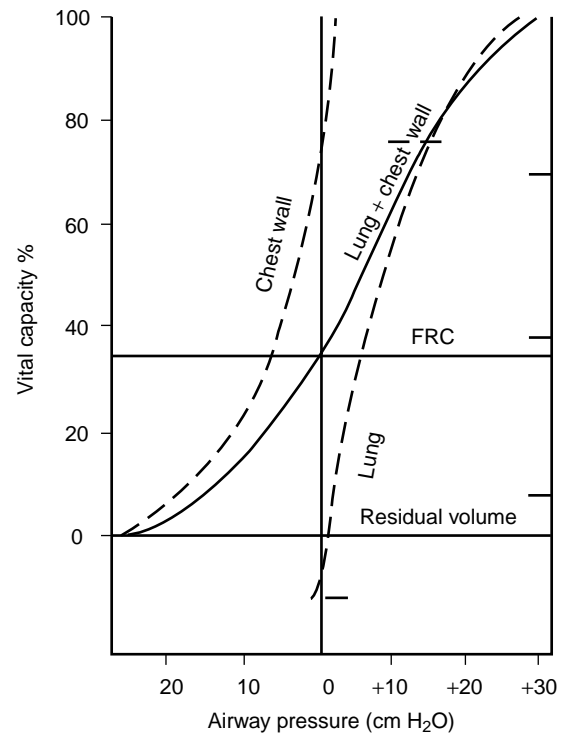

The approach to mechanical ventilation is best understood if the two variables of oxygenation and carbon dioxide (CO<sub>2</sub>) elimination are considered separately.<sup>14</sup>

### Carbon Dioxide Elimination

The primary purpose of ventilation is to eliminate CO<sub>2</sub>, which is accomplished by delivering tidal volume (V<sub>T</sub>) breaths at a designated rate. The product (V<sub>T</sub> × rate) determines the minute volume ventilation (V̇<sub>E</sub>). Although CO<sub>2</sub> elimination is proportional to V̇<sub>E</sub>, it is, in fact, directly related to the volume of gas ventilating the alveoli because part of the V̇<sub>E</sub> resides in the conducting airways or in nonperfused alveoli. As such, the portion of the ventilation that does not participate in CO<sub>2</sub> exchange is termed the dead space (V<sub>D</sub>).<sup>15</sup> In a patient with healthy lungs, this dead space is fixed or “anatomic” and consists of about one third of the tidal volume (V<sub>D</sub>/V<sub>T</sub> = 0.33). In a setting of respiratory insufficiency, the proportion of dead space (V<sub>D</sub>/V<sub>T</sub>) may be augmented by the presence of nonperfused alveoli and a reduction in V<sub>T</sub>. Furthermore, dead space can unwittingly be increased through the presence of extensions of the trachea such as the endotracheal tube, a pneumotachometer to measure tidal volume, an end-tidal CO<sub>2</sub> monitor, or an extension of the ventilator tubing beyond the “Y.” It is critical, therefore, that endotracheal tubes are shortened to a reasonable length and other safeguards are applied to ensure that the V<sub>D</sub> is minimized.

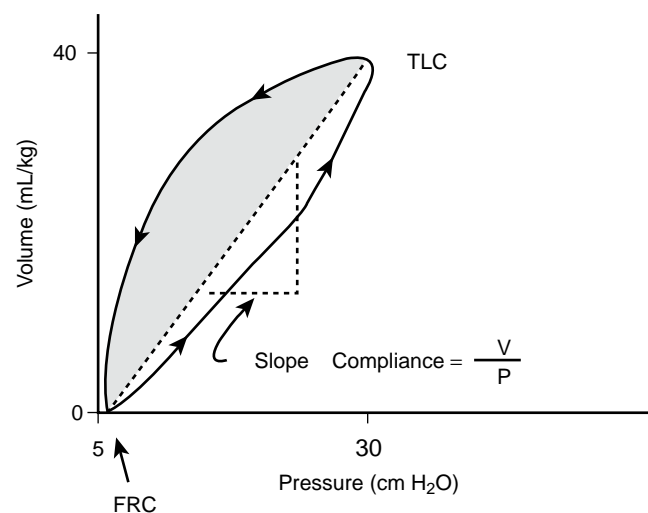

Tidal volume is a function of the applied ventilator pressure and the volume/pressure relationship (compliance), which describes the ability of the lung and chest wall to distend. At the functional residual capacity (FRC), the static point of end expiration, the tendency for the lung to collapse (elastic recoil) is in balance with the forces that promote chest wall expansion (Fig. 7-2).<sup>15</sup> As each breath develops, however, the elastic recoil of both the lung and chest wall work in concert to oppose lung inflation. Therefore, pulmonary compliance is a function of both the lung elastic recoil (lung compliance) and that of the rib cage and diaphragm (chest wall compliance).

The compliance can be determined in a dynamic or static mode. Figure 7-3 demonstrates the dynamic volume/pressure relationship for a normal patient. Note that application of 25 cm H<sub>2</sub>O of inflating pressure (ΔP) above static FRC at positive end-expiratory pressure (PEEP) of 5 cm H<sub>2</sub>O generates a V<sub>T</sub> of 40 mL/kg. The lung, at an inflating pressure of 30 cm H<sub>2</sub>O when compared with ambient (transpulmonary) pressure, is considered to be at total lung capacity (TLC) (Table 7-1). Note that the loop observed during both inspiration and expiration is curvilinear. This is due to the resistance that is present in the airways and describes the work required to overcome air flow resistance. As a result, at any given point of active flow, the

**Figure 7-2.** Pulmonary function as a function of chest wall and lung compliance in healthy patients. At functional residual capacity, the tendency for the chest wall to expand and the lung to collapse is balanced. (Adapted from West JB: *Respiratory Physiology: The Essentials*. Baltimore, Williams & Wilkins, 1985.)

measured pressure in the airways is higher during inspiration and lower during expiration than at the same volume under zero-flow conditions. Pulmonary compliance measurements, as well as alveolar pressure measurements, can be effectively performed only when no flow is present in the airways (zero flow),

**Figure 7-3.** Dynamic pressure/volume relation and effective pulmonary compliance (C<sub>eff</sub>) in the normal lung. The volume at 30 cm H<sub>2</sub>O is considered total lung capacity (TLC). C<sub>eff</sub> is calculated by ΔV/ΔP. (Adapted from Bhutani VK, Sivieri EM: *Physiological principles for bedside assessment of pulmonary graphics*. In Donn SM [ed]: *Neonatal and Pediatric Pulmonary Graphics: Principles and Applications*. Armonk, NY, Futura Publishing, 1998.)

Variable	Definition	Normal Value
TLC	Total lung capacity	80 mL/kg
FRC	Functional residual capacity	40 mL/kg
IC	Inspiratory capacity	40 mL/kg
ERV	Expiratory reserve volume	30 mL/kg
RV	Residual volume	10 mL/kg
V <sub>T</sub>	Tidal volume	5 mL/kg
$\dot{V}_E$	Minute volume ventilation	100 mL/kg/min
$\dot{V}_E$	Alveolar ventilation	60 mL/kg/hr
V <sub>D</sub>	Dead space	mL = wt in lbs
V <sub>D</sub> /V <sub>T</sub>	% Dead space	0.33
C <sub>St</sub>	Static compliance	2 mL/cm H <sub>2</sub> O/kg
C <sub>eff</sub>	Effective compliance	1 mL/cm H <sub>2</sub> O/kg

which occurs at FRC and TLC. The change observed is a volume of 40 mL/kg and pressure of 25 cm H<sub>2</sub>O pressure or 1.6 mL/kg/cm H<sub>2</sub>O. This is termed *effective* compliance because it is calculated only between the two arbitrary points of end inspiration and end expiration.

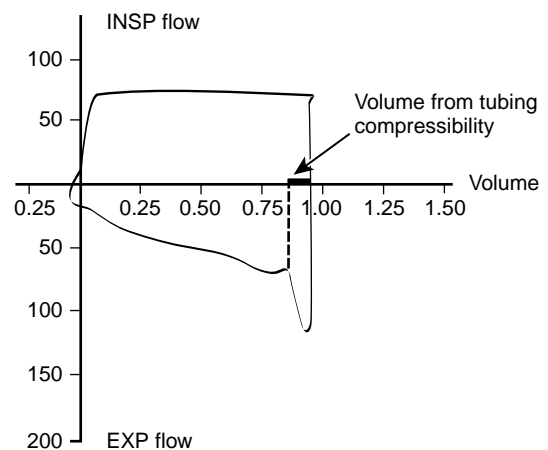

As can be seen from Figure 7-4, the volume/pressure relationship is not linear over the range of most inflating pressures when a static compliance curve is developed. Such static compliance assessments are most commonly performed via a large syringe in which aliquots of 1 to 2 mL/kg of oxygen, up to a total of 15 to 20 mL/kg, are instilled sequentially with 3- to 5-second pauses. At the end of each pause, zero-flow pressures are measured. By plotting the data, a static compliance curve can be generated. This curve demonstrates how the calculated compliance can change depending on the arbitrary points used for assessment of the effective compliance (C<sub>eff</sub>).<sup>16</sup>

**Figure 7-4.** Static lung compliance curve in a normal lung. Effective compliance would be altered depending on whether FRC were to be at a level resulting in lung atelectasis (A) or overdistention (C). Optimal lung mechanics are observed when FRC is set on the steepest portion of the curve (B). (Adapted from West JB: Respiratory Physiology. Baltimore, Williams & Wilkins, 1985.)

Alternatively, the pulmonary pressure/volume relationship can be assessed by administration of a slow constant flow of gas into the lungs with simultaneous determination of airway pressure.<sup>17,18</sup> A curve may be fit to the data points to determine the optimal compliance and FRC.<sup>19</sup> The compliance will change as the FRC or end-expiratory lung volume (EELV) increases or decreases. For instance, as can be seen in Figure 7-4, at low FRC (point A), atelectasis is present. A given  $\Delta P$  will not optimally inflate alveoli. Likewise, at a high FRC (point C), because of air trapping or application of high PEEP, the lung is already distended. Application of the same  $\Delta P$  will result only in overdistention and potential lung injury with little benefit in terms of added V<sub>T</sub>. Thus, optimal compliance is provided when the pressure/volume range is on the linear portion of the static compliance curve (point B). Clinically, the compliance at a variety of FRC or PEEP values can be monitored to establish optimal FRC.<sup>20</sup>

Finally, it is important to recognize that a portion of the V<sub>T</sub> generated by the ventilator is actually compression of gas within both the ventilator tubing and the airways (Fig. 7-5). The ratio of gas compressed in the ventilator tubing to that entering the lungs is a function of the compliance of the ventilator tubing and the lung. The compliance of the ventilator tubing is 0.3 to 4.5 mL/cm H<sub>2</sub>O.<sup>21</sup> A change in pressure of 15 cm H<sub>2</sub>O in a 3-kg newborn with respiratory insufficiency and a pulmonary compliance of 0.4 mL/cm H<sub>2</sub>O/kg would result in a lung V<sub>T</sub> of 18 mL and an impressive ventilator tubing/gas compression volume of 15 mL if the tubing compliance were 1.0 mL/cm H<sub>2</sub>O. The relative ventilator tubing/gas compression volume would not be as striking in an adult. The ventilator tubing compliance is characterized for all current ventilators and should be factored when considering V<sub>T</sub> data. The software in many ventilators corrects for ventilator tubing compliance when displaying V<sub>T</sub> values.

**Figure 7-5.** Flow/volume loops demonstrating the effect of ventilator tubing/gas compression volume in the ventilator tubing of a patient with respiratory insufficiency. The high flow during expiration results from gas decompressing from the ventilator tubing. (Adapted from Pilbeam SP: Mechanical Ventilation: Physiological and Clinical Applications. St. Louis, CV Mosby, 1998.)

Typical ventilator rate requirements in patients with healthy lungs range from 10 breaths/min in an adult to 30 breaths/min in a newborn. The  $V_T$  is maintained at 5 to 10 mL/kg, resulting in a  $\dot{V}_E$  of about 100 mL/kg/min in adults and 150 mL/kg/min in newborns. In healthy lungs, these settings should provide sufficient ventilation to maintain normal  $P_{aCO_2}$  levels of approximately 40 mm Hg and should generate peak inspiratory pressures of between 15 and 20 cm  $H_2O$  above an applied PEEP of 5 cm  $H_2O$ . Clinical assessment by observing chest wall movement, auscultation, and evaluation of gas exchange determines the appropriate  $V_T$  in a given patient.

## Oxygenation

In contrast to  $CO_2$  determination, oxygenation is determined by the fraction of inspired oxygen ( $F_{IO_2}$ ) and the degree of lung distention or alveolar recruitment, determined by the level of PEEP and the mean airway pressure ( $P_{aw}$ ) during each ventilator cycle. If  $CO_2$  was not a competing gas at the alveolar level, oxygen within pulmonary capillary blood would simply be replaced by that provided at the airway, as long as alveolar distention was maintained. Such apneic oxygenation has been used in conjunction with extracorporeal carbon dioxide removal (ECCO<sub>2</sub>R) or arteriovenous  $CO_2$  removal (AVCO<sub>2</sub>R), in which oxygen is delivered at the carina, whereas lung distention is maintained through application of PEEP.<sup>22,23</sup> Under normal circumstances, however, alveolar ventilation serves to remove carbon dioxide from the alveolus and to replenish the  $PO_2$ , thereby maintaining the alveolar/pulmonary capillary blood oxygen gradient.

Rather than depending on the degree of alveolar ventilation, oxygenation predominantly is a function of the appropriate matching of pulmonary blood flow to inflated alveoli (ventilation/perfusion matching [ $\dot{V}/\dot{Q}$ ]).<sup>15</sup> In normal lungs, the PEEP should be maintained at 5 cm  $H_2O$ , a pressure that allows maintenance of alveolar inflation at end expiration, balancing the lung/chest wall recoil. An  $F_{IO_2}$  of 0.50 should be administered initially. However, one should be able to wean the  $F_{IO_2}$  rapidly in a patient with healthy lungs and normal  $\dot{V}/\dot{Q}$  matching. Areas of ventilation but no perfusion (high  $\dot{V}/\dot{Q}$ ), such as in the setting of pulmonary embolus, do not contribute to oxygenation. Therefore, hypoxemia supervenes in this situation once the average residence time of blood in the remaining perfused pulmonary capillaries exceeds that necessary for complete oxygenation. Normal residence time is threefold that required for full oxygenation of pulmonary capillary blood.

The common pathophysiology observed in the setting of respiratory insufficiency, however, is that of minimal or no ventilation, with persistent perfusion (low  $\dot{V}/\dot{Q}$ ), resulting in right-to-left shunting and hypoxemia. Patients with the acute respiratory distress syndrome (ARDS) have collapse of the posterior, or dependent, regions of the lungs when supine.<sup>24,25</sup> Because the majority of blood flow is distributed to

these dependent regions, one can easily imagine the limited oxygen transfer and large shunt secondary to  $\dot{V}/\dot{Q}$  mismatch and the resulting hypoxemia that occurs in patients with ARDS. Attempts to inflate the alveoli in these regions, such as with the application of increased PEEP, can reduce  $\dot{V}/\dot{Q}$  mismatch and enhance oxygenation.

Just as partial pressure of carbon dioxide in the artery ( $P_{aCO_2}$ ) is used to evaluate ventilation, partial pressure of oxygen in arterial blood ( $P_{aO_2}$ ) and arterial oxygen saturation ( $S_{aO_2}$ ) levels are the measures most frequently used to evaluate oxygenation. Lung oxygenation capabilities are also frequently assessed as a function of the difference between the ideal alveolar and the measured systemic arterial oxygen levels (A-a gradient), the ratio of the  $P_{aO_2}$  to the  $F_{IO_2}$  (P/F ratio), the physiologic shunt ( $\dot{Q}_{ps}/\dot{Q}_t$ ), and the oxygen index (OI).

$$A-a \text{ gradient} = (F_{IO_2} \cdot [P_B - P_{H_2O}] - P_{aCO_2}/RQ) - P_{aO_2}$$

where  $F_{IO_2}$  is the fraction of inspired oxygen,  $P_B$  is the barometric pressure,  $P_{H_2O}$  is the partial pressure of water, and  $RQ$  is the respiratory quotient or the ratio of  $CO_2$  production ( $V_{CO_2}$ ) to oxygen consumption ( $V_{O_2}$ ).

$$\dot{Q}_{ps}/\dot{Q}_t = (C_{IO_2} - C_{aO_2}) / (C_{IO_2} - C_{vO_2})$$

where  $C_{vO_2}/C_{aO_2}/C_{IO_2}$  are the oxygen contents of venous, arterial, and expected pulmonary capillary blood, respectively.

$$OI = (P_{aw} \cdot F_{IO_2} \cdot 100) / P_{aO_2}$$

where  $P_{aw}$  represents the mean airway pressure.<sup>15</sup>

The overall therapeutic goal of optimizing parameters of oxygenation is to maintain oxygen delivery ( $DO_2$ ) to the tissues. Three variables ascertain  $DO_2$ : cardiac output ( $Q$ ), hemoglobin concentration (Hgb), and arterial blood oxygen saturation ( $S_{aO_2}$ ). The product of these three variables determines  $DO_2$  by the relation:

$$DO_2 = Q \cdot C_{aO_2} \\ \text{where } C_{aO_2} = (1.36 \cdot \text{Hgb} \cdot [S_{aO_2}/100]) \\ + (0.0031 \cdot P_{aO_2})$$

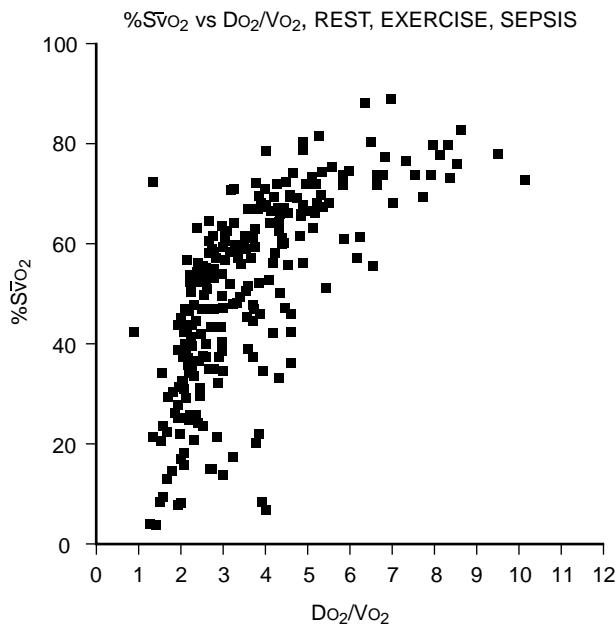

Note that the contribution of the  $P_{aO_2}$  to  $DO_2$  is minimal and, therefore, may be disregarded in most circumstances. If the hemoglobin concentration of the blood is normal (15 g/dL) and the hemoglobin is fully saturated with oxygen, the amount of oxygen bound to hemoglobin is 20.4 mL/dL (Fig. 7-6). In addition, approximately 0.3 mL of oxygen is physically dissolved in each deciliter of plasma, which makes the oxygen content of normal arterial blood equal to approximately 20.7 mL  $O_2$ /dL. Similar calculations reveal that the normal venous blood oxygen content is approximately 15 mL/ $O_2$ /dL.

Typically  $DO_2$  is four to five times greater than the associated oxygen consumption ( $V_{O_2}$ ). As  $DO_2$  increases or  $V_{O_2}$  decreases, more oxygen remains in the venous blood. The result is an increase in the oxygen hemoglobin saturation in the mixed venous pulmonary artery

**Figure 7-6.** Oxygen consumption ( $V_{O_2}$ ) and delivery ( $DO_2$ ) relations. (Adapted with permission from Hirschl RB: Oxygen delivery in the pediatric surgical patients. *Opin Pediatr* 6:341-347, 1994.)

blood ( $S\bar{V}O_2$ ). In contrast, if the  $DO_2$  decreases or  $V_{O_2}$  increases, relatively more oxygen is extracted from the blood, and therefore less oxygen remains in the venous blood. A decrease in  $S\bar{V}O_2$  is the result. In general, the  $S\bar{V}O_2$  serves as an excellent monitor of oxygen kinetics because it specifically assesses the adequacy of  $DO_2$  in relation to  $V_{O_2}$  ( $DO_2/V_{O_2}$  ratio; Fig. 7-7).<sup>26</sup> Many pulmonary arterial catheters contain fiberoptic bundles that provide continuous mixed venous oximetry data. Such monitoring provides a means for assessing the adequacy of  $DO_2$ , rapid assessment of the response to interventions such as mechanical ventilation, and cost savings due to a diminished need for sequential blood

**Figure 7-7.** The relation of the mixed venous oxygen saturation ( $S\bar{V}O_2$ ) and the ratio of oxygen delivery to oxygen consumption ( $DO_2/V_{O_2}$ ) in normal eumetabolic, hypermetabolic septic, and hypermetabolic exercising canines. (Reprinted from Hirschl RB: *Cardiopulmonary Critical Care and Shock: Surgery of Infants and Children: Scientific Principles and Practice*. Philadelphia, Lippincott-Raven, 1997.)

gas monitoring.<sup>26,27</sup> If a pulmonary artery catheter is unavailable, the central venous oxygen saturation ( $Sc\bar{V}O_2$ ) may serve as a surrogate of the  $S\bar{V}O_2$ .<sup>28</sup>

Four factors are manipulated in an attempt to improve the  $DO_2/V_{O_2}$  ratio: cardiac output, hemoglobin concentration,  $SaO_2$ , and  $V_{O_2}$ . The result of various interventions designed to increase cardiac output, such as volume administration, infusion of inotropic agents, administration of afterload-reducing drugs, and correction of acid/base abnormalities, may be assessed by the effect on the  $S\bar{V}O_2$  (Fig. 7-8). One of the most efficient ways to enhance  $DO_2$  is to increase the oxygen-carrying capacity of the blood. For instance, an increase in hemoglobin from 7.5 to 15 g/dL will be associated with a twofold increase in  $DO_2$  at constant cardiac output. However, blood viscosity is increased with blood transfusion, which may result in a reduction in cardiac output.<sup>29</sup> The  $SaO_2$  can often be enhanced through application of supplemental oxygen and mechanical ventilation.

Assessment of the “best PEEP” identifies the level at which  $DO_2$  and  $S\bar{V}O_2$  are optimal without compromising compliance.<sup>30,31</sup> Evaluation of the best PEEP should be performed in any patient requiring an  $FI_{O_2}$  greater than 0.60 and may be determined by continuous monitoring of the  $S\bar{V}O_2$  as the PEEP is sequentially increased from 5 to 15 cm H<sub>2</sub>O over a short period. The point at which the  $S\bar{V}O_2$  is maximal indicates optimal  $DO_2$ . The use of PEEP with mechanical ventilation is limited, however, by the adverse effects observed on cardiac output, the incidence of barotrauma, and the risk for ventilator-induced lung injury with application of peak inspiratory pressures greater than 30 to 40 cm H<sub>2</sub>O.<sup>32,33</sup> Furthermore, oxygen consumption may be elevated secondary to sepsis, burns, agitation, seizures, hyperthermia, hyperthyroidism, and increased catecholamine production or infusion. A number of interventions may be applied to reduce  $V_{O_2}$ , such as sedation and mechanical ventilation. Paralysis may enhance the effectiveness of mechanical ventilation while simultaneously reducing  $V_{O_2}$ .<sup>34,35</sup> In the appropriate setting, hypothermia may be induced with an associated reduction of 7% in  $V_{O_2}$  with each 1°C decrease in core temperature.<sup>36</sup>

**Figure 7-8.** Alterations in  $S\bar{V}O_2$  are shown as sodium nitroprusside is administered to reduce left ventricular afterload in the setting of cardiac insufficiency. ## MECHANICAL VENTILATION

As discussed earlier, failure of gas exchange ( $\text{CO}_2$  elimination or oxygenation) can be indications for mechanical ventilation. The ventilator can also be used to reduce the work of breathing and decrease oxygen consumption. Finally, mechanical ventilation is used in patients who are unable to breathe independently for neurologic reasons (primary hypoventilation, traumatic brain injury, inability to protect airway).

### The Mechanical Ventilator and Its Components

The ventilator must overcome the pressure generated by the elastic recoil of the lung at end inspiration plus the resistance to flow at the airway. To do so, most ventilators in the intensive care unit are pneumatically powered by gas pressurized at 50 pounds per square inch. Microprocessor controls allow accurate management of proportional solenoid-driven valves, which carefully control infusion of a blend of air or oxygen into the ventilator circuit while simultaneously opening and closing an expiratory valve.<sup>37</sup> Additional components of a ventilator include a bacterial filter, a pneumotachometer, a humidifier, a heater/thermostat, an oxygen analyzer, and a pressure manometer. A chamber for nebulizing drugs is usually incorporated into the inspiratory circuit. The  $V_T$  is not usually measured directly. Rather, flow is assessed as a function of time, thereby allowing calculation of  $V_T$ . The modes of ventilation are characterized by three variables that affect patient and ventilator synchrony or interaction: the parameter used to initiate or “trigger” a breath, the parameter used to “limit” the size of the breath, and the parameter used to terminate inspiration or “cycle” the breath (Fig. 7-9).<sup>38</sup>

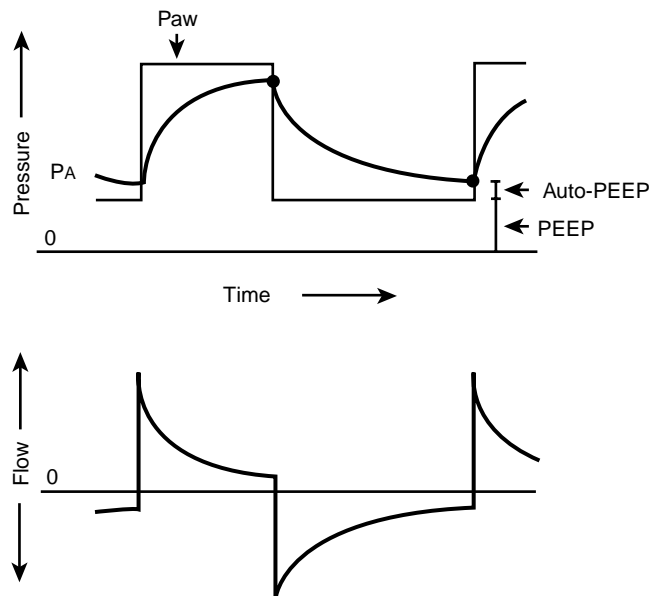

Gas flow in most ventilators is triggered either by time (controlled breath) or by patient effort (assisted breath). Controlled ventilation modes are time triggered: the inspiratory phase is concluded once a desired volume, pressure, or flow is attained, but the expiratory time will form the difference between the inspiratory time and the preset respiratory cycle time. In the assist mode, the ventilator is pressure or flow triggered. With the former, a pressure generated by the patient of approximately  $-1 \text{ cm H}_2\text{O}$  will trigger the initiation of a breath. The sensitivity of the triggering device can be adjusted so that patient work is minimized. Other ventilators detect the reduction in constant ventilator tubing gas flow that is associated with patient initiation of a breath. Detection of this decrease in flow results in initiation of a positive-pressure breath.

The magnitude of the breath is controlled or limited by one of three variables: pressure, volume, or flow. When a breath is volume, pressure, or flow “controlled,” it indicates that inspiration concludes once the limiting variable is reached. Pressure-controlled or pressure-limited modes are the most popular for all age groups, although volume-control ventilation may

**Figure 7-9.** Variables that characterize the mode of mechanical ventilation.

be of advantage in preterm newborns.<sup>39,40</sup> In the pressure modes, the respiratory rate, the inspiratory gas flow, the PEEP level, the inspiratory/expiratory (I/E) ratio, and the  $P_{aw}$  are determined. The ventilator infuses gas until the desired peak inspiratory pressure (PIP) is provided. Zero-flow conditions are realized at end-inspiration during pressure-limited ventilation. Therefore, in this mode, PIP is frequently equivalent to end-inspiratory pressure (EIP) or plateau pressure. In many ventilators, the gas flow rate is fixed, although some ventilators allow manipulation of the flow rate and therefore the rate of positive-pressure development. Those with rapid flow rates will provide rapid ascent of pressure to the preset maximum, where it will remain for the duration of the inspiratory phase. This “square wave” pressure pattern results in decelerating flow during inspiration (Fig. 7-10). Airway pressure is “front loaded,” which increases  $P_{aw}$ , alveolar volume, and oxygenation without increasing PIP.<sup>41</sup> However, one of the biggest advantages of pressure-controlled

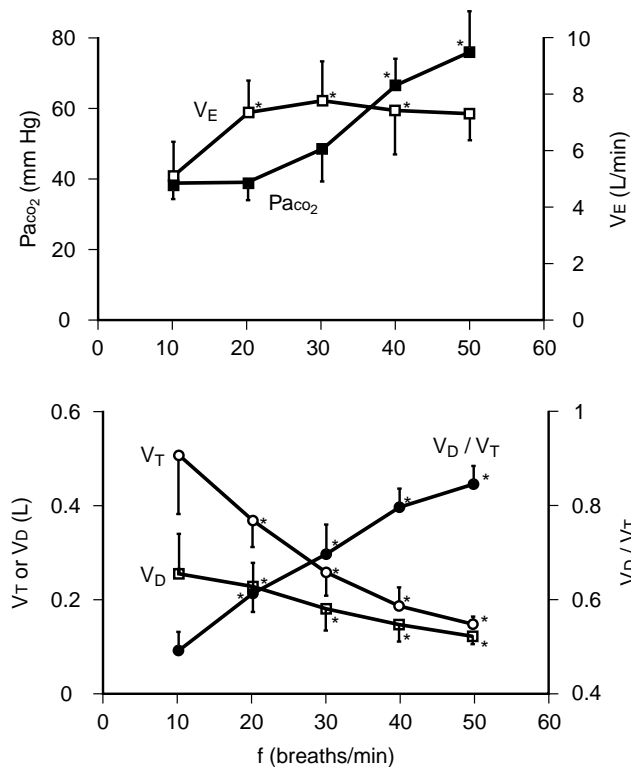

**Figure 7-10.** Pressure and flow waveforms during pressure-limited, time-cycled ventilation. Decelerating flow is applied, which “front loads” the pressure during inspiration. Auto-positive end-expiratory pressure is present when the expiratory time is inadequate for complete expiration. (Reprinted from Marini JJ: New options for the ventilatory management of acute lung injury. *New Horizons* 1:489-503, 1993.)

or pressure-limited ventilation is the ability to avoid lung overdistention and barotrauma/volutrauma (discussed later). The disadvantage of pressure-controlled or pressure-limited ventilation is that delivered volume varies with airway resistance and pulmonary compliance and may be reduced when short inspiratory times are applied (Fig. 7-11).<sup>42</sup> For this reason, both  $\dot{V}_T$  and  $\dot{V}_E$  must be monitored carefully.

Volume-controlled or volume-limited ventilation requires delineation of the  $V_T$ , respiratory rate, and inspiratory gas flow. Gas will be inspired until the preset  $V_T$  is attained. The volume will remain constant despite changes in pulmonary mechanics, although the resulting EIP and PIP may be altered. Flow-controlled or flow-limited ventilation is similar in many respects to volume-controlled or volume-limited ventilation. A flow pattern is predetermined, which effectively results in a fixed volume as the limiting component of inspiration.

The ventilator breath is concluded based on one of four variables: volume, time, pressure, or flow. With volume-cycled ventilation, inspiration is terminated when a prescribed volume is obtained. Likewise, with time-, pressure-, or flow-cycled ventilation, expiration begins after a certain period has passed, the airway pressure reaches a certain value, or when the flow has decreased to a predetermined level, respectively.

**Figure 7-11.** Effect of rate on tidal volume ( $V_D/V_T$ ) and minute ventilation ( $\dot{V}_E$ ) during pressure-limited ventilation. Note that  $\dot{V}_E$  remains unchanged above 20 breaths/min. Simultaneously,  $V_D/V_T$  and  $P_{aCO_2}$  increase, despite an increase in respiratory rate. (Reprinted from Nahum A, Burke WC, Ravenscraft SA: Lung mechanics and gas exchange during pressure-control ventilation in dogs: Augmentation of  $CO_2$  elimination by an intratracheal catheter. *Am Rev Respir Dis* 146:965-973, 1992.)

A factor that limits inspiration suggests that the chosen value limits the level of the variable during inspiration, but the inspiratory phase does not necessarily conclude once this value is attained. For instance, during “pressure-limited” ventilation, gas flow continues until a given pressure limit is attained. However, the inspiratory phase may continue beyond that point. The limitation only controls the magnitude of the breath but does not always determine the length of the inspiratory phase. In contrast, during pressure-controlled ventilation, both gas flow and the inspiratory phase terminate once the preset pressure is reached because pressure is used to limit the magnitude of the breath and the gas flow.

## Modes of Ventilation (Table 7-2)

### Controlled Mechanical Ventilation

Controlled mechanical ventilation (CMV) is time triggered, flow limited, and volume or pressure cycled. Spontaneous breaths may be taken between the mandatory breaths. However, no additional gas is provided during spontaneous breaths. Therefore, the work of breathing is markedly increased in the spontaneously breathing patient. This mode of ventilation is no longer used.

### Intermittent Mandatory Ventilation

Intermittent mandatory ventilation (IMV) is time triggered, volume or pressure limited, and either time, volume, or pressure cycled. A rate is set, as is a volume or pressure parameter. Additional inspired gas is provided by the ventilator to support spontaneous breathing when additional breaths are desired. The difference between CMV and IMV is that, in the latter, inspired gases are provided to the patient during spontaneous breaths.<sup>43</sup> IMV is useful in patients who do not have respiratory drive, for example, in those who are neurologically impaired or pharmacologically paralyzed. Work of breathing is still elevated in this mode in the awake and spontaneously breathing patient.

### Synchronized Intermittent Mandatory Ventilation

In the SIMV mode, the ventilator synchronizes IMV breaths with the patient’s spontaneous breaths (Fig. 7-12). Small, patient-initiated negative deflections in airway pressure (pressure triggered) or decreases in the constant ventilator gas flow (bias flow) passing through the exhalation valve (flow triggered) provide a signal to the ventilator that a patient breath has been initiated. Ventilated breaths are timed with the patient’s spontaneous respiration, but the number of supported breaths each minute is predetermined and remains constant. Additional constant inspired gas flow is provided for use during any other spontaneous breaths. Advances in neonatal ventilators have provided the means for detecting small alterations in bias flow. As such, flow-triggered SIMV can be applied

**Table 7-2** Modes of Ventilation

Mode	Trigger	Limit	Cycle	Comment
CMV	Time	Flow	Pressure/Volume	No longer used
IMV	Time	Volume/Pressure	Time Volume/Pressure	For no respiratory drive (neurologically impaired or paralyzed) Work of breathing elevated in spontaneously breathing patient
SIMV*	Pressure/Flow	Volume/Pressure	Time Volume/Pressure	Supports limited number of breaths
ACV*	Pressure/Flow	Volume/Pressure	Time Volume/Pressure	Supports all patient breaths Similar to IMV but patient controls breaths Sedation for hyperventilation and backup rate for apnea
PSV*	Pressure/Flow	Pressure	Flow Time	Supports all patient breaths Usually partially supported to allow for weaning Time cycled when termination-sensitivity for flow is off
VSV*	Pressure/Flow	Volume	Flow Time	Similar to PSV but volume used for partial support
VAPSV	Pressure/Flow	Pressure	Flow Time	Maintains a desired tidal volume using both VSV and PSV Dynamically maintains tidal volume
PAV*	Patient	Pressure	Patient	Size of the breath is determined by patient effort

\*Patient-controlled rate.

to newborns, which appears to enhance ventilatory patterns and allows ventilation with reduced airway pressures and  $\text{FiO}_2$ .<sup>44,45</sup> SIMV may be associated with a reduction in the duration of ventilation and the incidence of air leak in newborns in general, as well as in those premature infants with bronchopulmonary dysplasia and intraventricular hemorrhage.<sup>46,47</sup>

### Assist-Control Ventilation

In the spontaneously breathing patient, brain stem reflexes dependent on cerebrospinal fluid levels of  $\text{CO}_2$  and pH can be harnessed to determine the appropriate breathing rate.<sup>15</sup> As in SIMV, with ACV the assisted breaths can be either pressure triggered or flow triggered. The triggering-mechanism sensitivity can be set in most ventilators. In contrast to SIMV, the ventilator supports all patient-initiated breaths. This mode is similar to IMV but allows the patient inherently to control the ventilation needs and minimizes patient work of breathing in adults and neonates.<sup>48,49</sup> Occasionally, patients may hyperventilate, such as when they are agitated or have neurologic injury. Heavy sedation may be required if agitation is present. A minimal ventilator rate below the patient's assist rate should be established in case of apnea.

### Pressure Support Ventilation

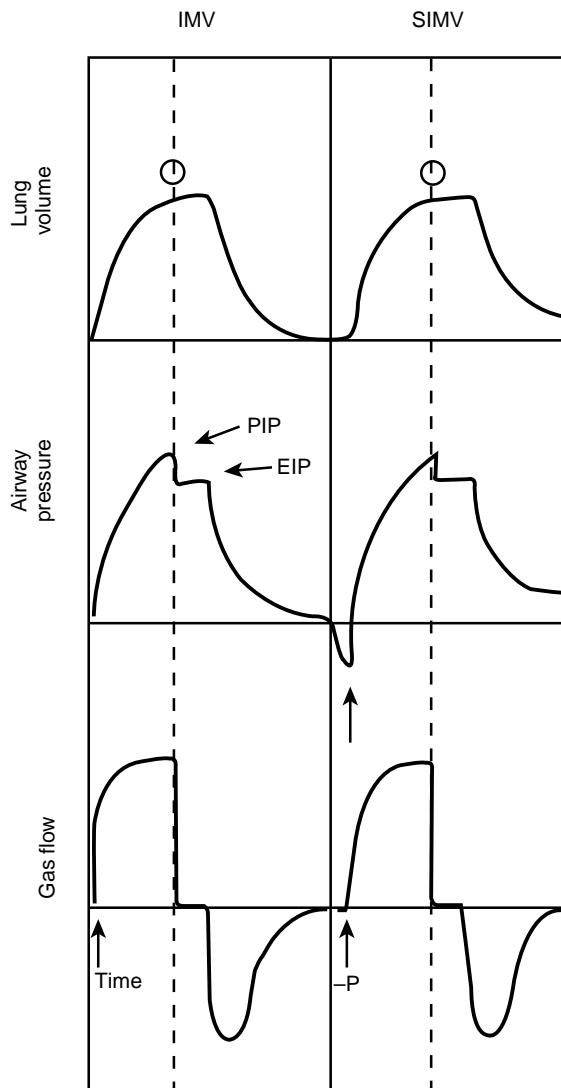

Pressure support ventilation (PSV) is a pressure- or flow-triggered, pressure-limited, and flow-cycled mode of ventilation. It is similar in concept to ACV, in that mechanical support is provided for each spontaneous breath and the patient determines the ventilator rate. During each breath, inspiratory flow is applied until a predetermined pressure is attained.<sup>50</sup> As the end of

inspiration approaches, flow decreases to a level below a specified value (2 to 6 L/min) or a percentage of peak inspiratory flow (at 25%). At this point, inspiration terminates. Although it may apply full support, PSV is frequently used to support the patient partially by assigning a pressure limit for each breath that is less than that required for full support.<sup>51</sup> For example, in the spontaneously breathing patient, PSV can be sequentially decreased from full support to a PSV 5 to 10 cm  $\text{H}_2\text{O}$  above PEEP, allowing weaning while providing partial support with each breath.<sup>52,53</sup> Thus, VT during PSV may be dependent on patient effort. PSV provides two advantages during ventilation of spontaneously breathing patients: (1) it provides excellent support and decreases the work of breathing associated with ventilation, and (2) it lowers PIP and Paw while higher VT and cardiac output levels may be observed.<sup>50,54,55</sup>

Pressure-triggered SIMV and PSV may be applied to newborns. Inspiration is terminated when the peak airway flow decreases to a set percentage between 5% and 25%. This flow cutoff for inspiration, known as the termination sensitivity, may be adjusted. The higher the termination sensitivity value, the shorter is the inspiratory time. The termination sensitivity function also may be disabled, at which point ventilation is time cycled instead of flow cycled. Studies have demonstrated a reduction in work of breathing and sedation requirements when SIMV with pressure support is applied to newborns.

### Volume Support Ventilation

Volume support ventilation (VSV) is similar to PSV except that a volume, rather than a pressure, is assigned to provide partial support. Automation with

**Figure 7-12.** Pressure, volume, and flow waveforms observed during intermittent mandatory ventilation (IMV) and synchronized IMV (SIMV). In this case, an end-inspiratory pause has been added. Note the difference between peak (PIP) and end-inspiratory (EIP) or plateau pressure. Arrows, triggering variables; open circles, cycling variables. (Adapted from Bartlett RH: Use of the Mechanical Ventilator: Surgery. New York, Scientific American, 1988.)

VSV is enhanced because less need occurs for manual changes to maintain stable tidal and minute volume during weaning.<sup>56</sup> Both VSV and PSV are equally effective at weaning infants and children from the ventilator.<sup>57</sup>

### Volume-Assured Pressure Support Ventilation

Volume-assured pressure support ventilation (VAPSV) attempts to combine volume- and pressure-controlled ventilation to ensure a desired  $V_T$  within the constraints of the pressure limit. It has the advantage of maintaining inflation to a point below an injurious PIP level while maintaining  $V_T$  constant in the face of changing pulmonary mechanics. Work of breathing

may be markedly decreased while  $C_{eff}$  is increased during VAPSV.<sup>58</sup>

### Proportional Assist Ventilation

Proportional assist ventilation (PAV) is an intriguing approach to the support of the spontaneously breathing patient. It relies on the concept that the combined pressure generated by the ventilator ( $P_{aw}$ ) and respiratory muscles ( $P_{mus}$ ) is equivalent to that required to overcome the resistance to flow of the endotracheal tube/airways ( $P_{res}$ ) and the tendency for the inflated lungs to collapse.<sup>59</sup>

With PAV, airway pressure generation by the ventilator is proportional at any instant to the respiratory effort ( $P_{mus}$ ) generated by the patient. Small efforts, therefore, result in small breaths, whereas greater patient effort results in development of a greater  $V_T$ . Inspiration is patient triggered and terminates with discontinuation of patient effort. Rate,  $V_T$ , and inspiratory time are entirely patient controlled. The predominant variable to be set on the ventilator is the proportional response between  $P_{mus}$  and the applied ventilator pressure. This proportional assist ( $P_{aw}/P_{mus}$ ) can be increased until nearly all patient effort is provided by the ventilator.<sup>60</sup> Patient work of breathing, dyspnea, and PIP are reduced.<sup>61,62</sup> Elastance and resistance are set, as is applied PEEP.  $V_T$  is variable, and risk of atelectasis may be present. PAV produces similar gas exchange with lower airway pressures when compared with conventional ventilation in infants.<sup>63</sup> Compared with preterm newborns being ventilated with the assist-control mode and with IMV, preterm newborns managed with PAV maintained gas exchange with lower airway pressures and a decrease in the oxygenation index by 28%.<sup>64</sup> Chest wall dynamics also are enhanced.<sup>65</sup> PAV represents an exciting first step in servoregulating ventilators to patient requirements.

### Continuous Positive Airway Pressure

During continuous positive airway pressure (CPAP), pressures greater than those of ambient pressure are continuously applied to the airways to enhance alveolar distention and oxygenation.<sup>66</sup> Both airway resistance and work of breathing may be substantially reduced. However, because no support of ventilation is provided, this mode requires that the patient provide all of the work of breathing. This mode should be avoided in patients with hypovolemia, untreated pneumothorax, lung hyperinflation, or elevated intracranial pressure and in infants with nasal obstruction, cleft palate, tracheoesophageal fistula, or untreated congenital diaphragmatic hernia. CPAP is frequently applied via nasal prongs, although it can be delivered in adult patients with a nasal mask.

### Inverse Ratio Ventilation

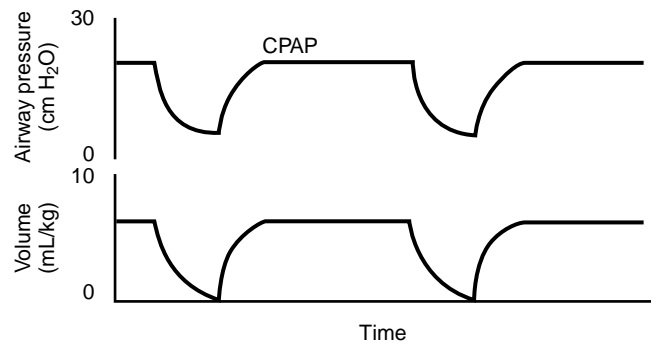

In the setting of respiratory failure, it would be helpful to enhance alveolar distention to reduce hypoxemia and shunt. One means to accomplish this is to

maintain the inspiratory plateau pressure for a longer proportion of the breath.<sup>67</sup> The inspiratory time may be prolonged to the point at which the I/E ratio may be as high as 4:1.<sup>68</sup> In most circumstances, however, the I/E ratio is maintained at approximately 2:1. Inverse ratio ventilation (IRV) is usually performed during pressure-controlled ventilation (PC-IRV), although prolonged inspiratory times can be applied during volume-controlled ventilation by adding a decelerating flow pattern or an end-inspiratory pause to the volume-controlled ventilator breath.<sup>69</sup> One advantage of IRV is the ability to recruit alveoli that are associated with high-resistance airways that inflate only with prolonged application of positive pressure.<sup>70</sup> Unfortunately, IRV is associated with a profound sense of dyspnea in patients who are awake and spontaneously breathing. Therefore, heavy sedation and pharmacologic paralysis is required during this ventilator mode.

Because Et is reduced, the risk for incomplete expiration, identified by the failure to achieve zero-flow conditions at end expiration, is increased. This results in “auto-PEEP” or a total PEEP greater than that of the preset or applied PEEP. Care should be taken to recognize the presence of auto-PEEP and to incorporate it into the ventilation strategy to avoid barotrauma.<sup>71</sup> IRV also may negatively affect cardiac output and, therefore, decrease  $\text{DO}_2$ .<sup>72</sup> Some studies using IRV revealed an increase in Paw and oxygenation while protecting the lungs by reducing PIP.<sup>73-76</sup> Likewise, others suggest that early implementation of IRV in severe ARDS enhances oxygenation and allows reduction in  $\text{FiO}_2$ , PEEP, and PIP.<sup>77</sup> On the contrary, a number of studies have failed to demonstrate enhanced gas exchange with this mode of ventilation. Some series have suggested that IRV is less effective at enhancing gas exchange than is application of PEEP to maintain the same mean airway pressure.<sup>78</sup> Overall, it appears that oxygenation is determined primarily by the mean airway pressure rather than specifically by the application of IRV. As such, the usefulness of IRV remains in question.<sup>79</sup> Continuous monitoring of the  $\text{S}\bar{\text{V}}\text{O}_2$  may aid in determining whether the addition of IRV has enhanced  $\text{DO}_2$ .

### Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) is a unique approach to ventilation in which CPAP at high levels is used to enhance mean alveolar volume while intermittent reductions in pressure to a “release” level provide a period of expiration (Fig. 7-13). Re-establishment of CPAP results in inspiration and return of lung volume back to the baseline level. The advantage of APRV is a reduction in PIP of approximately 50% in adult patients with ARDS when compared with other more conventional modes of mechanical ventilation.<sup>80,81</sup> Spontaneous ventilation also is allowed throughout the cycle, which may enhance cardiac function and renal blood flow.<sup>82,83</sup> Some data suggest that  $\dot{V}/\dot{Q}$  matching may be improved and dead space reduced.<sup>84,85</sup> In performing APRV, tidal volume is altered by adjusting the release pressure. Conceptually, ventilator management during APRV is the inverse of other modes of positive-pressure

**Figure 7-13.** Typical pressure and volume waveforms observed during airway pressure release ventilation (APRV).

ventilation in that the PIP, or CPAP, determines oxygenation, while the expiratory pressure (release pressure) is used to adjust  $\text{V}_\text{T}$  and  $\text{CO}_2$  elimination. APRV is very similar to modes of ventilation, such as IRV, that use prolonged I/E ratios. However, APRV appears to be better tolerated when compared with IRV in patients with acute lung injury/ARDS, as demonstrated by a reduced need for paralysis and sedation, increased cardiac performance, decreased pressor use, and decreased PIP requirements.<sup>86</sup> The clinical experience with APRV is limited in the pediatric population.<sup>87,88</sup>

### Bilevel Control of Positive Airway Pressure (BiPAP)

Although sometimes used in the setting of acute lung injury, BiPAP is frequently used for home respiratory support by varying airway pressure between one of two settings: the inspiratory positive airway pressure (IPAP) and the expiratory positive airway pressure (EPAP).<sup>89,90</sup> With patient effort, a change in flow is detected, and the IPAP pressure level is developed. With reduced flow at end expiration, EPAP is re-established. This device, therefore, provides both ventilatory support and airway distention during the expiratory phase. However, BiPAP ventilators should be used only to support the patient who is spontaneously breathing.

### Monitoring during Mechanical Ventilation

Current mechanical ventilators incorporate highly accurate solid-state pressure transducers that provide data on a variety of pressures and gas flows. Volume is not measured directly. Instead, flow is integrated over time in the determination of volume. Ventilators can also calculate and display a variety of pressure/volume, flow/volume, or volume/pressure waveforms as well as demonstrate volume, flow, and pressure over time. Low-pressure alarms are present to detect disconnection and leaks and are set at approximately 10 cm  $\text{H}_2\text{O}$  below the anticipated PIP. High-pressure alarms are set approximately 10 cm  $\text{H}_2\text{O}$  above PIP to avoid incidental application of excessive pressure to the lungs. Apnea alarms typically are triggered if  $\text{V}_\text{T}$

is not delivered for more than 10 seconds. Alarms for numerous other parameters such as PEEP, low  $V_T$ , low and high rate, and low and high  $FI_{O_2}$  may be adjusted on various ventilators. Most ventilators also have an indicator that notifies the operator if the ventilator settings result in an I/E ratio that is greater than 1:1.

In the setting of respiratory insufficiency, mechanical ventilation should be used in conjunction with invasive monitoring such as systemic arterial, central venous, and pulmonary arterial catheters, as well as pulse oximetry and end-tidal  $CO_2$  monitoring. Technology that allows frequent blood gas sampling without blood loss is now available for newborns and infants. It is likely that ventilators in the future will incorporate  $S\bar{V}O_2$  or  $Sc\bar{V}O_2$ ,  $SaO_2$ , and oxygen consumption data in determining online cardiac output and  $DO_2$  values to help guide management.<sup>91</sup> As online blood gas monitoring becomes more accurate,  $FI_{O_2}$ , rate, PIP, and PEEP will be servoregulated on the basis of  $SaO_2$ ,  $S\bar{V}O_2$ , and  $Paco_2$  values.

## Management of the Mechanical Ventilator

IMV and SIMV may suffice for patients with normal lungs, such as when needed after an operation.<sup>92</sup> If a patient is spontaneously breathing and is to be ventilated for more than a brief period, a flow- or pressure-triggered assist mode, pressure support, or PAV will result in maximal support and minimal work of breathing.<sup>48,49</sup> Ventilator modes that allow adjustment of specific details of pressure, flow, and volume are required in the patient with severe respiratory failure. With all these modes, the ventilator rate,  $V_T$  or PIP, PEEP, and either inspiratory time alone or I/E ratio (if ventilation is pressure limited) must be assigned. Other secondary controls such as the flow rate, the flow pattern, the trigger sensitivity for assisted breaths, the inspiratory hold, the termination sensitivity, and the safety pressure limit also are set on individual ventilators. The normal  $\dot{V}E$  is 100 to 150 mL/kg/min. The  $FI_{O_2}$  is usually initiated at 0.50 and decreased based on pulse oximetry. All efforts should be made to maintain the  $FI_{O_2}$  less than 0.60 to avoid alveolar nitrogen depletion and the development of atelectasis.<sup>93,94</sup> Oxygen toxicity likely is a result of this phenomenon, although free oxygen radical formation may play a role when an  $FI_{O_2}$  greater than 0.40 is applied for prolonged periods.<sup>95</sup> A short inspiratory phase with a low I/E ratio favors the expiratory phase and  $CO_2$  elimination, whereas longer I/E ratios enhance oxygenation. In the normal lung, I/E ratios of 1:3 and inspiratory time of 0.5 to 1 second are typical.

## Strategies in Respiratory Failure

### Preventing Ventilator-Induced Lung Injury

A decrease in pulmonary compliance and FRC is seen in the patient with acute lung injury ( $PaO_2/FI_{O_2}$  ratio, 200-300) or ARDS ( $PaO_2/FI_{O_2}$  ratio, < 200). This is

secondary to alveolar collapse and a decrease in the volume of lung available for ventilation and, in turn, to decreased pulmonary compliance. As a result, higher ventilator pressures are necessary to maintain  $V_T$  and  $\dot{V}E$ . However, any attempt to ventilate the patient with respiratory insufficiency due to parenchymal disease with higher pressures can result in compromise of cardiopulmonary function and the development of ventilator-induced lung injury.<sup>96</sup>

The concept of ventilator-induced lung injury was first demonstrated in 1974 by demonstrating the detrimental effects of ventilation at PIP of 45 cm  $H_2O$  in rats.<sup>97</sup> Electron microscopy has been used to document an increased incidence of alveolar stress fractures in ex-vivo, perfused rabbit lungs exposed to transalveolar pressures more than 30 cm  $H_2O$  (Fig. 7-14).<sup>98</sup> Other studies have demonstrated increases in albumin leak, elevation of the capillary leak coefficient, enhanced wet-to-dry lung weight, deterioration in gas exchange, and augmented diffuse alveolar damage on histology with application of increased airway pressure (45 to 50 cm  $H_2O$ ) in otherwise normal rats and sheep over a 1- to 24-hour period.<sup>31,99,100</sup> Pulmonary exposure to high pressures may potentially worsen nascent respiratory insufficiency and, ultimately, lead to the development of pulmonary fibrosis.

Such injury may be prevented during application of high PIPs by strapping the chest, thereby preventing lung overdistention, suggesting that alveolar distention or "volutrauma" is the injurious element, rather than application of high pressures or "barotrauma."<sup>101</sup> A low- $V_T$  (6 mL/kg) approach to mechanical ventilation in rabbits with *Pseudomonas aeruginosa*-induced acute lung injury appears to be associated with enhancement in oxygenation, increase in pH, increase in arterial blood pressure, and decrease in extravascular lung water when compared with a high- $V_T$  group (15 mL/kg).<sup>102</sup> A relation may also exist between ventilator gas flow rate and the development of lung injury.<sup>103</sup> Positive blood cultures have been seen in five of six animals exposed to high end-inspiratory pressure but rarely in those with low end-inspiratory pressure.<sup>104</sup>

Together, these data suggest that the method of ventilation has an effect on lung function and gas exchange as well as a systemic effect, which may include translocation of bacteria from the lungs. As such, avoidance of high PIPs and lung overdistention should be a primary goal of mechanical ventilation. Although the animal data would suggest that high PIPs and volumes may be deleterious, two multicenter studies have attempted to randomize patients with ARDS to high and low peak pressure or volume strategies. The first failed to demonstrate a difference in mortality or duration of mechanical ventilation in patients randomized to either the low-volume ( $7.2 \pm 0.8$  mL/kg) or the high-volume ( $10.8 \pm 1.0$  mL) strategy, although the applied PIP was not elevated to what would commonly be considered injurious levels in either group (low,  $23.6 \pm 5.8$  cm  $H_2O$ ; high,  $34.0 \pm 11.0$  cm  $H_2O$ ).<sup>105</sup> Another study revealed similar results but had similar design limitations.<sup>106</sup> A survival increase from 38% to 71% at 28 days, a higher

**Figure 7-14.** Scanning electron micrographs demonstrating disruptions in the blood-gas barriers (arrows) in rabbit lungs subjected to 20 cm H<sub>2</sub>O airway pressure and 75 cm H<sub>2</sub>O pulmonary arterial pressure. rate of weaning from mechanical ventilation, and a lower rate of barotrauma has been demonstrated in patients in whom a lung-protective ventilator strategy was used. This strategy consisted of lung distention to a level that prevented alveolar collapse during expiration (see later) and avoidance of high distending pressures.<sup>107</sup> One study identified a significant reduction over time in bronchoalveolar lavage concentrations of polymorphonuclear cells ( $P < .001$ ), interleukin

(IL)-1 $\beta$  ( $P < .05$ ), tumor necrosis factor (TNF)- $\alpha$  ( $P < .001$ ), interleukin (IL)-8 ( $P < .001$ ), and IL-6 ( $P < .005$ ) and in plasma concentration of IL-6 ( $P < .002$ ) among 44 patients randomized to receive a lung-protective strategy rather than a conventional approach.<sup>108</sup> The mean number of ventilator-free days at 28 days in the lung-protective strategy group was higher than in the control group ( $12 \pm 11$  vs.  $4 \pm 8$  days, respectively;  $P < .01$ ). Mortality rates at 28 days from

**Figure 7-15.** Probability of survival and of being discharged home and breathing without assistance during the first 180 days after randomization in patients with acute lung injury and the acute respiratory distress syndrome. The status at 180 days or at the end of the study was known for all but nine patients. (From The Acute Respiratory Distress Network: Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. *N Engl J Med* 342:1301-1308, 2000.)

admission were 38% and 58% in the lung-protective strategy and control groups, respectively ( $P = .19$ ).

The NIH's Acute Respiratory Distress Network convincingly demonstrated that mortality was reduced with the use of a low-volume (6 mL/kg, mortality of 31%) when compared with a high-volume (12 mL/kg, mortality of 39%;  $P = 0.005$ ) ventilator approach (Fig. 7-15).<sup>109</sup> Interestingly, no difference was found in gas exchange or pulmonary mechanics between groups to account for the difference in mortality. However, IL-6 levels and the incidence of organ failure were increased in the high-volume group when compared with the low-volume group. Similarly, multisystem organ failure scores increased significantly 72 hours after admission only in patients who were ventilated with a conventional rather than a lung-protective strategy, with renal failure being the most prevalent organ dysfunction.<sup>110</sup> Statistically significant correlations were noted between changes in overall multisystem organ failure score and changes in plasma concentration of inflammatory mediators, including IL-6, TNF- $\alpha$ , IL-1 $\beta$ , and IL-8. A significant correlation was also seen between the IL-6 level and the number of failing organs. Exposure of neutrophils (PMNs) to bronchoalveolar lavage fluid from a control group of ARDS patients resulted in increased PMN activation as compared with those exposed to bronchoalveolar lavage fluid from a group of patients managed with a lung-protective strategy.<sup>111</sup> The majority of clinicians are now convinced that avoidance of high PIP and support of lung recruitment, through the application of appropriate levels of PEEP (see later), should be a primary goal of any mechanical ventilatory program.

### Permissive Hypercapnia

To avoid ventilator-induced lung injury, practitioners have applied the concept of permissive hypercapnia. With this approach, PaCO<sub>2</sub> is allowed to increase to

levels as high as 120 mm Hg as long as the blood pH is maintained in the 7.1 to 7.2 range by administration of buffers.<sup>112</sup> Mortality was reduced to 26% when compared with that expected (53%;  $P < .004$ ) based on Acute Physiology and Chronic Health Evaluation II (APACHE II) scores when low-volume, pressure-limited ventilation with permissive hypercapnia was applied in the setting of ARDS in adults.<sup>113</sup> For burned children, the mortality rate was only 3.7% despite a high degree of inhalation injury when a ventilator strategy used a PIP of 40 cm H<sub>2</sub>O and accepted an elevated PaCO<sub>2</sub> as long as the arterial pH was greater than 7.20.<sup>114</sup> Other studies suggested that a strategy of high-frequency (40 to 120 breaths/min) ventilation with a low V<sub>T</sub>, low PIP, high PEEP (7 to 30 cm H<sub>2</sub>O), and mild hypercapnia (PaCO<sub>2</sub> from 45 to 60 mm Hg) enhances the survival rate in children with severe ARDS.<sup>115</sup>

### Using Protective Effects of PEEP

Although application of high, overdistingending airway pressures appears to be associated with the development of lung injury, a number of studies have demonstrated that application of PEEP or high-frequency oscillatory ventilation (HFOV) may allow avoidance of lung injury by the following mechanisms: (1) recruitment of collapsed alveoli, which reduces the risk for overdistention of healthy units; (2) resolution of alveolar collapse, which in and of itself is injurious; and (3) avoidance of the shear forces associated with the opening and closing of alveoli.<sup>116,117</sup> In the older child with injured lungs, a pressure of 8 to 12 cm H<sub>2</sub>O is required to open alveoli and to begin V<sub>T</sub> generation.<sup>107,118,119</sup> Alveoli will subsequently close unless the end-expiratory pressure is maintained at such pressures, and cyclic opening and closing is thought to be particularly injurious because of application of large shear forces.<sup>118</sup> One way to avoid this process is through the application of PEEP to a point above the inflection pressure (P<sub>flex</sub>), such that alveolar distention is maintained throughout the ventilatory cycle (Fig. 7-16).<sup>120,121</sup> In addition, as mentioned previously, it has been demonstrated that the distribution of infiltrates and atelectasis in the supine patient with ARDS is predominantly in the dependent regions of the lung.<sup>122</sup> This is likely the result of compression due to the increased weight of the overlying edematous lung. It has been shown that when the superimposed gravitational pressure from the weight of the overlying lung exceeded the PEEP applied to a given region of the lung, end-expiratory lung collapse increased, resulting in de-recruitment.<sup>123</sup> Thus, application of PEEP may result in recruitment of these atelectatic lung regions, simultaneously enhancing pulmonary compliance and oxygenation. PEEP and prone positioning (see later) are more effective if the need for ventilation is of extrapulmonary etiology rather than pulmonary etiology.<sup>124</sup>

As a result of these new data and concepts, the approach to mechanical ventilation in the patient with respiratory failure has changed drastically over

**Figure 7-16.** Static pressure/volume curve demonstrating the Pflex point in a patient with acute respiratory distress syndrome. Positive end-expiratory pressure should be maintained approximately 2 cm H<sub>2</sub>O above that point. The upper inflection point (UIP) indicates the point at which lung overdistention is beginning to occur. Ventilation to points above the UIP should be avoided in most circumstances. (Reprinted from Roupie E, Dambrosio M, Servillo G: Titration of tidal volume and induced hypercapnia in acute respiratory distress syndrome. *Am J Respir Crit Care Med* 152:121-128, 1995.)

the past few years (Table 7-3). Time-cycled, pressure-controlled ventilation has become favored because of the ability to limit EIP to noninjurious levels at a maximum of 35 cm H<sub>2</sub>O.<sup>119</sup> In infants and newborns, this EIP limit is set lower at 30 cm H<sub>2</sub>O. The V<sub>T</sub> should be maintained in the range of 6 mL/kg.<sup>109</sup> A lung-protective approach also incorporates lung distention and prevention of alveolar closure. Pressure/volume curves should be developed on each patient at least daily, so that the Pflex can be identified and the PEEP maintained above Pflex. If a pressure/volume curve cannot be determined, then Pflex can be assumed to be in the 7- to 12-cm H<sub>2</sub>O range, and PEEP, at that level or up to 2 cm H<sub>2</sub>O higher, can be applied.<sup>119,125,126</sup> Recruitment maneuvers that use intermittent sustained

inflations of approximately 40 cm H<sub>2</sub>O for up to 40 seconds often can be beneficial by initially inflating collapsed lung regions.<sup>127</sup> The inflation obtained with the recruitment maneuver is then sustained by maintaining PEEP greater than Pflex.

As both PIP and PEEP are increased, enhancements in compliance and reductions in V<sub>D</sub>/V<sub>T</sub> and shunt are to be expected. If they are not observed, then one should suspect the presence of overdistention of currently inflated alveoli instead of the desired recruitment of collapsed lung units. Application of increased levels of PEEP also may result in a decrease in venous return and cardiac output. In addition, West's zone I physiology, which predicts diminished or absent pulmonary capillary flow in the nondependent regions of the lungs at end inspiration, may be exacerbated with application of higher airway pressures. This may be especially detrimental, because it is the nondependent regions that are best inflated and to which one would wish to direct as much pulmonary blood flow as possible.<sup>15</sup> As a result, parameters of DO<sub>2</sub> should be carefully monitored during application of increased PEEP.<sup>128</sup> One approach for monitoring delivery is by applying close attention to the S $\bar{V}$ O<sub>2</sub> whenever the PEEP is increased to more than 5 cm H<sub>2</sub>O. As mentioned, increasing the PEEP gradually in increments of 2.5 cm H<sub>2</sub>O can be done until the desired level of oxygenation or lung protection is achieved or a decrease in S $\bar{V}$ O<sub>2</sub> to below the maximum is observed. Effective lung compliance also should be monitored to ensure that alveolar recruitment is being achieved.

If oxygenation remains inadequate with application of higher levels of PEEP, FIO<sub>2</sub> should be increased to maintain SaO<sub>2</sub> greater than 90%, although levels as low as 80% may be acceptable in patients with adequate DO<sub>2</sub>. As mentioned previously, one of the most effective ways to enhance DO<sub>2</sub> is with transfusion. All attempts should be made to avoid the atelectasis and oxygen toxicity associated with FIO<sub>2</sub> levels greater than 0.60.<sup>93</sup> Extending FIO<sub>2</sub> to levels more than 0.60 often has little effect on oxygenation, because severe respiratory failure is frequently associated with a large transpulmonary shunt. If inadequate DO<sub>2</sub> persists, a trial increase in PEEP level should be performed or institution of extracorporeal support considered.<sup>129</sup> Inflation of the lungs also can be enhanced by prolonging the inspiratory time by PC-IRV. Pharmacologic paralysis and sedation are required during performance of PC-IRV, although paralysis may have the additional benefit of decreasing oxygen consumption and enhancing ventilator efficiency.<sup>35</sup> Pao<sub>2</sub> may improve with application of PC-IRV.<sup>130,131</sup> Monitoring the effect on DO<sub>2</sub> and S $\bar{V}$ O<sub>2</sub> is critical, however, to ensure the benefit of this intervention. The advantages of the alveolar inflation associated with a decelerating flow waveform during pressure-limited modes of ventilation also should be used.<sup>41</sup>

### Prone Positioning

Altering the patient from the supine to the prone position appears to enhance gas exchange (Fig. 7-17).<sup>132,133</sup> Enhanced blood flow to the better-inflated

**Figure 7-17.** PaO<sub>2</sub> during supine (s) and prone (p) positioning. Note the increase in oxygenation when trauma patients with acute respiratory distress syndrome are in the prone position and a general trend toward increased PaO<sub>2</sub> with each return to the supine position. (Reprinted from Fridrich P, Krafft P, Hochleuthner H, Mauritz W: The effects of long-term prone positioning in patients with trauma-induced acute respiratory distress syndrome. *Anesth Analg* 83:1206-1211, 1996.)

anterior lung regions with the prone position would logically appear to account for the increase in oxygenation. However, data in oleic acid lung-injured sheep suggest that the enhancement in gas exchange may be due predominantly to more homogeneous distribution of ventilation, rather than to redistribution of pulmonary blood flow, because lung distention is more uniform in the prone position.<sup>134-136</sup> This effect may be reversed after a number of hours. Enhanced posterior region lung inflation frequently accounts for persistent increases in oxygenation when the patient is returned to the supine position. Therefore, benefit may be seen when the prone and supine positions are alternated, usually every 4 to 6 hours.<sup>122</sup> A randomized, controlled, multicenter trial evaluating the effectiveness of the prone position in the treatment of patients with ARDS was recently completed.<sup>137</sup> The prone group was placed in the prone position for 6 or more hours daily for 10 days while the control group remained in the supine position. Although the PaO<sub>2</sub>/F<sub>i</sub>O<sub>2</sub> ratio was greater in the prone when compared with the supine group (prone, 63.0 + 66.8, vs. supine, 44.6 + 68.2; *P* = 0.02), no difference in mortality was noted between groups. It is clear that some patients will not respond to altered positioning, in which case this adjunct should be discontinued. Meticulous attention to careful patient padding and avoidance of dislodgement of tubes and catheters is of the utmost importance in successful implementation of this approach.

### Adjunctive Maneuvers

Another means for enhancing oxygenation may be through administration of diuretics and the associated reduction of left atrial and pulmonary capillary hydrostatic pressure.<sup>138</sup> Diuresis results in a decrease in lung interstitial edema. In addition, reduction of lung edema decreases compression of the underlying dependent lung.<sup>139</sup> Collapsed dependent lung regions are thereby

recruited. Although this treatment approach has not been proved in randomized clinical trials, reduction in total body fluid in adult patients with ARDS appears to be associated with an increase in survival.<sup>140</sup> One must be cognizant of the risks of hypoperfusion and organ system failure, especially renal insufficiency, if overly aggressive diuresis is performed. Overall, however, a strategy of fluid restriction and diuresis should be pursued in the setting of ARDS, while monitoring organ perfusion and renal function.<sup>141</sup> In a randomized trial, a conservative fluid management strategy improved the oxygenation index, the lung injury score, the ventilator-free days, and the number of days spent out of the intensive care unit while the prevalence of shock and dialysis use did not increase.<sup>142</sup> Although the study was limited to 60 days, the results further support keeping a patient with acute lung injury in a state of fluid balance.

Applying noninjurious PIPs and enhancing PEEP levels limits the Δ*P* (the amplitude between the PIP and the PEEP) and V<sub>T</sub> and compromises CO<sub>2</sub> elimination. Therefore, the concept of permissive hypercapnia, which was discussed previously, is integral to the successful application of lung-protective strategies. PaCO<sub>2</sub> levels greater than 100 mm Hg have been allowed with this approach, although most practitioners prefer to maintain the PaCO<sub>2</sub> at less than 60 to 70 mm Hg.<sup>113</sup> Bicarbonate or tris(hydroxymethyl)aminomethane (THAM) may be used to induce a metabolic alkalosis to maintain the pH at greater than 7.20. Few significant physiologic effects are observed with elevated PaCO<sub>2</sub> levels as long as the pH is maintained at reasonable levels.<sup>143</sup> If adequate CO<sub>2</sub> elimination cannot be achieved while limiting EIP to noninjurious levels, then initiation of extracorporeal life support (ECLS) should be considered.

The one situation in which it may be acceptable to increase EIP to levels greater than 35 cm H<sub>2</sub>O (30 cm H<sub>2</sub>O in the infant and newborn) is in the patient with reduced chest wall compliance and relatively normal pulmonary compliance. Because pulmonary compliance is a combination of lung compliance and chest wall compliance, a decrease in chest wall compliance, such as due to abdominal distention, obesity, or chest wall edema, can markedly reduce pulmonary compliance despite reasonable lung compliance. This situation is analogous to studies discussed previously in which the lungs remain uninjured despite application of high airway pressures because the chest is strapped to prevent lung overdistention.<sup>101</sup> This is a frequent problem in secondary respiratory failure due to trauma, sepsis, and other frequent disease processes observed among surgical patients, including tightly placed dressings. A cautious increase in EIP in such patients may be warranted. Finally, a simple intervention, such as raising the head of the bed, may have marked effects on FRC and gas exchange in such patients.

### Weaning from Mechanical Ventilation

Once a patient is spontaneously breathing and able to protect the airway, consideration should be given to weaning from ventilator support. Weaning in the

majority of children should take 2 days or less.<sup>144</sup> The  $F_{IO_2}$  should be decreased to less than 0.40 before extubation. Simultaneously, PEEP should be lowered to 5 cm  $H_2O$ . The pressure support mode of ventilation is an efficient means for weaning because the preset inspiratory pressure can be gradually decreased while partial support is provided for each breath.<sup>145</sup> Adequate gas exchange with a pressure support of 7 to 10 cm  $H_2O$  above PEEP in adults and newborns is predictive of successful extubation.<sup>146</sup> Another study in adults demonstrated that simple transition from full ventilator support to a “T-piece,” in which oxygen flow-by is provided, is as effective at weaning as is gradual reduction in rate during IMV or pressure during PSV.<sup>147</sup> In all circumstances, brief trials of spontaneous breathing before extubation should be performed with flow-by oxygen and CPAP. Prophylactic dexamethasone administration does not appear to increase the odds of a successful trial in infants, except in “high risk” patients who receive multiple doses starting at least 4 hours before extubation.<sup>148,149</sup> Parameters during a T-piece trial that indicate readiness for extubation include the following: (1) maintenance of the pretrial respiratory and heart rates; (2) inspiratory force greater than 20 cm  $H_2O$ ; (3)  $\dot{V}_E$  less than 100 mL/kg/min; and (4)  $SaO_2$  greater than 95%. If the patient’s status is in question, transcutaneous  $CO_2$  monitoring, along with arterial blood gas analysis ( $Paco_2 < 40$  mm Hg;  $PaO_2 > 60$  mm Hg), may help to ascertain whether extubation is appropriate. The weaning trial should be brief. Under no circumstances should it last longer than 1 hour, because the narrow endotracheal tube provides substantial resistance to spontaneous ventilation. In most cases, the patient who tolerates spontaneous breathing through an endotracheal tube for only a few minutes will demonstrate enhanced capabilities once the tube is removed.

Frequent causes of failed extubation include persistent pulmonary parenchymal disease, interstitial fibrosis, and reduced breathing endurance. Pressure support ventilation is ideal for use in the difficult-to-wean patient because it allows gradual application of spontaneous support to enhance respiratory strength and conditioning (Table 7-4).<sup>145</sup> Enteral and parenteral nutrition should be adjusted to maintain the total caloric intake to no more than 10% above the estimated caloric needs of the patient. Excess calories will be converted to fat, with a high respiratory quotient and increased  $CO_2$  production. Nutritional support high in glucose will have a similar effect.<sup>149</sup> Manipulation of feedings along with treatment of sepsis may reduce  $VCO_2$  and enhance weaning. Pulmonary edema should be treated with diuretics. Some patients will benefit from a tracheostomy to avoid ongoing upper airway contamination, to decrease dead space and airway resistance, and to provide airway access for evacuation of secretions during the weaning process. In addition, the issue of “extubating” the patient is removed by tracheostomy tube placement. Spontaneous breathing trials, therefore, are easy to perform, and the transition from the mechanical ventilator is a much smoother and efficient process.<sup>150</sup> Tracheostomy in older patients can be performed by percutaneous

**Table 7-4** Management of the Patient for Whom Extubation Attempts Have Failed

Frequent spontaneous breathing trials

means at the bedside.<sup>151</sup> Long-term complications are fairly minimal in older patients. However, in newborns and infants, the rate of development of stenoses and granulation tissue may be significant.<sup>152,153</sup>

## NONCONVENTIONAL MODES AND ADJUNCTS TO MECHANICAL VENTILATION

### High-Frequency Ventilation

The concept of high-frequency jet ventilation (HFJV) was developed in the early 1970s to provide gas exchange during procedures performed on the trachea. HFJV uses small bursts of gas through a small “jet port” in the endotracheal tube typically at a rate of 420 breaths/min, with the range being 240 to 660 breaths/min.<sup>154</sup> The expiratory phase is passive.<sup>155</sup> The  $V_T$  is adjusted by controlling the PIP, which is usually initiated at 90% of conventional PIP.  $CO_2$  removal is most affected by the  $\Delta P$ . Therefore, an increase in the PIP or a decrease in the PEEP will result in enhanced  $CO_2$  elimination. Adjusting the  $Paw$ , PEEP, and  $F_{IO_2}$  alters oxygenation. HFJV is typically superimposed on background conventional  $V_T$  mechanical ventilation.

The utilization of HFJV has decreased in favor of high-frequency oscillatory ventilation (HFOV), which uses a piston pump–driven diaphragm and delivers small volumes at frequencies between 3 and 15 Hz.<sup>154</sup> Both inspiration and expiration are active. Oxygenation is manipulated by adjusting  $Paw$ , which controls lung inflation similar to the role of PEEP in conventional mechanical ventilation.  $CO_2$  elimination is controlled by manipulating the tidal volume, also known as the amplitude or power. In short, only four variables are adjusted during HFOV:

1. Mean airway pressure ( $Paw$ ) is typically initiated at a level 1 to 2 cm  $H_2O$  higher in premature newborns and 2 to 4 cm  $H_2O$  higher in term newborns and children than that used during conventional mechanical ventilation.<sup>155</sup> For most disease processes,  $Paw$  is adjusted thereafter to maintain the right hemidiaphragm at the rib 8 to 9 level on the anteroposterior chest radiograph.
2. Frequency (Hz) is usually set at 12 Hz in premature newborns and 10 Hz in term patients. Lowering the frequency tends to result in an increase in  $V_T$  and a decrease in  $Paco_2$ .

3. Inspiratory time, which may be increased to enhance tidal volume, is usually set at 33%.
4. Amplitude or power ( $\Delta P$ ) is set to achieve good chest wall movement and adequate  $\text{CO}_2$  elimination.

Gas exchange during high-frequency ventilation is thought to occur by convection involving those alveoli located close to airways. For the remaining alveoli, gas exchange occurs by streaming, a phenomenon in which inspiratory gas, which has a parabolic profile, tends to flow down the center of the airways whereas the expiratory flow, which has a square profile, takes place at the periphery (Fig. 7-18).<sup>157</sup> Other effects may play a role: (1) pendelluft, in which gas exchange takes place between lung units with different time constants, as some are filling while others are emptying; (2) the movement of the heart itself may enhance mixing of gases in distal airways; (3) Taylor dispersion, in which convective flow and diffusion together function to enhance distribution of gas; and (4) local diffusion.<sup>158</sup>

High-frequency ventilation should be applied to the newborn and pediatric patient for whom conventional ventilation is failing, because of either parameters of oxygenation or  $\text{CO}_2$  elimination. The advantage of high-frequency ventilation lies in the alveolar distention and recruitment that is provided while limiting exposure to potentially injurious high ventilator pressures.<sup>159</sup> Thus, the approach during high-frequency ventilation should be to apply a mean airway pressure that will effectively recruit alveoli and maintain oxygenation while limiting the  $\Delta P$  to that which will provide chest wall movement and adequate  $\text{CO}_2$  elimination.  $\text{CO}_2$  elimination at lower peak inspiratory pressures may be a specific advantage in patients with air leak, especially those with bronchopleural fistulas.<sup>160</sup> Once again, the effect on  $\text{DO}_2$ , rather than simply  $\text{PaO}_2$ , should be considered.

Although some studies with HFOV in preterm newborns suggested that the incidence of bronchopulmonary dysplasia was similar to that in the conventional

ventilation group and that adverse effects were noted on intraventricular hemorrhage and periventricular leukomalacia, other trials noted an increase in the rescue rate and a reduction in bronchopulmonary dysplasia in this population.<sup>161-165</sup> One multicenter, randomized trial revealed that 56% of preterm newborns managed with HFOV were alive without the need for supplemental oxygen at 36 weeks postmenstrual age as compared with 47% of those receiving conventional ventilation ( $P = .046$ ).<sup>166</sup> In an additional pilot study, those preterm infants managed with HFOV were extubated earlier and had decreased supplemental oxygen requirements.<sup>167</sup> Thus, although mixed, the data would suggest a reduction in pulmonary morbidity with the use of HFOV when compared with conventional ventilation.

In term newborns and pediatric patients with respiratory insufficiency, studies suggest that the rescue rate and survival in those treated with HFOV is significantly increased when compared with conventional mechanical ventilation.<sup>168-170</sup> In a randomized controlled trial of HFOV and inspired (inhaled) nitrous oxide (iNO) in pediatric ARDS, HFOV with or without iNO resulted in greater improvement in the  $\text{PAO}_2/\text{FIO}_2$  ratio than did conventional mechanical ventilation.<sup>171</sup> However, in contrast, one randomized controlled trial in term newborns failed to identify a significant difference in outcome between these treatment modalities.<sup>172</sup> In fact, a Cochrane Database review of randomized clinical trials comparing the use of HFOV versus conventional ventilation failed to show any clear advantage in the elective use of HFOV as a primary modality in the treatment of premature infants with acute pulmonary dysfunction.<sup>173</sup> Reductions in oxygenation index and  $\text{FIO}_2$  were observed during HFOV in 17 adult patients with ARDS.<sup>174</sup> A multicenter, randomized, controlled trial of HFOV for adults with ARDS demonstrated a nonsignificant trend toward improved 30-day mortality in the HFOV group when compared with the conventional ventilation group (37% vs. 52%, respectively;  $P = .102$ ).<sup>175</sup>

**Figure 7-18.** Streaming as a mechanism of gas exchange during high-frequency ventilation. Note that the parabolic wavefront of the inspiratory gas induces central flow in the airways, whereas expiratory gas flows at the periphery.

### Intratracheal Pulmonary Ventilation or Tracheal Gas Insufflation

Intratracheal pulmonary ventilation (ITPV) involves infusion of fresh gas (oxygen) into the trachea via a cannula placed at the tip of the endotracheal tube. This gas flow effectively replaces the central airway dead space with fresh oxygen during the expiratory phase of the ventilatory cycle and functions to reduce dead space, which augments  $\text{CO}_2$  elimination. For this purpose, a special “reverse thruster catheter” (RTC) was developed for gas insufflation that reverses the flow of gas at the tip such that it follows a retrograde path up the endotracheal tube (Fig. 7-19).<sup>176</sup> The catheter, which entrains gas, produces a Venturi effect and provides for more effective dead space reduction during expiration. ITPV has been shown to maintain reasonable levels of ventilation in normal animals at PIPs one half to one third of those required during conventional mechanical ventilation.

**Figure 7-19.** The reverse-thruster catheter used in performance of intratracheal pulmonary ventilation (ITPV). During inspiration, the exhalation valve on the ventilator closes, and gas flows prograde, filling the lung with a tidal volume of oxygen gas. During expiration, the gas flows retrograde, entraining and replacing the gas in the airways, thereby reducing dead space and  $\text{PaCO}_2$ . (Reprinted with permission from Wilson JM, Thompson JR, Schnitzer JJ, et al: Intratracheal pulmonary ventilation and congenital diaphragmatic hernia: A review of two cases. *J Pediatr Surg* 28:484-487, 1993.)

This same group also demonstrated the ability to maintain adequate levels of  $\text{CO}_2$  during ITPV, but not during CMV, in lambs in whom only 12.5% of the lung parenchyma remained available for gas exchange.<sup>177</sup> Others have demonstrated that PIPs could be reduced from 28.3 cm  $\text{H}_2\text{O}$  on CMV to 10.3 cm  $\text{H}_2\text{O}$  during ITPV ( $P = .028$ ) in term lambs while maintaining gas exchange.<sup>178</sup> In the same study, initiation of ITPV in lambs resulted in a decrease in PIP from 44 to 32 cm  $\text{H}_2\text{O}$  ( $P = .002$ ), with a simultaneous decrease in  $\text{PaCO}_2$  from 52.2 to 31.9 mm Hg ( $P = .029$ ). This same group also demonstrated that initiation of ITPV in newborn lambs with congenital diaphragmatic hernia led to a decrease in  $\text{PaCO}_2$  from  $110 \pm 21$  to  $52 \pm 24$  ( $P = .0014$ ).<sup>179</sup> The concept of reducing dead space by replacing upper airway gas during the expiratory phase also was applied by using a simple catheter, rather than the RTC, and has been termed *tracheal gas insufflation*.<sup>42,180</sup>

Clinical studies have demonstrated the ability of ITPV to reduce airway dead space and therefore the ventilator pressures required to achieve equivalent rates of  $\text{CO}_2$  elimination when compared with those observed during conventional mechanical ventilation in adult patients with ARDS, pediatric patients on venoarterial ECLS, and newborns with congenital diaphragmatic hernia after ECLS.<sup>181-183</sup> Tracheal gas insufflation was compared with conventional ventilation in a randomized, controlled trial in preterm newborns: PIP and PEEP were lower, while generating the same  $\text{PaCO}_2$ , and the time to extubation also was reduced.<sup>184</sup> In adult patients with ARDS, tracheal gas insufflation allowed a reduction in PIP without an increase in  $\text{PaCO}_2$ .<sup>185</sup>

## Inhaled Nitric Oxide Administration

Nitric oxide (NO) is an endogenous mediator that serves to stimulate guanylate cyclase in the endothelial cell to produce cyclic guanosine monophosphate

**Figure 7-20.** Mechanism of action of inhaled nitric oxide (iNO) in inducing vascular smooth muscle relaxation. Zaprinas is a phosphodiesterase inhibitor that may increase the potency and duration of the effect of iNO. GTP, guanosine triphosphate; cGMP, cyclic guanosine monophosphate. (Reprinted from Hirschl RB: Innovative therapies in the management of newborns with congenital diaphragmatic hernia. *Semin Pediatr Surg* 5:255-265, 1996.)

(cGMP), which results in relaxation of vascular smooth muscle (Fig. 7-20).<sup>186</sup> NO is rapidly scavenged by heme moieties. Therefore, inhaled nitric oxide (iNO) serves as a selective vasodilator of the pulmonary circulation but is inactivated before reaching the systemic circulation. Diluted in nitrogen and then mixed with blended oxygen and air, iNO is administered in doses of 1 to 80 parts per million (ppm).

Initial studies in adults with ARDS who were treated with iNO demonstrated a decrease in pulmonary vascular resistance and an increase in  $\text{PaO}_2$ , without change in systemic arterial pressure. In addition, a prospective, multicenter randomized trial of iNO in 177 adults with ARDS demonstrated a significant improvement in oxygenation compared with placebo over the first 4 hours of treatment ( $\text{PaO}_2$  increase = 20%: iNO, 60%; CMV, 24%;  $P = .00002$ ).<sup>187-189</sup> The initial increase in oxygenation translated to a reduction in  $\text{FiO}_2$  over the first day and in the intensity of mechanical ventilation over the first 4 days of treatment. However, no differences were observed between the pooled iNO groups and placebo groups with respect to mortality rate and number of days alive and off mechanical ventilation. A subgroup of patients who received iNO at a dose of 5 ppm showed an improvement in the number of patients alive and off mechanical ventilation at day 28 (62% vs. 44%;  $P < .05$ ). In another randomized, controlled trial in adults, iNO increased  $\text{PaO}_2/\text{FiO}_2$  at 1 hour and 12 hours.<sup>190</sup> Beyond 24 hours, the two groups demonstrated an equivalent improvement in  $\text{PaO}_2/\text{FiO}_2$ . Pediatric patients with respiratory failure demonstrate increases in  $\text{PaO}_2$  with iNO at 20 ppm.<sup>191</sup>

Unfortunately, a prospective, randomized, controlled trial investigating the effects of iNO therapy in children with respiratory failure revealed that although pulmonary vascular resistance and systemic oxygenation were acutely improved at 1 hour by administration of 10 ppm iNO, a sustained improvement at 24 hours was not identified.<sup>192</sup>

Only 40% of the iNO-treated term infants with pulmonary hypertension required ECLS when compared with 71% of the control subjects.<sup>193</sup> These results were corroborated by demonstrating a reduction in the need for ECLS in control newborns (ECLS, 64%) when compared with iNO-treated newborns (ECLS, 38%;  $P = 0.001$ ).<sup>194</sup> The incidence of chronic lung disease was decreased in newborns managed with iNO (7% vs. 20%). Similar results were noted for infants with persistent pulmonary hypertension of the newborn (PPHN) who were on HFOV. The need for ECLS was decreased from 55% in the control HFOV group to 14% in the combined iNO and HFOV group ( $P = .007$ ).<sup>195</sup> In a clinical trial conducted by the Neonatal Inhaled Nitric Oxide Study (NINOS) Group, neonates born at 34 weeks or older gestational age with hypoxic respiratory failure were randomized to receive 20 ppm iNO or 100% oxygen as a control.<sup>196</sup> If a complete response, defined as an increase in  $\text{PaO}_2$  of more than 20 mm Hg within 30 minutes after gas initiation, was not observed, then iNO at 80 ppm was administered. Sixty-four percent of the control group and 46% of the iNO group died within 120 days or were treated with ECLS ( $P = .006$ ). No difference in death was found between the two groups (iNO, 14% vs. control, 17%), but significantly fewer neonates in the iNO group required ECLS (39% vs. 54%). Follow-up at age 18 to 24 months failed to demonstrate a difference in the incidence of cerebral palsy, rate of sensorineural hearing loss, and mental developmental index scores between the control and iNO patients.<sup>197</sup> Other studies have similarly failed to identify a difference in pulmonary, neurologic, cognitive, or behavioral outcomes between survivors managed with iNO and those in the conventional group.<sup>198</sup>

An associated, but separate, trial demonstrated no difference in death rates and a significant increase in the need for ECLS when neonates with congenital diaphragmatic hernia (CDH) were treated with 20 or 80 ppm of iNO versus 100% oxygen as control.<sup>199</sup> It should be noted, however, that some investigators have suggested that the efficacy of iNO in patients with CDH may be more substantial after surfactant administration or at the point at which recurrent pulmonary hypertension occurs.<sup>200</sup> iNO administration also may be helpful in the moribund CDH patient until ECLS can be initiated.

Some concern has been expressed for the development of intracranial hemorrhage in premature newborns treated with iNO. More than a 25% increase in the arterial/alveolar oxygen ratio ( $\text{PaO}_2/\text{PAO}_2$ ) was observed in 10 of 11 premature newborns, with a mean gestational age of 29.8 weeks and severe RDS, in response to administration of 1 to 20 ppm iNO. However, in 7 of these 11 newborns, intracranial

hemorrhage developed during their hospitalization.<sup>201</sup> Also, a meta-analysis of the three completed studies evaluating the efficacy of iNO in premature newborns suggests no significant difference in survival, incidence of chronic lung disease, or rate of development of intracranial hemorrhage between iNO and control patients.<sup>202</sup>

NO is associated with the production of potentially toxic metabolites. When combined with  $\text{O}_2$ , iNO produces peroxy nitrates, which can be damaging to epithelial cells and also can inhibit surfactant function.<sup>203,204</sup> Nitrogen dioxide, which is toxic, also can be produced, and hemoglobin may be oxidized to methemoglobin. Additional concerns exist about the immunosuppressive effects and the potential for platelet dysfunction.

## Surfactant Replacement Therapy

The use of exogenous surfactant has been responsible for a 30% to 40% reduction in the odds of death among very low birth weight newborns with RDS (Fig. 7-21).<sup>205,206</sup> In addition, in those premature neonates with birth weight more than 1250 g, mortality in a controlled, randomized, blinded study decreased from 7% to 4%.<sup>207</sup> Two general forms of surfactant are available: synthetic surfactant (e.g., Exosurf; Burroughs Wellcome, Raleigh-Durham, NC), which is made of dipalmytoyl phosphatidylcholine and is protein free; and natural surfactant (e.g., Survanta; Ross Laboratories, Columbus, OH; or Infasurf; ONY, Inc., Amherst, NY), which contains bovine surfactant extracts and associated proteins. Studies reveal

**Figure 7-21.** A meta-analysis of studies evaluating the outcome and complications of the prophylactic use and treatment approach to exogenous natural and synthetic surfactant administration in preterm newborns. BPD, bronchopulmonary dysplasia; PTX, pneumothorax; ICH, intracranial hemorrhage; PDA, patent ductus arteriosus. (Adapted from Jobe AH: Pulmonary surfactant therapy. *N Engl J Med* 328:861-868, 1993.)

a significantly lower risk of chronic lung disease in Survanta (27%), when compared with Exosurf (34%) infants with birth weights of 1001 to 1500 g.<sup>208</sup> Compared with Exosurf, Infasurf treatment results in a 62% decrease in the incidence of RDS (Infasurf, 16%, vs. Exosurf, 42%) and a 70% decrease in death due to RDS (Infasurf, 1.7%, vs. Exosurf, 5.4%).<sup>209</sup> On the other hand, intraventricular hemorrhage occurs more frequently in Infasurf-treated infants (Infasurf, 39.0%, vs. Exosurf, 29.9%). Another natural surfactant, porcine-derived poractant alfa (Curosurf; Chiesi Farmaceutici, Italy) has been shown to improve oxygenation more rapidly when compared with beractant (Survanta).<sup>210</sup>

A randomized, prospective, controlled trial in term newborns with respiratory insufficiency demonstrated that the need for extracorporeal membrane oxygenation (ECMO) was significantly reduced in those managed with surfactant when compared with placebo.<sup>211</sup> The benefit of surfactant was greatest in those with a lower oxygenation index (< 23). Another controlled, randomized study demonstrated the utility of surfactant in term newborns with the meconium aspiration syndrome.<sup>212</sup> The oxygen index minimally decreased with the initial dose but markedly decreased with the second and third doses of surfactant from a baseline of 23.7 to 5.9 (Fig. 7-22). After three doses of surfactant, PPHN had resolved in all but one of the infants in the study group versus none of the infants in the control group. The incidence of air leaks and need for ECLS were markedly reduced in the surfactant group compared with the control patients.

Studies have concluded that surfactant phospholipid concentration, synthesis, and kinetics are not significantly deranged in infants with CDH compared with controls, although surfactant protein A concentrations may be reduced in CDH newborns on ECMO.<sup>213-215</sup> Animal and human studies have suggested that surfactant administration before the first breath is associated with enhancement in  $\text{PaO}_2$  and pulmonary mechanics.<sup>216,217</sup> However, among CDH patients on ECLS, no difference between those randomized to receive surfactant ( $n = 9$ ) and those control patients receiving air ( $n = 8$ ) was noted in terms of lung compliance, time to extubation, period of oxygen requirement, and the total number of hospital days.<sup>213</sup>

## Liquid Ventilation with Perfluorocarbon

Perfluorocarbons are clear, colorless, odorless, relatively dense fluids (1.9 g/mL) with relatively low surface tension (19 din/cm) that carry large amounts of oxygen (50 mL  $\text{O}_2$ /dL) and carbon dioxide (210 mL  $\text{CO}_2$ /dL).<sup>218</sup> Liquid ventilation has been performed by one of two methods<sup>219</sup>: (1) total liquid ventilation (TLV), in which the lungs are filled with perfluorocarbon to a volume equivalent of FRC, on which a device is used to generate tidal volumes of perfluorocarbon in the perfluorocarbon-filled lung<sup>220</sup>; and (2) administration of intratracheal perfluorocarbon to a volume

**Figure 7-22.** The effect of exogenous surfactant administration on oxygen index in term newborns with meconium-aspiration syndrome. (Reprinted from Findlay RD, Taeusch HW, Walther FJ: Surfactant replacement therapy for meconium aspiration syndrome. *Pediatrics* 97:48-52, 1996.)

equivalent of FRC followed by standard gas mechanical ventilation of the perfluorocarbon-filled lung, otherwise known as partial liquid ventilation (PLV).<sup>221</sup> The former technique appears to be somewhat more effective at enhancing gas exchange, whereas the latter technique is more easily generalized to critical care clinicians managing patients with severe respiratory insufficiency.

A number of studies have demonstrated the efficacy of PLV in enhancing gas exchange in animal models of respiratory insufficiency.<sup>222-225</sup> It appears that intratracheal administration of perfluorocarbon acts as a surrogate surfactant, recruits atelectatic lung regions, and redistributes pulmonary blood flow toward the better-ventilated, nondependent regions of the lungs in the patient with ARDS.<sup>226</sup> Of great interest is the demonstration of enhanced gas exchange with aerosolized perfluorocarbon in saline-lavaged, surfactant-depleted piglets.  $\text{PaO}_2$  was higher and  $\text{Paco}_2$  lower in the PLV and aerosolized perfluorocarbon group compared with that in the standard mechanical-ventilation animals.<sup>227</sup> The response was sustained even after discontinuation of aerosolization but not standard PLV. A number of phase I and II clinical studies have demonstrated the efficacy of PLV in enhancing oxygenation and pulmonary mechanics in adults, children, and newborns with respiratory insufficiency, including those with CDH and those who are premature.<sup>228-231</sup> Studies in pediatric and adult patients have demonstrated decreases in the (A-a) $\text{DO}_2$  from approximately 450 to 250 mm Hg within the first 48 hours after initiation of PLV.<sup>232</sup> Prospective, controlled, randomized pilot studies evaluating the safety and efficacy of PLV in adult and pediatric patients with respiratory insufficiency have shown no differences between the PLV and CMV groups since a surprisingly low mortality of 20% among the pediatric patients with isolated respiratory failure prohibited successful completion of the study, which was subsequently discontinued. Among adult patients with acute lung injury or ARDS, no

differences in ventilatory pulmonary mechanics, gas-exchange parameters, or survival were noted between the PLV ( $n = 65$ ) and CMV ( $n = 25$ ) patients.<sup>233</sup> In May 2001, the results of a multicenter, prospective randomized study comparing PLV and CMV in adults with ARDS revealed no significant difference in mortality or 28-day ventilator-free days in the PLV compared with the CMV group.<sup>234</sup> Although PLV may be further evaluated in subgroups of adult and pediatric patients with respiratory failure, it is unlikely that PLV will play a general role in the treatment of adult or pediatric ARDS.

Premature newborns in whom surfactant therapy fails demonstrate a twofold increase in mean pulmonary compliance and a decrease in mean oxygen index from approximately 50 to 10 over the 24-hour period after initiation of PLV, although a pilot randomized study failed to reveal increased survival in the PLV compared with the CMV group.<sup>235</sup> Likewise, a prospective, randomized, controlled pilot trial evaluating PLV in term newborns with respiratory failure did not demonstrate an increase in survival in the PLV group compared with the CMV patients.

Studies have demonstrated the ability of in-utero tracheal ligation to correct the structural and physiologic effects of pulmonary hypoplasia in the sheep fetus with CDH.<sup>236,237</sup> The ability to induce lung growth has been demonstrated by distention of the isolated right upper lobe in newborn sheep with perflubron (LiquiVent; Alliance Pharmaceutical Corp., San Diego, CA) to a pressure of 7 to 10 mm Hg.<sup>238</sup> An increase in size and alveolar number in the right upper lobe was noted, while maintaining the air-space fraction and the protein/DNA ratio. The alveolar/arterial ratio was unchanged compared with that in the nondistended control animals. This technique of perfluorocarbon-induced lung growth (PILG) would apply to patients with CDH who required ECLS. The use of PILG demonstrated radiologic evidence of an increase in ipsilateral lung size in those patients managed with PILG (Fig. 7-23).<sup>239</sup> A randomized, prospective, controlled pilot study demonstrated encouraging survival rates in six (75%) of eight PILG-treated CDH patients on ECLS compared with two (40%) of five conventionally treated patients on ECLS.<sup>240</sup>

In 1989, the first report of the use of TLV in humans was published.<sup>238,241</sup> Three moribund, preterm newborns, for whom surfactant therapy had failed, were managed with TLV. Pulmonary compliance increased during the period of TLV. However, the gas-exchange response was variable, though for the first time the ability to sustain gas exchange during TLV in humans was demonstrated. A multicenter study of TLV in pediatric models of ARDS demonstrated increased oxygenation and pulmonary function with enhancement in cardiac output and decrease in histologic parameters of lung injury in the TLV group.<sup>242</sup> Although not yet effectively tested in the clinical setting, these data suggest that TLV may play a significant role in lavaging, re-inflating, and ventilating injured lungs.

## VENTILATOR-ASSOCIATED PNEUMONIA

Ventilator-associated pneumonia (VAP), diagnosed at 48 hours or later on mechanical ventilation, is the second most common hospital-acquired infection in the neonatal (NICU) and pediatric (PICU) intensive care units. Occurring in 3% to 10% of all ventilated PICU patients and 6% to 32% of NICU patients, VAP results in higher mean lengths of ICU stay, increased mortality rates, and increased hospital costs.<sup>243,244</sup> Controversies exist on the definition, treatment, and prevention of VAP. Finally, many studies do not incorporate the pediatric population and therefore cannot be blindly applied to all patients.

Definitions for VAP differ for infants 1 year or younger (Table 7-5), children between 1 and 12 years old (Table 7-6), and those older than 12 years of age (Table 7-7). In all patients, mechanical ventilation must be present for more than 48 hours.<sup>243,245</sup> Microbial confirmation is not necessary for the NNIS/CDC criteria defined in the tables, and the use of quantitative cultures for diagnosis in children and neonates is variable. The technique of fiberoptic bronchoalveolar lavage (BAL) has been described in children but is not routinely used. Blind BAL findings of a bacterial index (defined as the  $\log_{10}$  of the colony-forming units of microorganisms per milliliter of BAL fluid) greater than 5 are the most reliable method for diagnosing VAP in mechanically ventilated children and should be used most often.<sup>246</sup>

Investigations on the treatment of VAP focus on empirical use of antibiotics and duration of therapy. Broad-spectrum, early empirical antibiotics, when appropriately chosen, have been shown to decrease mortality in adults, but overuse can increase antibiotic resistance.<sup>247,248</sup> Risk factors for multidrug-resistant pathogens in pediatric patients include younger age, increasing pediatric risk of mortality score, previous PICU admissions, exposure to household contacts hospitalized over the past year, intravenous antibiotic use in the past 12 months, and exposure to chronic care facilities.<sup>249,250</sup> Once final cultures are available, it is important to de-escalate therapy to prevent overuse of antibiotics and the breeding of multidrug-resistant organisms. The question of optimal duration of therapy in adults was addressed using a multicenter, randomized, controlled trial comparing 8 days of antibiotic therapy versus 15 days. There was no difference in the mortality rates. Patients infected with nonfermenting gram-negative bacilli, however, benefited from the longer duration of therapy with a reduced relapse rate. Finally, patients treated for 8 days also had a reduced incidence of multidrug-resistant pathogens on relapse when compared with those treated for 15 days.<sup>251</sup>

Guidelines for the prevention of VAP have been established based on current evidence by the VAP Guidelines Committee and the Canadian Critical Care Trials Group.<sup>244</sup> Recommended therapeutic interventions include orotracheal route of intubation, a

**Figure 7-23.** Progression of the distended lungs ipsilateral to the hernia with time (the perfluorocarbon is radiopaque) in the three patients who received 7 days of pulmonary distention with perfluorocarbon. Notice the evident increase in lung size, which was not observed in the contralateral lungs. ventilator circuit specific for each patient, circuit changes if soiled or damaged but no scheduled changes, change of heat and moisture exchangers every 5 to 7 days or as indicated, use of closed endotracheal suctioning system changed for each patient and as clinically indicated, subglottic secretion drainage in patients expected to be mechanically ventilated for more than 72 hours, and the head of bed elevated at 45 degrees when possible. Consideration should be given to the use of rotating beds and oral antiseptic rinses.<sup>252</sup> Finally, in adult patients, a team approach and implementation of a VAP bundle encompassing all the evidence-based guidelines has successfully improved outcomes.<sup>253</sup>

## VASCULAR ACCESS

Ravindra K. Vegunta, MBBS

One of the well-recognized challenges in providing medical care for infants and children is access to the vascular system. Pediatric surgeons are frequently called to provide vascular access in various settings and for a variety of indications. The most commonly used device for venous access in children is a peripheral intravenous (PIV) cannula. In adults, achieving venous access is often accomplished with minimal distress. However, in children, placement of an intravenous catheter can be quite traumatic to the child, the parents, and the attendant health care providers. In some situations it can be a fairly frustrating and time-consuming procedure.<sup>1</sup> In an emergency, alternative means of vascular access should be sought relatively quickly. Particular circumstances of each child may demand specific solutions for vascular access, namely, the choice of device and site chosen for its placement (see [Table 8-1](#) for indications for vascular access and the respective device choices). It is imperative that one is aware of the limitations and potential adverse effects of the various vascular access devices (VADs) that are available. Unfortunately, practitioners often persist with a PIV cannula for a long time instead of committing to a higher level of access early. This reluctance is seen in all clinical settings, such as the emergency department, operating room, neonatal intensive care unit (NICU), and other patient care units. For example, a child may stay on low osmolar and inadequate intravenous nutrition through a PIV cannula instead of total parenteral nutrition (TPN) through a central vascular device. In an emergency, one should move on to other options promptly after a few failed attempts at PIV cannula placement. In the past, the options were a venous cutdown or an emergency central venous catheter (CVC) placement. These methods take considerable time and frequently require the availability of a pediatric surgeon. Over the past several years, intraosseous (IO) needle placement has become the most common contingency method of emergency vascular access in children ([Fig. 8-1](#)). The newer mechanical devices have allowed easier training of emergency medical personnel and improved the success rate of IO placement in the prehospital setting. In fact, with appropriate training, an IO needle

can be placed more quickly than a PIV cannula.<sup>2</sup> Umbilical vessels are frequently used in sick neonates but can only be used for a finite period—maximum of 5 days for an umbilical artery catheter (UAC) and 14 days for an umbilical venous catheter (UVC).<sup>3</sup> Early placement of a peripherally introduced central venous catheter (PICC) is preferable in these infants. Persistence with using PIV cannulas leads to higher complication rates and reduces the number of future PICC placement sites. Local availability and policies of home health care personnel should be considered in deciding if a CVC or PICC would be more appropriate for home antibiotic therapy or home parenteral nutrition therapy that is indicated for a medium term (a few weeks). In choosing the appropriate VAD for an oncology patient, the requirements of the oncologist, the patient's age, expected activity level, expected chance of cure, number of previous VADs placed, and patency of the central veins all should be considered. The number of lumens, size of the catheter, type of catheter, and its location can all be tailored to the specific patient. Long-term maintenance of central venous access in patients suffering from intestinal malabsorption is particularly challenging. Once the six conventional sites of central venous access—bilateral internal jugular, subclavian, and femoral veins—are exhausted, one must become more creative in gaining central access.

Complications that are common to all types of VADs are extravasation of infusate, hemorrhage, phlebitis, septicemia, thrombosis, and thromboembolism. Prevention is the best way to manage these complications. Careful placement, with the use of ultrasound and/or fluoroscopic guidance as appropriate, can save time and reduce injury to adjacent structures. Maximal sterile barrier precautions are recommended during placement of the lines to reduce colonization and bloodstream infection rates.<sup>4,5</sup> Good stabilization will prevent dislodgement of the catheters and/or flipping of subcutaneous ports. Use of heparin-bonded catheters and heparin infusion have reduced the incidence of thrombosis of the veins while antibacterial-coated catheters are recommended for infection prevention.<sup>4</sup>

**Table 8-1** Indications for Vascular Access in Infants and Children and the Recommended Devices

Indications	PIV	PICC	IO	CVC		
				Non-tunneled	Tunneled	Subcutaneous Port
Emergency venous access	X		X	X		
Short-term venous access	X			X		
Medium-term venous access	X	X		X		
Long-term venous access		X			X	X

PIV, peripheral intravenous catheter; PICC, peripherally introduced central venous catheter; IO, intraosseous needle; CVC, central venous catheter.

## PERIPHERAL VENOUS ACCESS

As previously described, peripheral intravenous catheter placement is the most frequently used method of accessing the vascular compartment. Devices designed for this purpose are universally available, and the expertise needed for their placement is widely dispersed. Training new health care providers in these techniques is relatively straightforward. Nonetheless, obtaining PIV access in children in an emergency and in children who have had multiple previous intravenous catheters is particularly challenging.

In infants and children, PIV access is usually achieved by using the veins on the dorsum of the hand, forearm, dorsum of the foot, medial aspect of the ankle, and the scalp. In infants, the median vein tributaries on the ventral aspect of the distal forearm and wrist and the lateral tributaries of the dorsal venous arch on the dorsum of the foot may be available but typically admit only the finest-diameter catheters. The position of the distal long saphenous vein, anterior to the medial malleolus, is fairly constant and is frequently palpable, making it one of the most popular veins used for PIV access, particularly in infants. It allows a larger size catheter, and it is also possible to stabilize the catheter well. Several techniques have been shown to be beneficial in cannulating a peripheral vein, namely, warming the

extremity, transillumination, and epidermal vasodilators.<sup>6</sup> Ultrasound guidance has been used to obtain access to basilic and brachial veins in the emergency department.<sup>7</sup> VeinViewer (Luminetx Corporation, Memphis, TN) is a device that is slowly gaining popularity based on near-infrared imaging and digital light processing technology.<sup>8,9</sup> It projects a real-time image of all the patent subcutaneous veins on the overlying skin. Unlike ultrasonography, there is no physical contact with the overlying skin and hence there is no compression or distortion of the veins. Scalp veins can be readily visible and accessible but tend to be difficult to maintain access for any length of time. Similarly, external jugular vein catheters tend to get dislodged promptly in a moving patient and may only be useful for a short time. Significant complications associated with PIV catheters include phlebitis, thrombosis, and extravasation with chemical burn or necrosis of surrounding soft tissue.

## UMBILICAL VEIN AND ARTERY ACCESS

Sick neonates are often managed with catheters placed either in the umbilical vein (UVC) and/or one of the umbilical arteries (UAC). They are used for monitoring central venous or arterial pressure, blood sampling, fluid resuscitation, medication administration, and TPN. To minimize infectious complications, the UVCs are usually removed after a maximum of 14 days.<sup>10</sup> These catheters are typically placed by neonatal nurse practitioners or neonatologists by dissecting the umbilical cord stump within a few hours of birth. It is possible for the pediatric surgeon to cannulate the umbilical vessels after the umbilical stump has undergone early desiccation. A small vertical skin incision is made above or below the umbilical stump to access the umbilical vein or artery, respectively. Once the fascia is incised, the appropriate vessel is identified, isolated, and cannulated. The tip of the UVC is placed at the junction of the inferior vena cava (IVC) and the right atrium (RA).<sup>11</sup> The catheter is cut to reach the xiphisternum from the insertion site to locate the tip correctly. On the chest radiograph, the tip of the UVC should be above or at the level of the diaphragm. The tip of the UAC is positioned between the sixth and tenth thoracic vertebrae, cranial to the celiac axis (Fig. 8-2). Various calculations have been proposed to estimate the correct length of the catheter before insertion,

**Figure 8-1.** An intraosseous line has been inserted into the tibia of a young child for vascular access.

**Figure 8-2.** This abdominal and chest film in this newborn shows the UAC catheter at the level of the seventh vertebral body (*solid arrow*) and the umbilical venous catheter (*dotted arrow*) above the level of the diaphragm. These are the recommended positions for these catheters.

based on weight and other biometric measures of the infant.<sup>12,13</sup> The long-standing argument about the safety of a “high” versus “low” position for the UAC tip<sup>14</sup> has been laid to rest; the “high” position just described has been shown to be associated with a low incidence of clinically significant aortic thrombosis without any increase in other adverse sequelae.<sup>15</sup> Whereas the umbilical vessel catheters, without doubt, have saved many lives, they have also been associated with various complications. In addition to tip migration, sepsis, and thrombosis that are common to both, UVCs are associated with perforation of the IVC, extravasation of infusate into the peritoneal cavity, and portal vein thrombosis.<sup>16</sup> UACs are associated with aortic injuries, thromboembolism of aortic branches, aneurysms of the iliac artery and/or the aorta, paraplegia, and gluteal ischemia with possible necrosis.<sup>11</sup> Pooled rates of bloodstream infections associated with umbilical and CVCs in NICUs is reported to be 11.6 per 1000 catheter-days for premature infants with birth weight of less than 1000 g, 7.0 for infants weighing 1000 to 1500 g, and 4.0 for those weighing more than 2500 g.<sup>17</sup>

## PERIPHERALLY INTRODUCED CENTRAL CATHETER

PICC lines provide a reliable central venous access in neonates and older children of all sizes without a need for directly accessing the central veins. Hence

the potential for morbidity is low. PICC lines are suitable for infusion of fluids, medications, TPN, and blood products. They can be placed by specially trained registered nurses, advanced practice nurses, interventional radiologists, intensivists, and surgeons. Many institutions caring for sick children on a routine basis have developed special teams and protocols for placement of PICC lines to reduce variations in practice and increase availability.<sup>18</sup> Broadly, two techniques are used in the placement of PICC lines. The traditional technique involves placement of a relatively large cannula (about 19 gauge) in the vein of choice, through which the PICC is introduced. The technique that is currently most popular is the modified Seldinger technique. A regular small peripheral intravenous catheter (about 24 gauge) is first placed in a suitable extremity vein such as the basilic, cephalic, or long saphenous vein. A fine guide wire is advanced through this, the initial catheter is removed, the track is dilated, and the peel-away PICC introducer cannula is advanced over the guide wire. The guide wire is then removed, and the PICC line is introduced through the introducer (*Fig. 8-3*).<sup>19</sup> The tip of the PICC should be placed at the superior vena cava (SVC)/RA junction or the IVC/RA junction. Locations other than these are considered non-central and are associated with higher complications.<sup>20</sup> Lack of visible or palpable peripheral veins may necessitate use of ultrasound guidance to access a deeper vein such as the brachial vein. Accumulating evidence suggests that early placement of a PICC line is beneficial to the neonates compared with management with several peripheral venous catheters.<sup>21,22</sup> Delayed attempts

**Figure 8-3.** Placement of a PICC using the modified Seldinger technique described in the text. The axillary vein is being accessed in this premature infant.

at placement of a PICC line in these sick neonates may preclude its success because of lack of a suitable patent peripheral vein.<sup>19</sup> PICC lines are also eminently suitable for short- to medium-term (weeks) home intravenous therapy of antibiotic or parenteral nutrition.<sup>23</sup> The most common complications associated with PICC lines are infections, occlusion, and dislodgement of the catheter.<sup>24</sup> Symptomatic upper extremity venous thrombosis is seen as often as 7% in adults receiving chemotherapy through PICC lines versus 1% in those receiving no chemotherapy.<sup>25</sup>

## CENTRAL VENOUS CATHETERS

Until recently, CVCs have been the mainstay of reliable central vascular access in children. With the development of PICC teams<sup>18</sup> and the increasing use of PICC lines, there has been a decline in the use of CVCs in neonates and older children. Non-tunneled CVCs are used for short- and medium-term indications, whereas surgically placed tunneled CVCs are used for medium- and long-term indications. In premature neonates, if PICC placement is not successful, tunneled CVCs are preferentially used because of their smaller size and durability as opposed to non-tunneled CVCs. The central veins accessed for placement of CVCs are the bilateral internal jugular veins, subclavian veins, and femoral veins. In older children and full-term neonates, the percutaneous Seldinger technique is used. In premature neonates and occasionally in older children, the relevant central vein or one of its tributaries, common facial vein<sup>26</sup> or external jugular vein in the neck, cephalic vein in the deltopectoral groove, or the long saphenous vein at the groin (Fig. 8-4)<sup>27,28</sup>, is exposed surgically and cannulated directly. In the emergency situation, percutaneous femoral vein access is preferred because this area is away from all the other activity centered around the head, neck, and chest. Despite accumulating evidence,

**Figure 8-4.** This broviac catheter was placed through a cutdown at the groin to access the long saphenous vein close to the saphenofemoral junction. The catheter is positioned in a subcutaneous tunnel in the thigh to exit just above the knee on the anteromedial aspect.

familiarity continues to dictate the choices made by pediatric surgeons in choosing the site of placement of CVCs.<sup>28,29</sup> In a recent, unpublished survey of 282 practicing North American pediatric surgeons, 84% preferred placing tunneled CVCs in NICU infants around the neck with the left subclavian, right internal jugular, and right external jugular veins being the vessels of choice (in that order), citing familiarity as the main reason. The tip of a CVC placed from the lower body should be positioned at the junction of the IVC and RA. The xiphoid process is a good surface landmark to estimate the length of catheter needed. On a radiographic image, the tip should project just above the diaphragm. Placing the tip high will ensure prompt dilution of the infusate and is likely to be associated with lower chance of thrombosis. If the tip is placed close to the IVC bifurcation or in the iliac veins, it cannot be considered truly “central,” and hyperosmolar infusions should be avoided. A CVC placed through an upper body vein should be positioned such that the tip is at the junction of the SVC and RA. Surface landmarks for this location are less reliable. A point about 1 cm caudal to the manubriosternal junction, at the right sternal border, gives a close estimate to the SVC/RA junction in toddlers and older children. The lower margin of the third right costosternal junction has been shown to be the best surface landmark in adults for placement of the CVC tip at the SVC/RA junction.<sup>30</sup> Length recommendations have been made based on a child’s weight for placement of right internal jugular and right subclavian CVCs.<sup>31</sup> On a chest radiograph, the tip of the catheter should project about two vertebral bodies caudal to the carina. The tunneled, surgically placed CVC can be left in for several months to years. The Broviac and Hickman catheters (Bard Access Systems, Salt Lake City, UT) are made of silicone and are available in various sizes, the smallest being a 2.7-Fr single-lumen catheter. These catheters have a Dacron cuff that allows tissue ingrowth, resulting in anchoring of the catheter within the subcutaneous tunnel. The cuff can be placed close to the exit site of the catheter to facilitate easier removal by dissection through the exit site itself. Placement of the Dacron cuff midway between the venotomy site and the exit site has the advantage of reduced chance of unintended removal of the catheter.

There is mounting evidence demonstrating the virtue of ultrasound guidance for percutaneous central venous access. Two devices developed for this purpose have been well studied: SiteRite (Bard Access Systems, Salt Lake City, UT) and SonoSite (SonoSite Inc, Bothel, WA). Real-time 2D ultrasound guidance is now recommended as the preferred method when placing a CVC into the internal jugular vein in adults and children in elective situations.<sup>32,33</sup> In a randomized controlled trial, real-time ultrasound guidance has been shown to be beneficial in internal jugular vein catheterization in infants weighing less than 7.5 kg when compared with an ultrasound image-based skin surface marking.<sup>34</sup> The benefits of ultrasound guidance include higher success rate,

**Figure 8-5.** **A**, Representative ultrasound image of the right internal jugular vein and carotid artery as seen from the cranial end of an adult. **B**, The *circle* outlines the artery. The vein is just anterior and lateral to the artery and is shown by the *irregular ellipse*. The sternomastoid muscle is seen just anterior to the vein.

faster access, fewer needle passes, and fewer arterial punctures.<sup>32-36</sup> The ultrasound transducer is wrapped in a sterile sleeve, and sterile gel is used to obtain real-time images of the vessel being accessed. Either a short-axis view—across the diameter of the vessel (Fig. 8-5)—or the long axis view—along the length of the vessel—is used to visualize the needle approaching and entering the vessel. A guide wire is then passed into the vessel, followed by the routine Seldinger technique for placement of the CVC.<sup>33,35</sup> Because of the proximity of the clavicle, visualization of the subclavian vein is poor with ultrasound. Infraclavicular axillary vein cannulation has been performed with 96% success with ultrasound guidance for tunneled CVC placement into the subclavian vein.<sup>37</sup> There is limited evidence suggesting ultrasound guidance is helpful for subclavian vein and femoral vein cannulation in adults.<sup>32</sup>

The majority of bloodstream infections in children are associated with the use of a vascular access device. The pooled rate of catheter-associated bloodstream infections in pediatric intensive care units (PICUs) is reported to be 7.7 per 1000 catheter-days.<sup>17</sup> The incidence of umbilical catheter- and CVC-associated bloodstream infections in neonates is 4 to 11.3 per 1000 catheter-days. Tunneled CVCs placed in neonates in the NICU at the neck have been associated with a higher rate of complications than those placed in the groin; infection rates were 5.8 versus 0.7 per 1000 catheter-days.<sup>28</sup> Acute CVCs placed in 289 pediatric burn care unit patients also resulted in higher infection rates associated with subclavian and internal jugular CVCs compared with the femoral CVCs: 10 and 13.6 versus 8.2 per 1000 catheter-days.<sup>29</sup> This is thought to be due to the higher nursing and respiratory therapy activity at the head and neck in these patients who require intensive care. Although prophylactic antibiotics reduced the rate of CVC-associated septicemia in neonates, they are not recommended because no reduction in mortality was shown. Moreover, there is a potential risk for selection of resistant organisms.<sup>38</sup>

## TOTALLY IMPLANTED CENTRAL VENOUS CATHETERS

Totally implantable intravascular devices (ports) are subcutaneous reservoirs attached to CVCs. The reservoirs are made with a metal or hard plastic shell and a silicone septum that is penetrated for access. They provide a reliable, long-lasting solution for patients who need intermittent access to their central veins. They are ideal for patients who desire to be involved in aquatic sports and other physical activities. They are most useful for patients with malignancies, coagulopathies, hemolytic syndromes, and renal failure, requiring recurrent vascular access. Ports are available with a low profile and as small as 5-Fr catheters for infants, with progressively larger ones for older children. Larger ports are available with dual lumens. More recently, some high-flow ports have been introduced (PowerPort-Bard Access Systems, Salt Lake City, UT) that allow high-pressure injection of intravenous contrast for radiologic imaging. Ports require special noncoring needles to keep the septum from leaking. Regular hypodermic needles should not be used with ports because they tend to cut out small cores of the silicone septum with each penetration. The cutting edge of the noncoring needle is in line with the needle, keeping it from cutting a core of the septum. The reservoir should be implanted in a subcutaneous pocket, over a firm base such as the chest wall. Placing the port in the abdominal wall is not acceptable because penetration of the skin and septum against a soft base is difficult, if not impossible. Preferred sites for port placement include the pectoral area, parasternal area, above and medial to the areola, and the subclavicular area, medial to the anterior axillary fold. In patients with a concern for cosmesis, the low pre-sternum area and the lateral chest wall are two locations that hide the scar when the port is eventually removed. In determining port placement, consideration should be given to the age of the patient, the intended activities, as well as the convenience of the caregivers. Placing a lateral chest wall port will make it difficult for an

infant to be picked up under the axillae. Subclavicular placement will make it easy to access the port with minimal disrobing; in obese girls and young women, it is less likely to get displaced by the highly mobile breast tissue. However, the resultant scar is very difficult to hide. The presternal location will provide a very stable foundation for the port, even in the obese child. When placed over the lower sternum, it can be accessed with opening the front of a button-down top or shirt. Once the port is removed, the scar can be hidden nicely. Complications that are unique to a port are inability to access the port, disconnection of the catheter from the reservoir with extravasation, flipping of the port, fracture and embolization of the catheter, and breakdown of the overlying skin.<sup>39</sup> Unlike silicone catheters, polyurethane catheters have a tendency to adhere to the vein if left in place for more than 20 months.<sup>40</sup>

## INTRAOSSUEOUS ACCESS

Several studies have been published over the past 60 years establishing the safety and effectiveness of IO access for infusion of fluids and medications in children. Safety and efficacy of IO access in neonates has been specifically addressed in some recent studies.<sup>41,42</sup> IO access has also been shown to be faster than access with a PIV<sup>2</sup> and safer than an emergency CVC.

Bone marrow consists of rich lattice network of vessels. Whereas the peripheral veins collapse in patients in shock, the vascular spaces in the bone marrow do not.<sup>43</sup> The bioavailability of resuscitative drugs administered through IO access has been well established<sup>44</sup> and shown to be better than that of those administered through an endotracheal tube.<sup>45</sup> The current Pediatric Advanced Life Support (PALS) recommendation is to establish IO access promptly if PIV access cannot be attained rapidly in neonates and children of all ages who need intravenous drugs or fluids urgently.<sup>46</sup> Training in the technique of IO access placement is included in the PALS and the Advanced Trauma Life Support (ATLS) provider courses.<sup>47</sup> In children, the long bones of the lower extremities are used preferentially for IO placement. The proximal tibia is the most common site used, with the distal femur being the next most common. With full sterile precautions, a needle designed for bone marrow aspiration is advanced through the cortical bone to access the bone marrow. In an infant, a spinal needle may be used,<sup>48</sup> but in an older child, a generic bone marrow needle or a purposely designed IO needle such as the widely used Jamshidi needle (Cardinal Health, McGraw Park, IL) is used (see Fig. 8-1).<sup>45</sup> In the case of the proximal tibia, the subcutaneous, anteromedial flat surface of the tibia, 1 to 3 cm distal to the tibial tuberosity, is chosen. A small skin incision is made using the tip of a pointed scalpel or a large-bore hypodermic needle. The IO needle is positioned pointing posteriorly and angled slightly caudad. It is then advanced through the cortical bone using a screwing and unscrewing motion with constant pressure. Once the needle penetrates the outer cortex, a

sudden “give” is felt. The needle is held in this position and the obturator is removed. A syringe is attached and bone marrow is aspirated to confirm correct placement. The IO needle is stabilized with a dressing. The femoral location is accessed by placing the needle 1 to 3 cm cephalad to the patella, angled slightly cranial to avoid the growth plate. Contraindications for IO placement include injury or suspected injury to the bone or soft tissue overlying the placement site. Recently introduced mechanical devices such as the Bone Injection Gun (BIG, Wasimed, Caesarea, Israel), FAST1 System (Pyng Medical Corporation, Vancouver, Canada), and EZ-IO (Vidacare, San Antonio, TX)<sup>2,45</sup> have helped to expand the use of IO access. The first two are spring-loaded devices. The FAST1 System is designed for sternal use in adults. The EZ-IO is a power drill–assisted device that makes IO placement easier in older children and adults.

Early concerns about potential adverse effects on the growth plates of long bones used for IO access have been allayed by animal studies.<sup>48</sup> The overall complication rate is estimated to be about 1%.<sup>45</sup> Extravasation of fluid is the most common adverse event. Compartment syndrome, osteomyelitis, skin and soft tissue infection, bone fractures, and fat embolism, although rare, have also been reported.<sup>45</sup>

## VENOUS CUTDOWN

Although the advent and eventual broader acceptance of IO infusion has almost eliminated the need for venous cutdown and reduced the role of emergency placement of CVCs,<sup>6</sup> pediatric surgeons should maintain the knowledge and skills required to perform this procedure. The vessel of choice is the long saphenous vein near the medial malleolus. The vein is superficial and is of satisfactory size and there is minimal subcutaneous fat in this location. A transverse incision is made anterior and cephalad to the medial malleolus. The vein is readily identified by dissecting through the thin subcutaneous tissue and is stabilized by placing proximal and distal stay ligatures. The vein is then directly cannulated using a venous catheter of appropriate size relative to the vein. The catheter is anchored to the adjacent skin.

## ALTERNATE ROUTES FOR CENTRAL VENOUS ACCESS

Patients who have had multiple previous CVCs can have unrecognized thrombosis or stenosis of the central veins that precludes the successful placement of a new catheter. Doppler ultrasonography or magnetic resonance angiography should be used to survey the central veins, including the brachiocephalic vein, the SVC, and the IVC.<sup>49</sup> Percutaneous access can be gained via a patent IVC by interventional radiologists either by a translumbar or a transhepatic approach.<sup>50</sup> A tunneled catheter can then be placed to reach the IVC/RA junction. The translumbar IVC catheters are quite durable, but the transhepatic ones tend to get

withdrawn from the vascular space owing to the constant respiratory excursions of the diaphragm. The brachiocephalic vein, if patent, can similarly be accessed by interventional radiologists through a suprasternal route. In the absence of these options, the azygos vein may be accessed through one of the intercostal veins percutaneously<sup>51</sup> or surgically through a thoracotomy<sup>52</sup> or with thoracoscopic assistance.<sup>53</sup> Direct right atrial access has been used to manage patients with intestinal failure and occluded central veins<sup>54</sup> for long periods and in cardiac patients in an acute situation.

---

## ARTERIAL CATHETER

Intra-arterial catheters allow continuous hemodynamic monitoring and blood sampling. Radial arteries at the wrist are most commonly used for intra-arterial access because of good collateral circulation. Dorsalis pedis and posterior tibial arteries are the other peripheral sites that are sometimes used. Femoral arteries are frequently used by cardiologists for catheter-based cardiac interventions and occasionally for monitoring. However, in general, it is advisable not to use the main artery of an extremity for chronic arterial catheter placement to avoid thromboembolic and ischemic complications. The adequacy of collateral arterial supply through the ulnar artery should be confirmed before placement of a radial arterial line by using the Allen test.<sup>55-57</sup> The right radial artery allows preductal monitoring and sampling. Percutaneous cannulation is often successful. If not, an arterial cutdown may be

performed. Vasospasm is common and is self-limiting, reversing within a few hours. Thromboembolism can result in limb loss if the axillary, brachial, or femoral artery is catheterized. Digital ischemia can result from radial artery catheters. Local infections can occur when the catheters are left for several days. A pseudoaneurysm can result from injury to the adjacent vein during placement.

---

## HEMODIALYSIS CATHETERS

The current recommendation is to use an autologous arteriovenous fistula (AVF) as the route of choice for hemodialysis.<sup>58</sup> AVFs permit high flow rates that facilitate effective dialysis. They also are reliable, are durable, and, once established, have low complication rates. Because patients are often referred late and AVFs take time to mature, there is frequently a need for CVCs for immediate dialysis. Temporary and tunneled long-term double-lumen hemodialysis catheters are placed preferentially through the right internal jugular vein, either percutaneously or by cutdown. The larger size of the vein and the straight internal path of the catheter allow a larger catheter to be placed safely through the right internal jugular vein. The long-term, cuffed hemodialysis catheters are precurved to allow right internal jugular placement with tunneling to the pectoral area. Flow rates achieved through hemodialysis catheters tend to be lower and they last a relatively short time. Totally implanted subcutaneous hemodialysis access systems are being developed.<sup>59</sup>

# SURGICAL INFECTIOUS DISEASE

Bethany J. Slater, MD • Thomas M. Krummel, MD

Despite improvements in antimicrobial therapy, surgical technique, and postoperative intensive care, infection continues to be a significant source of mortality and morbidity for the pediatric patient. Widespread antibiotic use has brought with it the complication of resistant organisms,<sup>1</sup> and antibiotic selection has become increasingly complex as newer antibiotics are continually developed.<sup>2</sup> In addition, infections with uncommon organisms are becoming more common with diminished host resistance from immunosuppressive states such as immaturity, cancer, systemic diseases, and medications after transplant procedures. Surgical infections generally require some surgical intervention, such as drainage of an abscess or removal of necrotic tissue, as opposed to being treated solely with antibiotics.

Two broad classes of infectious disease processes affect a surgical practice: those infectious conditions brought to the pediatric surgeon for treatment and cure and those that arise in the postoperative period as a complication of surgical intervention.<sup>3</sup>

## COMPONENTS OF INFECTION

The pathogenesis of infection involves a complex interaction between the host and pathogens. Four components are important: virulence of the organism, size of inoculum, presence of nutrient source for the organism, and a breakdown in the host's defense.

The virulence of any microorganism depends on its ability to cause damage to the host. Exotoxins, such as streptococcal hyaluronidase, are digestive enzymes released locally that allow the spread of infection by breaking down host extracellular matrix proteins. Endotoxins, such as lipopolysaccharides, are components of gram-negative cell walls that are released only after bacterial cell death. Once systemically absorbed, endotoxins trigger a severe and rapid systemic inflammatory response by releasing various endogenous mediators such as cytokines, bradykinin, and prostaglandins.<sup>4</sup> Surgical infections are often polymicrobial, involving various interactions among the species of microorganisms.

The size of the inoculum is the second component of an infection. The number of colonies of microorganisms per gram of tissue is a key determinant. The smallest number of bacteria required to cause clinical infection varies from species to species. Predictably, any decrease in host resistance decreases the absolute number of colonies necessary to cause clinical disease. In general, if the bacterial population in a wound exceeds 100,000 organisms per gram of tissue, invasive infection is present.<sup>5</sup>

For any inoculum, the ability of the organisms to find suitable nutrients is essential for their survival and comprises the third component of any clinical infection. Accumulation of necrotic tissue, hematoma, or other environmental contamination offers nutrient medium for continued organism growth and spread. Of special importance to the surgeon is the concept of necrotic tissue and infection. This tissue is recognized as a nutrient source for invading microorganisms.<sup>6</sup> Also, complement proteins and neutrophils accumulate in necrotic tissue that diverts them from the invading microorganisms.<sup>7</sup>

Finally, for a clinical infection to arise, the body's defenses must be broken. Even highly virulent organisms can be eradicated before clinical infection occurs if resistance is intact. Evolution has equipped humans with numerous mechanisms of defense, both anatomic and systemic.

## DEFENSE AGAINST INFECTION

### Anatomic Barriers

Intact skin and mucous membranes provide an effective surface barrier to infection.<sup>8</sup> These tissues are not merely a mechanical obstacle. The physiologic aspects of skin and mucous membranes provide additional protection. In the skin, the constant turnover of keratinocytes, temperature of the skin, and acid secretion from sebaceous glands inhibits bacterial cell growth. The mucosal surfaces also have developed advanced defense mechanisms to prevent and combat microbial invasion. Specialized epithelial layers provide resistance

to infection. In addition, mechanisms such as the mucociliary transport system in the respiratory tract and normal colonic flora in the gastrointestinal tract prevent invasion of organisms. Any pathologic situation affecting the normal function of these anatomic barriers increases the host's susceptibility to infection. A skin injury or a burn provides open access to the soft tissues, and antibiotic use disrupts normal colonic flora. Such breakdowns in surface barriers are dealt with by the second line of defenses, the immune system.<sup>9</sup>

## Immune Response

The immune system involves complex pathways and many specialized effector responses. The first line of defense is the more primitive and nonspecific innate system, which consists primarily of phagocytic cells and the complement system. The neutrophil is able to rapidly migrate to the source of the infection and engulf and destroy the infecting organisms by phagocytosis. Cytokines, low molecular weight proteins including tumor necrosis factor (TNF), and many interleukins attract and activate neutrophils and play a significant role in mediating the inflammatory response. In addition, the complement system, when activated, initiates a sequential cascade that also enhances phagocytosis, stimulates inflammation, and leads to lysis of pathogens. Neonates, in particular premature infants, have an immature immune system and must rely solely on the innate immune system and the protective agents in human breast milk.<sup>10</sup> The more specialized, adaptive immune system involves a highly specific response to antigens as well as the eventual production of a variety of humoral mediators.<sup>11</sup>

## Humoral and Cell-Mediated Immunity

Specific, adaptive immunity has two major components. The humoral mechanism (B-cell system) is based on bursa cell lymphocytes and plasma cells. The cellular mechanism (T-cell system) consists of the thymic-dependent lymphocytes.<sup>12</sup> The adaptive immune system is an antigen-specific system that is regulated by the lymphocytes. A myriad of receptors on the T cells that are matched to particular individual antigens create these specific responses. Furthermore, antibody production from B cells enhances the antigen-specific interaction. The receptors of the T cells are produced by genes that undergo rearrangements, accounting for the enormous diversity of the unique receptors.<sup>11</sup>

Immunity provided by the B-cell system consists primarily of specific antibodies. Human antibodies are classified into five basic types of immunoglobulins. The first exposure of an antigen leads to the production of IgM antibodies, whereas subsequent exposure to the same antigen results in rapid production of IgG antibodies. Humoral antibodies may neutralize toxins, tag foreign matter to aid phagocytosis (opsonization), or lyse invading cellular pathogens. Plasma cells and non-thymic-dependent lymphocytes that reside in the bone marrow and in the germinal centers and

medullary cords of lymph nodes produce the reactive components of this humoral system. These agents account for most of the human immunity against extracellular bacterial species.

The cellular or T-cell component of immunity is based on sensitized lymphocytes located in the subcortical regions of lymph nodes and in the periarterial spaces of the spleen. These lymphocytes form a part of the recirculating lymphocyte pool. The T cells are specifically responsible for immunity to viruses, most fungi, and intracellular bacteria. They produce a variety of lymphokines, such as transfer factors, that further activate lymphocytes, chemotactic factors, leukotrienes, and interferons.

## Immunodeficiencies

Susceptibility to infection is increased when some component of the host defense mechanism is absent, reduced in absolute numbers, or significantly curtailed in function. Some of these derangements may have a congenital basis, although the majority are acquired as a direct result of drugs, radiation, endocrine disease, surgical ablation, tumors, or bacterial toxins. Immunodeficiencies from any cause significantly increase the risk of surgical infections both in hospitalized and postoperative patients. In addition, mycotic infections are an increasing problem in immunocompromised pediatric patients.<sup>13</sup>

Systemic diseases lead to diminished host resistance. For example, in diabetes mellitus, leukocytes often fail to respond normally to chemotaxis. Therefore, more severe and unusual infections often occur in diabetic patients.<sup>14</sup> In addition, tumors and other conditions that impair hematopoiesis lead to derangements in phagocytosis, resulting in an increased predilection for infection. Human immunodeficiency virus (HIV) infection in children is another major source of immunodeficiency. Vertical transmission from mother to child is the dominant mode of HIV acquisition among infants and children. Most of this transmission is thought to occur late in pregnancy or postnatally through breast feeding. Finally, poor nutritional status has adverse effects on immune function owing to a wide variety of negative influences on specific defense mechanisms, including decreased production of antibodies and phagocytic function.<sup>15</sup>

In patients with a primary immune defect, susceptibility to a specific infection is based on whether the defect is humoral, cellular, or a combination. Primary immunodeficiencies are rare but important because prompt recognition can lead to lifesaving treatment or significant improvement in the quality of life.<sup>16</sup> B-cell deficiencies are associated with sepsis from encapsulated bacteria, especially pneumococcus, *Haemophilus influenzae*, and meningococcus. Often a fulminating course rapidly ends in death, despite timely therapeutic measures. Although congenital agammaglobulinemia or dysgammaglobulinemia has been widely recognized, other causes of humoral defects include radiation, corticosteroid and antimetabolite therapy, sepsis, splenectomy, and starvation. Chronic

granulomatous disease is caused by a deficiency in the respiratory burst action of phagocytes that leads to severe and recurrent bacterial and fungal infections in early childhood. Children with chronic granulomatous disease are prone to develop hepatic abscesses as well as suppurative adenitis of a single node or multiple nodes, both of which may require surgical drainage or excision.<sup>17</sup>

T-cell deficiencies are responsible for many viral, fungal, and bacterial infections. Cutaneous candidiasis is a good example of a common infection seen with a T-cell deficiency. DiGeorge syndrome is a developmental anomaly in which both the thymus and the parathyroid glands are deficient, thus increasing the risk for infection and hypocalcemic tetany during infancy. Bacterial toxins, immunosuppressive drugs, malnutrition, and radiation also can produce defects in cellular immunity.<sup>18</sup>

## ANTIBIOTICS

The several classes of antibiotics are based on their molecular structure and site of action. The varying classes of antibiotics may be divided into bacteriostatic, which inhibit bacterial growth, and bactericidal, which destroy bacteria. The early initiation and correct choice of antibiotics is essential for timely and successful treatment of infections. In addition, it is important to have knowledge of the specific susceptibility patterns in a particular hospital or intensive care unit (ICU) to direct initial empirical antibiotic therapy. Finally, awareness of interactions and adverse reactions in pediatric patients of commonly utilized medications is critical.

The pharmacokinetics and monitoring of drug dosages in children is also important when treating patients with antibiotics. The efficacy and safety of many drugs have not been established in the pediatric patient, especially in the newborn.<sup>19</sup> Dosages based on pediatric pharmacokinetic data offer the most rational approach. The assumption that a child is a miniature adult as the basis for extrapolation of adult dosages to children is not ideal. Dosage requirements constantly change as a function of age and body weight. Furthermore, the volume of distribution and half-life of many drugs are often increased in neonates and children compared with adults for a variety of reasons.<sup>20,21</sup> Knowledge of a drug's pharmacokinetic profile allows manipulation of the dose to achieve and maintain a given plasma concentration. The body surface area (BSA) method of calculating drug dosages ( $\text{Child's BSA [determined using nomogram]} / 1.7 \times \text{Adult dose}$ ) approximates the pediatric dose of many drugs but does not always accurately determine dosage requirements in the premature and term newborn.

Newborns usually have extremely skewed drug-distribution patterns. The entire body mass can be considered as if it were a single compartment for purposes of dose calculations. For the majority of drugs, dose adjustments can be based on plasma drug concentration. Administering a loading dose is advisable when

rapid onset of drug action is required. For many drugs, loading doses (milligrams per kilogram) are generally greater in neonates and young infants than in older children or adults.<sup>22</sup> However, prolonged elimination of drugs in the neonate requires lower maintenance doses, given at longer intervals, to prevent toxicity. Monitoring serum drug concentrations is useful if the desired effect is not attained or if adverse reactions occur. In the sick premature newborn, almost all medications are administered intravenously because gastrointestinal function and drug absorption are unreliable.

The neonate undergoing extracorporeal membrane oxygenation (ECMO) presents a special challenge to drug delivery and elimination. Because the ECMO circuit may bind or inactivate drugs and make them unavailable to the patient, dosing of drugs requires careful attention to drug response and serum levels. The pharmacokinetics under these conditions generally include a larger volume of distribution and prolonged elimination, with a return to baseline after decannulation.<sup>23</sup>

## PREVENTION OF INFECTIONS

The most effective way to deal with surgical infectious complications is to prevent their occurrence. The clinician must recognize the variables that increase the risk of infection and attempt to decrease or eliminate them. A summary of the category I recommendations published by the Hospital Infection Control Practices Advisory Committee (HICPAC) of the Centers for Disease Control and Prevention that can be implemented by the surgical team is listed in [Table 9-1](#).

### Patient Characteristics

In the adult surgical population, patient characteristics and co-morbidities such as diabetes, liver failure, systemic corticosteroid use, obesity, extremes of age, and poor nutritional status are associated with an increased risk of surgical site infection. However, these chronic disease states are infrequently encountered in children. A prospective multicenter study of surgical wound infections in the pediatric surgical population found that postoperative wound infections were related to factors at the operation rather than to patient characteristics.<sup>24</sup> In this study of more than 800 pediatric patients, the only factors associated with increased surgical site infection were contamination at the time of operation and the duration of the procedure. In contrast, the presence of co-existing disease or anomalies, concurrent distant site infection, or American Society of Anesthesiologists (ASA) perioperative assessment score were not found to be associated with an increase in wound infection. Other investigators have similarly found that local factors at the time of operation, such as degree of contamination, tissue perfusion, and operative technique, play a more important role in initiation of a pediatric surgical site infection than the general condition of the patient.<sup>25</sup>

**Table 9-1** Guidelines for Prevention of Surgical Site Infections

- Treat remote infections before elective surgery.
- Do not remove hair preoperatively unless it will interfere with operation.
- Adequately control serum blood glucose levels perioperatively.
- Require patients to shower or bathe with an antiseptic agent before the operative day.
- Use an appropriate antiseptic agent for skin preparation.
- Perform a surgical scrub for at least 2 to 5 minutes using an appropriate antiseptic.
- Administer a prophylactic antimicrobial agent only when indicated.
- Administer an antimicrobial agent such that bactericidal concentration of the drug is established in serum and tissues when the incision is made and maintained throughout the operation.
- Sterilize all surgical instruments.
- Wear a surgical mask.\*
- Wear a cap or hood to fully cover hair on head and face.\*
- Wear sterile gloves.\*
- Use sterile gowns and drapes that are effective barriers when wet.
- Handle tissue gently, maintain effective hemostasis, minimize devitalized tissue and foreign bodies, and eradicate dead space at the surgical site.
- If drainage is necessary, use closed suction drain.
- Protect with a sterile dressing for 24 to 48 hours postoperatively an incision that has been closed primarily.

\*Required by OSHA regulations.

From Mangram AJ, Horan TC, Pearson ML, et al. Guideline for Prevention of Surgical Site Infection, 1999. Centers for Disease Control and Prevention (CDC) Hospital Infection Control Practices Advisory Committee. *Am J Infect Control* 27:97-132, 1999.

## Surgical Preparation

Preoperative preparation of the operative site and the sterility of the surgical team are very important in reducing the risk of postoperative infection. Hand scrubbing remains the most important proactive mechanism to reduce infection by reducing the number of microorganisms present on the skin during the surgical procedure. In the United States, the conventional method for scrubbing consists of a 5-minute first scrub followed by subsequent 2- or 3-minute scrubs for subsequent cases with either 5% povidone-iodine or 4% chlorhexidine gluconate. These scrubbing protocols can achieve a 95% decrease in skin flora.<sup>26,27</sup> Newer alcohol-based antiseptic cleaners with shorter applications, usually 30 seconds, have been developed and have been shown to be as effective as or even more effective than hand washing in decreasing bacterial contamination.<sup>28-30</sup> In addition, these solutions increase compliance and are less drying to the surgeon's skin. Preoperative showering with an antiseptic can reduce colony counts up to ninefold. Despite reducing the colony counts, no definitive data suggest that this actually reduces the risk of infection.<sup>31</sup> A similar reduction in the patient's skin flora can be achieved with aggressive preoperative cleansing and sterile draping.

Shaving the operative field, if necessary, should be done just before prepping the skin, and preferably with electric clippers or depilatory creams.<sup>31-34</sup> Preoperative shaving the night before has been shown to increase rates of infection.<sup>32,33,35</sup>

Normothermia has also been suggested as a means to decrease the incidence of surgical wound infections. Pediatric patients are at particular risk for experiencing hypothermia during surgery due to an increased area-to-body weight ratio leading to greater heat loss.<sup>36</sup> Intraoperative hypothermia can potentially lead to serious complications, including coagulopathy, surgical site infections, and cardiac complications. A prospective randomized trial of 200 adult patients undergoing colorectal surgery showed that intraoperative hypothermia caused delayed wound healing and a greater incidence of infections.<sup>37</sup> A number of techniques are available to warm infants and children during surgery, including warming intravenous fluids or using a warming mattress. In addition, supplemental oxygen given during the perioperative period in adult patients has been shown to decrease the rate of wound infection by as much as 40% to 50%.<sup>38,39</sup> Finally, adequate control of glucose levels perioperatively has also been demonstrated to decrease morbidity and mortality in both adult and pediatric surgical patients, particularly in those patients undergoing cardiac surgery.<sup>40,41</sup>

## Antibiotic Prophylaxis

Operative procedures can be classified into one of four types, as outlined in Table 9-2. In adults, several well-designed prospective trials have documented a decreased infection rate for all types of operative procedures with established antibiotic recommendations.<sup>42</sup> Important points for surgical antibiotic prophylaxis include using agents that cover the most

**Table 9-2** Wound Classification

Class	Definition
Clean	An uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, genital, or infected urinary tract is not entered. In addition, clean wounds are closed primarily and, if necessary, drained with closed drainage.
Clean-contaminated	An operative wound in which the respiratory, alimentary, genital, or urinary tract is entered under controlled conditions and without unusual contamination
Contaminated	Open, fresh, accidental wounds. This includes operations with major breaks in sterile technique or gross spillage from the gastrointestinal tract and incisions in which acute, nonpurulent inflammation is encountered.
Dirty	Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera

probable intraoperative contaminants for the operation, optimal timing for the initial dose of antibiotic so that bactericidal concentrations are reached at the time of incision, and maintaining the contribution levels throughout the operation.<sup>31</sup> Timing of the perioperative antibiotic coverage is crucial. The first dose is generally given 30 minutes to 1 hour before the start of the operation. In operations that take more than the half-life of the administered drug, a second dose of prophylactic antibiotics is indicated to re-achieve adequate serum levels.<sup>43</sup>

Prophylaxis accounts for nearly 75% of antibiotic use on pediatric surgical services. Additionally, prophylaxis is the major cause of the inappropriate use of antimicrobials in children. In one study of children younger than 6 years of age undergoing surgical procedures, prophylactic antibiotics were administered inappropriately to 42% of children receiving preoperative antibiotics, 67% of children receiving intraoperative antibiotics, and 55% of those receiving postoperative antibiotics.<sup>44</sup> In pediatric surgery, it is clear that antibiotic coverage is required during clean-contaminated, contaminated, or dirty cases. However, some disagreement exists concerning antimicrobial prophylaxis in clean operations. Antibiotic prophylaxis in a clean case in the pediatric population is now at the discretion of the operating surgeon.

## Bowel Preparation

The efficacy of bowel preparation before an elective colon operation is well documented.<sup>45,46</sup> Bowel preparation includes mechanical irrigation and flushing of the colon to remove stool, oral antibiotics against colonic aerobes and anaerobes, and preoperative intravenous antibiotics that cover both common skin and colonic flora.<sup>47</sup> The preparation can be started on an outpatient basis the day before the operation, and the parenteral drugs are added to the regimen just before the procedure. Recently, there has been debate in the adult literature regarding the necessity of mechanical bowel preparation. In infants and children, protocols for bowel preparation have largely been extrapolated from the adult colorectal literature. It appears that the majority of pediatric surgeons use bowel preparations for elective colorectal surgery in an attempt to reduce surgical site infections.<sup>48</sup> Recently, others have proposed that omitting mechanical bowel preparation carries no increased risk of infectious or anastomotic complications.<sup>49</sup> If bowel preparation is used in the pediatric population, care must be taken to avoid dehydration.

## Drains and Irrigation

The use of drains varies widely. Drains are indicated in those surgical procedures in which one expects an accumulation of blood, serum, exudate from the wound, and potential dead space.<sup>50</sup> Drains also are indicated when closure of a hollow viscous is imperfect. When a drain is used, a closed drainage system brought out through a separate stab incision away from

the operative incision is preferable. Drains should be removed as soon as possible because they are foreign bodies that can impede wound healing and because bacteria can colonize the wound via a drain or its exit site.<sup>51</sup>

Irrigating the operative field is an important component in preventing postoperative infectious complications.<sup>52</sup> Irrigation with copious amounts of sterile saline mechanically removes loose debris, necrotic tissue, serum, and excess clot. Use of various types of irrigation solution have been used such as antibiotic or dilute povidone-iodine solutions.<sup>53,54</sup>

## TYPES OF INFECTION

### Postoperative Surgical Site Infection

Despite meticulous technique, perioperative antibiotics, and the proper use of drains and irrigation, surgical infectious complications still occur. Postoperative soft tissue infections can be divided into confined local lesions and invasive, spreading ones. Early diagnosis and prompt intervention help to avoid morbidity and occasional mortality. Erythema, fever, leukocytosis, tenderness, crepitus, and suppuration are diagnostic signs but are not always present. When confronted with one or more of these signs, clinical judgment must be made. Treatment should be suited to the extent of the infection and may include oral or intravenous antibiotics, simple incision and drainage, or extensive surgical debridement. Fortunately, soft tissue infections are uncommon in the pediatric surgical population, ranging from 2% to 20%.<sup>25,55</sup> The incidence of wound infection depends on the type of operative classification, varying from 1% to 11% in clean wounds and from 6% to 20% in contaminated wounds.

An abscess is a localized collection of pus in a cavity formed by an expanding infectious process. The pus is a combination of leukocytes, necrotic material, bacteria, and extracellular fluid. The usual cause is the staphylococcal species in combination with one or more organisms. The treatment is incision and drainage with packing to allow healing by secondary intention, followed by antibiotic therapy if associated with localized cellulitis or an immunocompromised patient. Drainage must be complete, or the abscess will reform. A phlegmon is an area of diffuse inflammation with little pus and some necrotic tissue. A phlegmon can often be treated with antibiotics, although it can progress to an abscess.

Streptococcal soft tissue infections are probably the most virulent and can arise within a few hours after surgical procedures. High fever, delirium, leukocytosis, and severe pain are hallmarks of the patient's presentation. Penicillin in high doses is the appropriate initial management for streptococcal infections, followed by operative debridement of necrotic tissue. *Bacillus* infections are the next most virulent infections. Inspection of the wound will show dark, mottled areas, as opposed to the bright pink of a streptococcal cellulitis.

Less than half of the patients with *Bacillus* infections have detectable gas crepitation. Severe pain is the most telling clinical symptom of this type of infection. High doses of penicillin (500,000 to 800,000 U/kg/day) are the hallmarks of treatment for these patients.

## Nosocomial Infection

Nosocomial infections are defined as those infections that are hospital acquired.<sup>56</sup> As such, they are a potential threat to all hospitalized patients and increase morbidity and mortality significantly. Their incidence appears to be increasing as surgical care becomes more advanced and patients survive longer from previously fatal conditions. One report describing 676 operative procedures in 608 pediatric patients showed a nosocomial infection rate of 6.2%.<sup>57</sup> Fifty-three infectious complications were tabulated: wound, 17 (2.5%); septicemia, 14 (2.1%); pulmonary, 10 (1.5%); urinary tract, 5 (0.7%); abdominal, 5 (0.7%); and diarrhea, 2 (0.3%). The highest overall occurrence of infection was in the infant group (1 month to 1 year; 13 [8.1%] of 161). The probability of septicemia was highest in neonates (4.2%) compared with infants (3.1%) and older children (1.2%) ( $P < .05$ ). The most common isolates were *Staphylococcus epidermidis* (10 of 17) from septic patients and gram-negative enteric bacteria (27 of 50) from organ and wound infections. Infection was associated with impaired nutrition, multiple disease processes, and multiple operations. In another study, ECMO use correlated with an increased incidence of nosocomial infection.<sup>58</sup> Two other factors that have been found to increase the risk of nosocomial infection in pediatric patients in ICUs are the length of the preoperative stay and exposure to invasive medical devices.<sup>59</sup>

Pneumonia can be a lethal nosocomial infection, with mortality ranging from 20% to 70% and accounting for 10% to 15% of all pediatric hospital-acquired infections.<sup>60</sup> The mortality rate is dependent on the causative organism. The risk factors for nosocomial pneumonia in the pediatric population include serious underlying illness, immunosuppression, length of time on a ventilator, and nasopharyngeal flora changes with prolonged hospitalization.<sup>61</sup> An increased risk has been found in patients with gastric alkalization because the use of antacids in the ICU to prevent stress ulceration increases bacterial counts in the stomach and may potentially predispose the patient to increased bacterial translocation.<sup>62</sup>

*Clostridium difficile* is a well-recognized cause of infectious diarrhea that develops after antibiotic therapy in many patients, although it likely only accounts for 20% of antibiotic-associated diarrhea. It is a very common cause of nosocomial infection, and its incidence is increasing in frequency with associated increasing mortality.<sup>63,64</sup> The best method of prevention is the judicious and appropriate use of antibiotics. Prolonged antibiotic use has an association with increased rates of *C. difficile* colitis. Some studies have suggested the use of probiotics for the prevention and treatment of antibiotic-associated diarrhea.<sup>65,66</sup> The rationale for their use is

that probiotics modify the makeup of colonic microflora. Some of the reports on the efficacy of probiotics in children are conflicting. However, a number of randomized controlled studies have demonstrated only a moderate beneficial effect of some strains of bacteria in preventing antibiotic-associated diarrhea. Until better evidence is available, the best method of prevention is the judicious and appropriate use of antibiotics.<sup>67</sup>

To decrease nosocomial infections in hospitals, the Centers for Medicare and Medicaid Services (CMS) released a proposal in 2008 to expand the list of hospital-acquired conditions (HAC) that would not be reimbursed by Medicare. These have been termed "Never Events" and include surgical site infections after specific elective surgeries, extreme glycemic aberrancies, ventilator-associated pneumonia, and *C. difficile*-associated diseases among others. Under this proposal, CMS will not reimburse hospitals for treatment (medical or surgical treatment) of these nosocomial entities.

## Catheter Infections

Central venous catheters (CVCs) are essential in managing critically ill pediatric patients. The use of CVCs in pediatric patients has increased as prolonged vascular access has become increasingly necessary to provide parenteral nutrition, chemotherapy, antimicrobial therapy, and hemodynamic monitoring to an increasing number of children. However, the complication of catheter-related infection is common, despite considerable effort to reduce its occurrence. It is important to recognize the difference between colonization of the catheter and CVC infection. Colonization is defined as the presence of a positive culture without signs and symptoms of clinical infection. Infection is manifested as erythema at the site of insertion, tachycardia, and/or leukocytosis. Rates of infection are influenced by patient-related factors, by type and severity of illness, and by catheter-related parameters (catheter type, purpose, and conditions under which it was placed).<sup>68</sup> Coagulase-negative staphylococci, followed by enterococci, were the most frequently isolated causes of hospital-acquired bloodstream infections reported from National Nosocomial Infections Surveillance System report.<sup>69</sup> A number of factors are associated with the development of catheter-related infections, including the sterility of the insertion technique, type of solution being administered through the line, care of the catheter once inserted, proximity of the catheter to another wound, and the presence of another infection elsewhere.

The location of the catheter, such as the subclavian, internal jugular, or femoral veins, may be correlated with the risk of infection. Studies in pediatric patients have shown that femoral lines have an equivalent rate of infection to that of non-femoral lines.<sup>68</sup> For catheters that will remain for a long time, tunneling the catheter has been shown to significantly reduce the risk of catheter-related infection.<sup>70,71</sup>

Absolute sterile techniques should be maintained in all instances of line insertion whenever possible.

Emergency situations may necessitate less-than-sterile technique. The use of maximal sterile barriers, including sterile gown and gloves and a large sterile sheet, has been shown in adults to greatly reduce the risk of catheter-related infection.<sup>72,73</sup> Povidone-iodine has long been the standard for cleansing of the skin before catheter insertion. However, recent studies suggest that chlorhexidine significantly reduces the incidence of microbial colonization compared with povidone-iodine.<sup>74</sup>

The skin and catheter hub are the most common sources of colonization and infection. Thus, various methods have been tried to combat these risks. Silver ions have broad antimicrobial activity, and the use of silver-impregnated cuffs have been proposed as a preventive measure.<sup>75,76</sup> In addition, antimicrobial and antiseptic catheters and cuffs may decrease the incidence of catheter-related infections and potentially decrease hospital costs associated with these infections.<sup>77,78</sup> Catheters have been coated with chlorhexidine/silver sulfadiazine as well as minocycline/rifampin along with other agents. The use of these catheters in children is still under investigation but they have been approved by the U.S. Food and Drug Administration for use in patients weighing more than 3 kg. It is likely that these catheters become less effective in reducing infection risks after being in place for longer than 3 weeks because of a decrease in their antimicrobial activity.<sup>78</sup> Of note, no studies in adults have demonstrated a benefit for systemic antibiotic prophylaxis after insertion of a CVC. Studies in high-risk neonates and children have demonstrated conflicting results, although a few studies have found that vancomycin led to a reduction in catheter infections in select patient populations. However, concern exists for the emergence of resistance with the routine use of antimicrobial prophylaxis.<sup>79,80</sup>

## Other Infections Requiring Surgical Care and Treatment

Although the infections discussed previously are possibly preventable and occur after surgical procedures or hospitalization, some infections are seen by the pediatric surgeon for treatment and cure for the first time.

### *Necrotizing Soft Tissue Infection*

Necrotizing fasciitis is a rapidly progressing infection of the fascial tissues and overlying skin. Although it can occur as a postoperative complication or as a primary infection, necrotizing fasciitis is more likely in immunocompromised patients.<sup>81</sup> However, in the pediatric population, necrotizing fasciitis often affects previously healthy children.<sup>82</sup> Because the diagnosis is often not obvious, the clinician must look for clinical clues such as edema beyond the area of erythema, crepitus, skin vesicles, or cellulitis refractory to intravenous antibiotics. Skin necrosis is generally a late sign and is indicative of thrombosis of vessels in the subcutaneous tissue. Pediatric necrotizing fasciitis often occurs in the truncal region, as opposed to the extremities as is most common in adults (Figs. 9-1 and 9-2).<sup>83</sup> Although infections with a single organism often occur in adults with necrotizing fasciitis, polymicrobial infections predominate in children.<sup>84</sup> Prompt surgical intervention, including wide excision of all necrotic and infected tissue, along with the institution of antibiotics including penicillin, is mandatory to avoid progression and mortality. Necrotizing fasciitis can also occur as a complication of chickenpox.<sup>85</sup> Extensive debridement and antibiotic therapy initiated early are necessary to decrease the mortality from this rare complication of varicella lesions.

**Figure 9-1.** This 15-year-old was sick for 2 weeks with perforated appendicitis and presented in shock. After a midline incision for exploration for a rigid abdomen, his appendix was removed. The peritoneal cavity was extensively and copiously irrigated and the abdominal incision was left open. He returned to the operating room 2 days later for evaluation and was found to have necrotizing fasciitis of the rectus abdominis muscles bilaterally. Eventually, despite aggressive surgical debridement, this process spread to the retroperitoneum and down the left inguinal canal through a patent processus vaginalis. One week postoperatively, he was found to have edema and erythema of the left leg that prompted exploration. The necrotizing fasciitis had progressed down all compartments of the left thigh and the lateral compartment of the left lower leg. In the upper thigh, the semimembranosus and semitendinosus muscles had to be excised due to necrotic musculature. These photographs were taken on his ninth postoperative day. In **A**, the abdomen is seen to be open and the medial aspect of the left thigh is visualized. In **B**, the incisions in the left buttock area, the left lateral thigh, and the left lateral lower leg are seen.

**Figure 9-2.** This photomicrograph depicts the histologic findings of necrotizing fasciitis in the patient shown in Figure 9-1. Note the inflammatory infiltrate on both sides of the fascia. The fascial cultures grew *Escherichia coli*.

## Sepsis

Sepsis, by contemporary definition, distinguishes the systemic derangements that are caused by the infectious organisms and their byproducts from those that are caused by the host-systemic inflammatory response. In 1992, the Society of Critical Care Medicine published the results of a consensus conference to define accurately the terms regarding sepsis and the inflammatory response to injury and infection.<sup>86</sup> These definitions were updated in the 2001 Consensus Conference.<sup>87</sup> Although there has been a significant decrease in the mortality rate among children with sepsis, severe sepsis remains one of the leading causes of death in the pediatric population. In 2002, a group of experts gathered to focus specifically on pediatric sepsis.<sup>88</sup> Systemic inflammatory response syndrome (SIRS) has previously been defined in adults as the nonspecific inflammatory process after a variety of insults with sepsis specifically occurring from infection.<sup>89</sup> The main pediatric modifications for the definitions of SIRS and sepsis include the inclusion of temperature or leukocyte abnormalities in addition to tachycardia and tachypnea because these last two indices are common in many pediatric disease processes. Another difference was that hypotension is not necessary for the diagnosis of septic shock but rather cardiovascular dysfunction must be present. SIRS may progress to multiorgan dysfunction and death. Gram-negative organisms possess a lipopolysaccharide moiety on the cell wall that has been shown to incite most, if not all, of the toxic effects of end-organ failure.

Neonatal sepsis is defined as a generalized bacterial infection accompanied by a positive blood culture within the first month of life.<sup>90</sup> Neonatal sepsis occurring during the first week of life is caused primarily by maternal organisms transferred during delivery. Maternal contamination of the neonate can be transmitted through the placenta, via the birth canal, or by direct contamination of the amniotic fluid. The mortality of this early-onset variety approaches 50%. Late-onset neonatal sepsis is primarily nosocomial and is

most often secondary to indwelling catheters or bacterial translocation from the gut. In the surgical neonate, three factors promote bacterial translocation and sepsis: (1) intestinal bacterial colonization and overgrowth, (2) compromised host defenses, and (3) disruption of the mucosal epithelial barrier.<sup>91</sup> The mortality of late-onset sepsis approaches 20%. The clinician must be alert for the subtle signs and symptoms of neonatal sepsis, which include lethargy, irritability, temperature instability, and a change in respiratory or feeding pattern. Neonates may not demonstrate leukocytosis. Empirical triple-antibiotic coverage may be started, pending the results of blood and other cultures.

## Peritonitis

Peritonitis is defined as inflammation of the peritoneum.<sup>92</sup> It is divided into primary, secondary, and tertiary, depending on the cause. Spontaneous primary peritonitis is a bacterial infection without enteric perforation. Primary peritonitis is usually caused by a single organism. An infant with primary peritonitis usually does not exhibit signs of peritonitis but may have poor feeding, lethargy, distention, vomiting, and mild to severe abdominal tenderness. Definitive treatment may require only a course of broad-spectrum antibiotics. Secondary peritonitis is associated with gastrointestinal tract disruption. This can be caused directly by intestinal perforation, bowel-wall necrosis, or trauma or postoperatively as a result of iatrogenic injury or an anastomotic leak. In addition, secondary peritonitis also may result from an indwelling dialysis catheter or ventriculoperitoneal shunt.<sup>93</sup> These infections are generally polymicrobial. Treatment of secondary peritonitis is a combination of surgical intervention, removal of any prosthetic device, and antibiotics. Tertiary peritonitis, also called recurrent peritonitis, is characterized by organ dysfunction and systemic inflammation in association with recurrent infection. The mortality rate is very high, and treatment is very difficult.<sup>94</sup> Treatment consists of broad-spectrum antibiotics because the infection often includes nosocomial organisms and multidrug-resistant bacteria.

## CONCLUSION

Infectious diseases can lead to significant morbidity and mortality for the pediatric surgical patient. Surgical infectious diseases may be encountered both as a complication of surgery post-operatively or as the primary reason for surgical intervention. The immune system has developed as a complex defense mechanism against infections. However, patients are particularly vulnerable to developing certain infections when their immune system is compromised by various immunodeficiencies. Given the substantial morbidity from infectious complications, pediatric surgeons have devoted much attention to the prevention of surgical infectious diseases by implementing measures such as antibiotic prophylaxis before skin incision, scrubbing, and sterile barriers. Early diagnoses and execution of effective treatment for surgical infectious diseases can decrease the morbidity and mortality in the pediatric population.

# FETAL THERAPY

Shinjiro Hirose, MD • Michael R. Harrison, MD

New advances in imaging modalities have allowed clinicians to make early and accurate diagnoses of fetal anomalies. Most of these anomalies are best treated expectantly, with definitive therapy performed after birth. A subset of conditions can be treated by early delivery if the abnormality poses a threat to the fetus and if the fetus has reached a viable gestational age. An even smaller group of patients may have progression of their condition that can be corrected with in-utero treatment. Certain anomalies have been studied for the past 25 years and their natural history has been delineated. This time frame has allowed the development of potential strategies for ameliorating the derangement in pathophysiology associated with the condition. While advances in radiology have led to an earlier diagnosis of these abnormalities, techniques have also been developed to allow fetal intervention. These techniques, including maternal hysterotomy, minimal access fetoscopy, and percutaneous fetal access, were initially tested and validated in animal models. Further validation in humans was stringent because the mother's safety is of utmost importance in fetal surgery. In this chapter, we present an overview of the current state of fetal surgery, review specific fetal problems, and outline current management strategies.

## GENERAL PRINCIPLES

Fetal intervention is complicated by both the risk to the unborn patient and to the mother. The mother has nothing to gain in terms of health benefits from any fetal intervention, yet she is at a significant risk for morbidity and even potential mortality with fetal surgery. To date, there have been no reported maternal deaths from fetal surgery, although significant short-term maternal morbidity is known. Complications can arise from endotracheal intubation, blood transfusion, premature rupture of membranes, chorioamniotic separation, chorioamnionitis, and placental abruption. Therefore, fetal surgery should be considered only if there is a severe, life-threatening or

debilitating anomaly in the fetus that has been thoroughly investigated in animal models and has been shown to be improved by in-utero intervention.

Initial fetal surgical experiments were carried out in a variety of animal models (e.g., rat, rabbit, sheep, and nonhuman primates). These studies showed it was that in utero surgery could be performed safely and it was subsequently attempted in humans. The first open fetal surgical procedure was performed at the University of California, San Francisco (UCSF), and was reported in 1982.<sup>1</sup> Since that report, more than 380 fetal interventions have been performed at UCSF over the past 27 years with no maternal mortality. The primary morbidity after fetal surgery has been, and remains, preterm labor, resulting in premature delivery at 25 to 35 gestational weeks. Notably, in reviewing our experience, subsequent fertility after fetal intervention has been good.<sup>2</sup>

A crucial component contributing to the success of a fetal treatment program is a multidisciplinary approach, utilizing the skills of various specialists working in concert. At UCSF, all fetal referrals are presented at an open weekly meeting involving a multidisciplinary group consisting of perinatologists, anesthesiologists, neonatologists, cardiologists, radiologists, geneticists, and pediatric surgeons. In addition, specific subspecialists are involved for certain cases, such as pediatric neurosurgeons for fetal myelomeningocele (MMC) repair. The weekly discussion not only covers the medical and surgical aspects of the patient's care, but also includes the ethical and social concerns with each case. Finally, a special institutional fetal treatment oversight committee reviews all fetal interventions on a monthly basis. This group serves as a quality control mechanism as well as an ethical review board.

## FETAL ACCESS

There are three general methods for accessing the fetus: (1) percutaneously, with ultrasound guidance; (2) minimally invasive fetoscopy; and (3) open

hysterotomy. In all of these approaches, preoperative and intraoperative ultrasonography is crucial for defining the anomaly or anomalies, delineating the placental anatomy, determining the position of the fetus, detecting the location of the maternal blood vessels, and monitoring the fetal heart rate during the procedure. With percutaneous and fetoscopic procedures, ultrasonography is particularly important owing to the lack of direct exposure to the fetus and uterus during the procedure.

The mother is usually positioned supine with her left side down to minimize compression of her vena cava by the gravid uterus. Maternal anesthesia can be either spinal or general, depending on the nature and duration of the intervention. In addition, fetal anesthesia is needed when operating on the fetus. An intramuscular injection of an opiate and a nondepolarizing neuromuscular blocking agent are usually utilized.

Ultrasound-guided percutaneous procedures are performed through small skin incisions in the mother's skin. During these procedures, real-time ultrasonography is needed because the only visualization of the fetal and maternal anatomy is through these images.<sup>3</sup> Through ultrasound visualization, catheters and shunts can be inserted into the fetus for draining cystic masses, ascites, or pleural fluid into the amniotic space. In addition, radiofrequency ablation (RFA) probes can be deployed into the amniotic space to treat various twin gestational anomalies. The needles used to place these catheters, as well as the RFA device, are 1.5 to 2 mm in diameter, resulting in minimal morbidity to the mother.<sup>4,5</sup>

Fetoscopic procedures are generally performed using a 3-mm fetoscope and instruments or, sometimes, standard 5-mm laparoscopic telescopes and instruments. For many fetoscopic procedures, the 3-mm fetoscope with its 1-mm working channel is sufficient. It is important to identify a "window" in the uterus that is devoid of the placenta to reduce the risk of maternal bleeding, placental abruption, and fetal morbidity. When multiple ports and standard laparoscopic instruments are needed, we prefer a maternal laparotomy and direct uterine closure of the port sites. Occasionally, the amniotic fluid is not clear enough for adequate visualization. In such cases, we perform amniotic fluid exchange, using warmed crystalloid solutions to provide a clear operative view.

Open fetal procedures require general anesthesia and a combination of preoperative indomethacin and inhalational agents with a high mean alveolar concentration to maintain uterine relaxation.<sup>6-8</sup> The maternal incision is low and transverse with a vertical or transverse fascial incision, depending on the exposure needed. Preoperative and intraoperative ultrasonography is again crucial to avoid injury to the placenta. Uterine staplers with absorbable staples have been developed specifically for fetal surgery and allow a hemostatic hysterotomy with minimal blood loss. The fetus is monitored using ultrasonography and continuous pulse oximetry. The uterus is stabilized within the maternal abdomen. It is important to prevent herniation of the uterus, which would

increase the tension on the uterine blood vessels. Also, fetal exposure is limited to the specific body part in question. Most of the fetus is left inside the uterus, and great care is taken not to handle or stretch the umbilical cord because this can cause fetal ischemia from injury or vasospasm. After the fetal procedure is completed, the fetus is returned to the uterus, the amniotic fluid is replaced, and the uterus is closed in multiple layers using absorbable sutures. Postoperatively, the mother and fetus are monitored continuously for uterine contractions and heart rate, respectively. Often, the uterus is irritable and contractions require control with tocolytic regimens. Also, open fetal surgery requires lifelong cesarean section for future pregnancies owing to the potential for uterine rupture with subsequent births.

Complications can occur after all types of fetal intervention. Bleeding can originate from the fetus, the placenta, the uterine wall, or the maternal abdominal wall. The uterine vessels are identified with ultrasonography and specifically avoided to prevent injury and minimize bleeding. Premature rupture of membranes and preterm labor remain problems after fetal surgery and are often the result of inadequate membrane closure, chorioamnionitis, chorioamniotic separation, and uterine contractions.

## ANOMALIES AMENABLE TO FETAL SURGERY

### Congenital Diaphragmatic Hernia

Despite significant advances in neonatal respiratory support, survival for children born with congenital diaphragmatic hernia (CDH) remains only 60% to 70% throughout the United States. Additionally, survival for all fetuses diagnosed with CDH may be as low as 20% to 27% owing to in-utero demise or death of infants with unrecognized CDH.<sup>9-11</sup> We have studied fetal lung development extensively and theorized that in-utero intervention may allow increased antenatal lung growth, pulmonary function, and survival postnatally.<sup>12,13</sup> In a fetal lamb model, compression of the lungs during the last trimester, either with an intrathoracic balloon or by creation of a diaphragmatic hernia, results in fatal pulmonary hypoplasia. In addition, removal of the compressing lesion allows the lung to grow and develop sufficiently to permit survival at birth.<sup>14</sup>

Initial attempts at fetal surgery for CDH involved in utero diaphragmatic hernia repair. Analysis of this initial group of patients revealed that open fetal surgery for CDH was feasible but did not show a survival advantage.<sup>15</sup> Fetuses with severe lung hypoplasia continue to have a poor prognosis and are identifiable prenatally by ultrasonography and magnetic resonance imaging. The factors associated with a poor outcome that can be assessed prenatally by ultrasonography are the presence of liver herniation into the chest and a low lung-to-head ratio (LHR). In our experience, survival has been 100% in fetuses with CDH without liver herniation on prenatal ultrasonography and 56% in fetuses with CDH and liver herniation into the chest.

The LHR is calculated as the area of the contralateral lung at the level of the cardiac atria divided by the head circumference. This value has been shown to correlate with survival: 100% survival with an LHR greater than 1.35, 61% survival with an LHR between 0.6 and 1.35, and 0% survival with an LHR less than 0.6.<sup>16</sup> Ultrasonography is critical in identifying other anomalies associated with CDH, particularly cardiac anomalies, because those portend an extremely poor prognosis. Magnetic resonance volumetric imaging of the lung for CDH is a promising modality for prognostic purposes.<sup>17</sup>

Over the past 20 years, we have been able to stratify the risk for fetuses with CDH. Over this same time period, extensive animal studies and observation in human fetuses born with congenital high airway obstruction have shown that lung growth may be driven by tracheal obstruction or occlusion, leading to pressurized fluid accumulating in the airway.<sup>18-20</sup> These reports led to the hypothesis that lung growth, resulting from the tracheal occlusion, may reduce the postnatal sequelae of CDH. Thus, our group has focused on in-utero tracheal occlusion as a method of augmenting lung growth in fetuses with CDH. Our preliminary efforts looked at the effect of in-utero extrinsic tracheal occlusion by placing an obstructing clip across the trachea using both an open and fetoscopic approach.<sup>21</sup> In a small number of patients, we found that survival was increased in the fetoscopic, but not the open, group, as compared with the control group, which consisted of patients undergoing standard postnatal care. This led to a National Institutes of Health (NIH)-funded trial comparing in-utero fetoscopic tracheal occlusion with standard postnatal care for fetuses diagnosed with severe left-sided CDH and no other detectable anomalies. Results of the trial showed a 75% overall survival with no difference between the tracheal occlusion group and the standard postnatal care group.<sup>22</sup> Interestingly and unexpectedly, the survival in the postnatal care group was considerably greater when compared with historical controls. Although this study did not demonstrate a difference in survival between the prenatal intervention group and the postnatal group, the results of this trial demonstrate the tremendous importance of proper randomized controlled trials for novel fetal surgical procedures.

Tracheal occlusion techniques have progressed from tracheal clipping to percutaneous, fetoscopic placement of a detachable, intratracheal balloon (Fig. 10-1). Animal studies have demonstrated complete tracheal occlusion with this approach, and it has now become the current method of choice for fetal tracheal occlusion in human fetuses.<sup>23</sup> Further data regarding tracheal occlusion have suggested that temporary, short-term reversible tracheal occlusion may be preferable to a longer duration of occlusion. Animal models of tracheal occlusion have demonstrated that long-term tracheal occlusion can be deleterious to type II pneumocytes (the cells that secrete surfactant) and that this effect is not seen with a shorter duration of tracheal occlusion.<sup>24</sup> Other studies have also demonstrated the

**Figure 10-1.** This schematic diagram shows the method of fetoscopic tracheal occlusion. A fetoscope is placed into the fetal mouth, the airway is identified, and a balloon is inserted into the trachea by using both fetoscopic and ultrasonographic visualization.

efficacy of short-term, reversible tracheal occlusion on lung growth in animals. A recent report demonstrated improved lung volumes after temporary balloon tracheal occlusion in human fetuses.<sup>25</sup> In 36 of 40 patients, the tracheal balloon was removed prenatally, limiting the duration of occlusion. In this group of patients, improved lung growth was associated with improved postnatal survival. Although reversal of the tracheal occlusion requires a second maternal and fetal intervention for the removal of the fetal intratracheal balloon, it obviates the need for an ex-utero intrapartum treatment (EXIT) approach at birth.<sup>26,27</sup> The EXIT procedure was initially developed to reverse the tracheal occlusion in this cohort of patients (Fig. 10-2). Therefore, with in-utero removal of the tracheal balloon, the EXIT procedure is no longer needed.

Based on these data, as part of a U.S. Food and Drug Administration (FDA)-sponsored trial, our group is currently offering reversible, fetal tracheal occlusion for fetuses with liver herniation in the chest and an LHR of less than 1.0, because these infants, as a group, continue to have greater than a 60% mortality.<sup>28</sup> In this study, we occlude the trachea at between 24 and 26 weeks' gestation and remove the balloon at between 32 and 34 weeks' gestation.

## Tumors

Fortunately, fetal tumors are rare. When they do occur, most are benign. However, when they become large enough to impede the venous return to the heart or create high-output heart failure via arteriovenous shunts, they can cause nonimmune hydrops in the fetus. Hydropic changes include polyhydramnios, placentalomegaly, fetal skin and scalp edema, and pleural, pericardial, and peritoneal fluid accumulation. If left untreated, fetal hydrops is nearly always fatal.<sup>29,30</sup> The two most common prenatally diagnosed tumors that cause nonimmune hydrops are congenital pulmonary

**Figure 10-2.** The EXIT procedure was initially developed as a means to reverse the in-utero tracheal occlusion in infants with a significant congenital diaphragmatic hernia. In the photograph, this infant is undergoing bronchoscopy as an EXIT procedure to remove the intratracheal balloon.

airway malformations (CPAMs) and sacrococcygeal teratoma (SCT).

### **Congenital Pulmonary Airway Malformations**

CPAMs are pulmonary lesions with a broad range of clinical presentations. This new terminology includes congenital cystic adenomatoid malformations (CCAMs) and pulmonary sequestrations. CCAMs are much more likely than sequestrations to cause non-immune hydrops in the fetus. CCAMs are characterized by an overgrowth of respiratory bronchioles with the formation of cysts of various sizes. Classification of CCAMs has historically been based on the size of the cysts.<sup>31-34</sup> Most fetuses diagnosed with a CCAM in utero develop normally and can be monitored with serial ultrasound studies. These asymptomatic patients can then undergo standard, postnatal resection. A small percentage of patients with the prenatal diagnosis of CCAM will develop nonimmune hydrops.<sup>33,34</sup> Various measurements have been developed to predict which fetuses are at risk for developing hydrops. The most accepted measurement is the CCAM volume ratio (CVR), defined as the product of the three longest cyst measurements on ultrasonography, multiplied by the constant 0.52, and then divided by the head circumference. In a recent paper, Crombleholme and colleagues identified a CVR of 1.6 as a cutoff for an increased likelihood of developing hydrops.<sup>35</sup>

Interestingly, CCAMs that are predominantly microcystic have a more predictable course than those that are macrocystic. Microcystic CCAMs undergo steady growth and tend to plateau at 26 to 28 weeks' gestation. In contrast, macrocystic CCAMs can have abrupt enlargements in size owing to rapid fluid accumulation in a large cyst. For these reasons, patients with microcystic CCAMs can be followed closely up to 26 to 28 weeks' gestation. At that point,

the interval between ultrasound examinations can be lengthened. On the other hand, macrocystic CCAMs require close follow-up throughout the duration of the pregnancy.<sup>32,36</sup>

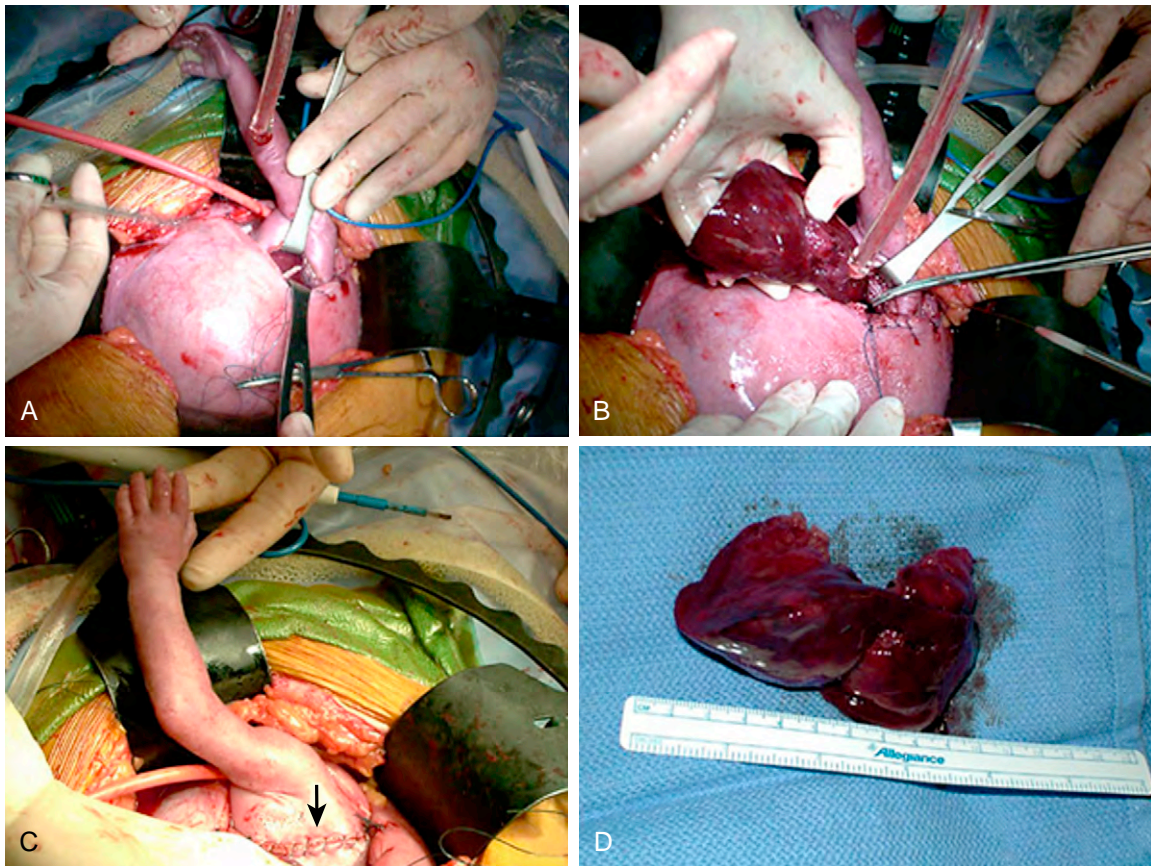

Once the fetus with hydrops reaches a viable gestational age, early delivery should be considered. In fetuses who are not yet viable outside the uterus and have one dominant macrocystic lesion, a thoracoamniotic shunt may reverse the hydrops fetalis.<sup>37</sup> Needle drainage has not proved to be an effective option because rapid reaccumulation of fluid occurs. Fetal thoracotomy with CCAM resection is an option in the pre-viable fetus with a microcystic CCAM or one without the presence of a dominant cyst. The fetal thoracic space is exposed through a fifth intercostal space thoracotomy after maternal hysterotomy (Fig. 10-3). The lobe containing the CCAM is identified and exteriorized through the incision. The pulmonary hilar structures are then mass ligated using an endoloop or endoscopic stapler. The thoracotomy is closed in layers.<sup>38,39</sup>

The experience with CCAM at UCSF and the Children's Hospital of Philadelphia has been published.<sup>40</sup> One hundred and thirty-four women pregnant with fetuses with CCAM were evaluated. Of this group, 120 elected to continue their pregnancies. Seventy-nine fetuses had no evidence of hydrops. Of these, 76 were followed and all survived. Three fetuses without evidence of hydrops and with large dominant cysts underwent thoracoamniotic shunt placement. All three fetuses survived. Twenty-five hydropic fetuses were followed with no intervention. All mothers delivered prematurely, and all fetuses died perinatally. Sixteen fetuses with hydrops underwent intervention: 13 underwent open fetal surgery while 3 underwent thoracoamniotic shunt placement. Two of the 3 survived in the group that underwent shunt placement, and 8 of 13 survived in the open fetal surgery group.

Recently, it has been shown that fetuses with large CCAMs and hydrops can be treated with maternal corticosteroids. This finding was discovered serendipitously at UCSF during the preparation of several hydropic fetuses for fetal surgery.<sup>41</sup> In these cases, maternal corticosteroids were administered to enhance fetal lung maturity. Subsequent ultrasound surveys showed resolution of the hydrops. These findings were later identified in similar patients at Children's Hospital of Philadelphia.<sup>42</sup> A multicenter, prospective trial is now underway to investigate the role of corticosteroids in the treatment and management of hydrops in fetuses with a large fetal CCAM.

### **Sacrococcygeal Teratoma**

Sacrococcygeal teratoma is a rare tumor that is being diagnosed with increasing frequency in utero, allowing for observation of the prenatal natural history of the disease and appropriate perinatal management. As with CCAM, fetuses with SCT are susceptible to in-utero demise. SCTs can grow to a tremendous size in relation to the fetus and can cause high-output cardiac

**Figure 10-3.** These photographs depict an infant with a large left upper lobe CCAM undergoing in-utero left lobectomy. **A,** The infant's left arm is visualized. Note the maternal hysterotomy and the left fetal thoracotomy (with retractors inserted) through the fifth intercostal space. **B,** The left upper lobe containing the CCAM has been identified and exteriorized through the thoracotomy incision. The pulmonary hilar structures were mass ligated using an endoloop. **C,** The fetal thoracotomy incision (arrow) has been closed. **D,** The left upper lobe specimen containing the CCAM is seen.

failure and nonimmune hydrops through vascular shunting. Rarely, tumors can hemorrhage internally or externally, resulting in fetal anemia and hypovolemia. Other potential problems with a fetus with a large SCT are dystocia and preterm labor. Delivery can be particularly difficult when the diagnosis has not been made prenatally. A traumatic delivery may result in hemorrhage or tumor rupture. Most clinicians favor cesarean delivery for fetuses with large SCTs. Thus, prenatal diagnosis and careful obstetric planning are critical in the appropriate management of such fetuses.

We have reported our initial experience with 17 fetuses and mothers with a prenatally diagnosed SCT.<sup>43</sup> Of the 17 fetuses, 12 developed hydrops. All 5 of the nonhydropic fetuses were delivered near term and survived. Of the 12 hydropic fetuses, 7 underwent fetal intervention with 3 survivors. Five hydropic fetuses were followed without fetal intervention, and none in this group survived. Other groups have also found an exceedingly high rate of fetal demise in fetuses with an SCT and hydrops. The group at Children's Hospital of Philadelphia recently published their experience with 30 fetuses with SCT.<sup>44</sup> There were 14 survivors, and four pregnancies were terminated. Fifteen fetuses had

solid tumors. Of those, 4 developed signs of hydrops and underwent fetal debulking operations. Three of the 4 survived.

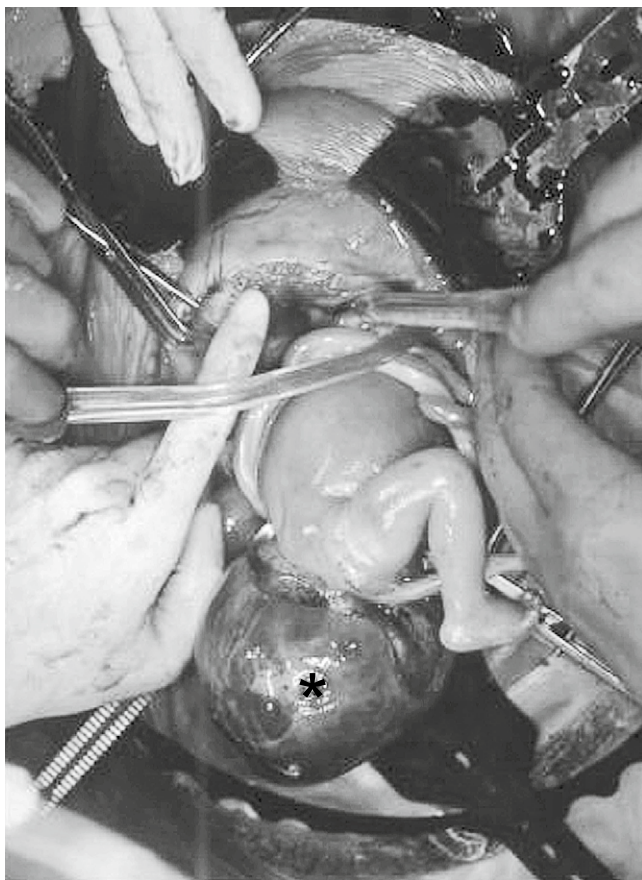

The most common approach for fetal intervention for an SCT is a maternal hysterotomy with resection or debulking of the tumor (Fig. 10-4). A predominantly cystic lesion may be amenable to percutaneous drainage or placement of a shunt. Also, tumor debulking using percutaneous coagulation techniques, such as with RFA or laser coagulation to decrease the vascular shunt, are minimally invasive alternatives to open resection that warrant further investigation.<sup>30,45</sup>

## Abnormalities of Twin Gestations

### *Twin-Twin Transfusion Syndrome*

Twin-twin transfusion syndrome (TTTS) is the most common complication (10%) of monochorionic twin pregnancies.<sup>46</sup> In monochorionic twin pregnancies, the two fetuses share one placenta and there are normal vascular connections between the fetuses. TTTS occurs when there is net flow from one twin to the other. As a result of the transfusion of blood from the donor twin to the recipient twin, hemodynamic

**Figure 10-4.** The sacrococcygeal teratoma (asterisk) was exposed after maternal laparotomy and excised in standard fashion.

compromise can occur in either, or both, twins. The donor twin suffers from a low flow state with resulting ischemia to the brain and kidneys. Conversely, the recipient twin has fluid overload and may develop congestive heart failure and hydrops. The hallmark of TTTS is oligohydramnios in the donor twin and polyhydramnios in the recipient. In addition, often there is a size discordance between the twins, with the donor being smaller than the recipient. Advanced disease is evidenced by progressive discordance in fluid volumes, with the donor becoming “stuck” in the amniotic sac owing to a lack of amniotic fluid. Moreover, worsening cardiac changes in the recipient twin portend a grave prognosis. If left untreated, TTTS carries an 80% to 90% mortality for both twins. In addition, in monochorionic twins, if one twin dies, the other is at risk for neurologic injury owing to a sump phenomenon in the placenta and demised fetus, and also for embolism.<sup>47-49</sup>

Clinicians have attempted a variety of treatments aimed at achieving improved outcome in one or both twins. The most commonly used approach is high-volume amnioreduction of the fluid in the polyhydramniotic sac. Because polyhydramnios may incite labor, the initial aim of amnioreduction is to reduce uterine volume to decrease the risk of preterm labor. In the International Amnioreduction Registry, high-volume

amnioreduction has resulted in a survival rate of almost 60%.<sup>50</sup>

Several groups have used fetoscopic guidance to laser ablate the intertwin vascular connections. This can be done either nonselectively by ablating all intertwin connections or selectively by ablating only arteriovenous connections with flow in the causative direction. Fetoscopic laser ablation can be performed either percutaneously (using 1- or 2-mm endoscopes) or by maternal laparotomy (with 3- or 5-mm endoscopes). If the larger scopes are used, a maternal laparotomy is favored to close the uterine defect created by insertion of these larger ports. The telescopes are introduced through cannulas that have side channels for irrigation and for insertion of a laser. Recently, two large prospective trials have been published comparing amnioreduction to laser ablation of intertwin vessels.<sup>51,52</sup> The European trial enrolled 70 women in the amnioreduction arm and 72 women in the laser ablation arm. The trial was stopped early after interim analysis showed a clear survival advantage to laser therapy: 76% vs. 51% single survivor and 36% vs. 26% for dual survivors.<sup>51</sup> The North American trial also was stopped early after randomizing 42 mothers: 20 in the amnioreduction arm and 22 in the laser ablation one.<sup>52</sup> There was no survival benefit to either intervention, but the study was underpowered due to the early termination of the trial. This trial was complicated by the reluctance of referring physicians to send their patients to the various centers for randomization.

### *Twin Reversed Arterial Perfusion*

Twin reversed arterial perfusion sequence (TRAP) is a rare disease of monochorionic twins that occurs when one normal twin acts as a “pump” for an acardiac, acephalic twin. The normal twin is put at risk for high-output heart failure and hydrops because of the need to maintain blood flow throughout the entire placenta as well as to the acardiac twin. The vascular flow in the acardiac twin is characteristically reversed. Thus, the acronym TRAP was coined to describe this anomaly. The natural history of TRAP is greater than a 50% mortality in the pump twin due to hydrops.<sup>53,54</sup> The risk of hydrops increases as the mass of the acardiac twin increases relative to the normal twin. Generally, intervention is needed when there is evidence of hydrops in the pump twin or when the estimated fetal weight of the acardiac twin is 50% or more relative to the twin functioning as the pump.

Multiple techniques have been used to separate the vascular connections in TRAP pregnancies. These include open hysterotomy and delivery, fetoscopic ligation, bipolar cautery, harmonic scalpel division, thermal coagulation, and laser coagulation. At UCSF, RFA is used to coagulate the umbilical cord insertion site on the acardiac twin’s abdomen.<sup>55-57</sup> RFA was originally designed for ablation of solid tumors, but its small size and effective coagulation has been ideal for this application.<sup>58</sup> We have published our results with RFA for TRAP in 29 patients who underwent RFA between

18 and 24 weeks' gestation.<sup>5</sup> Survival was 86% percent overall, with 92% survival in monochorionic, diamniotic pregnancies.

## Myelomeningocele

Myelomeningocele, or spina bifida, is characterized by an open neural tube and exposed spinal canal elements. MMC can occur anywhere along the spine, but most commonly occurs in the lumbar or cervical vertebral levels. Complications include neurologic deficits with motor and somatosensory abnormalities that correspond to the level of the spinal defect. In addition, autonomic function is also commonly deranged with an inability to control bladder or bowel function. Also, nearly all patients with MMC develop the Arnold-Chiari type II malformation of the hindbrain, and most will require ventriculoperitoneal shunting for hydrocephalus. Unlike patients who have been considered for fetal intervention, fetuses with MMC are generally born alive and healthy. However, the attendant morbidity from the neurologic abnormalities is severe, as up to 30% of patients die before reaching adulthood owing to respiratory, urinary, or central nervous system complications. Standard current therapy for MMC is postnatal repair of the spinal defect and extensive rehabilitation.<sup>59</sup>

The rationale for fetal intervention in MMC is the "two-hit" hypothesis, in which the first hit is the original neural tube defect that results in an open spinal canal. The second hit is postulated to be due to direct trauma to the exposed neural elements while the fetus is in utero.<sup>60,61</sup> It is this second hit that could potentially be ameliorated by fetal intervention.<sup>62</sup> Various animal models for fetal MMC have been created in rats, lambs, rabbits, and nonhuman primates to test this hypothesis. The data from these animal studies showed improved distal neurologic function, as well as correction of the Arnold-Chiari type II malformation, after in utero repair.<sup>61,63</sup>

Based on these animal data, two pilot studies in human fetuses have utilized MMC repair via an open hysterotomy (Fig. 10-5) and fetoscopy, with primary repair or skin allografts.<sup>64-67</sup> Preliminary results did not show improvement in lower extremity neurologic function, but did show improvement in the Arnold-Chiari type II malformation with reduced hindbrain herniation.<sup>68-70</sup> In addition, a possible decrease in the need for ventriculoperitoneal shunting was found when compared with historical controls.

MMC is unique in that it is the first nonlethal anomaly for which fetal surgery has been undertaken. However, it is associated with significant morbidity. Refinement in operative technique has minimized as much as possible the risk to the mother during these open fetal operations. Based on these data, the NIH has sponsored a prospective, multicenter, randomized controlled trial to investigate the efficacy of fetal surgery for MMC.<sup>71</sup> The results from this trial should be known in the near future.

**Figure 10-5.** The myelomeningocele is exposed after maternal hysterectomy. The defect is closed by pediatric neurosurgeons using an operating microscope.

## STEM CELLS AND GENE THERAPY

Gene therapy for prenatally identifiable diseases is being actively pursued for specific disorders. However, it is currently experimental. The rationale behind in-utero therapy with stem cells and/or virally directed genes includes avoiding the progression of disease in the fetus during gestation, as well as taking advantage of the developing immune system of the fetus, thus potentially negating postnatal problems of tolerance, rejection, and graft-versus-host disease.<sup>72</sup>

Specific issues for in-utero treatment of genetic diseases include the timing of diagnosis and therapy, how to deliver the stem cells or genes, the sources of the stem cells, and the longevity of treatment. With the advent of chorionic villus sampling, genetic diseases can now be identified in the first trimester. Timing of potential treatments is crucial to take advantage of the possible "pre-immune" status of the fetus, making fetuses potentially more receptive to exogenous genes or cells. Several investigators have utilized hematopoietic stem cells as a vector in an attempt to induce chimerism to treat the diseases.<sup>73-75</sup> Others have investigated the use of retroviral vectors to insert genetic material into the fetus.<sup>76,77</sup> This approach reduces the problem of obtaining the large numbers of stem cells needed to create even a modest amount of chimerism. Other approaches include using maternal stem cells or genetic material because studies have demonstrated early cross-trafficking of maternal cells in the fetus. Diseases that are a candidate for this approach include hematologic, immunologic, metabolic, and neurologic abnormalities (Table 10-1). To date, there have been over 30 reports of in-utero therapy with hematopoietic stem cells. However, the only durable treatment has been in patients with preexisting immunologic defects.<sup>78,79</sup> Currently, in-utero gene therapy and stem cell therapy are in their infancy but remain an active topic of research and investigation.

**Table 10-1** Diseases for Which In Utero Stem Cell or Gene Therapy May Be Applicable**Hematologic**

 Leigh disease

**SUMMARY**

Fetal surgery has progressed from an investigational therapy to an accepted mode of therapy for selected fetal diseases. Multidisciplinary teams are critical for the success of any fetal treatment program. Regular, weekly meetings are necessary to keep all members of the team abreast of developments and new patients. Some diseases that historically have had a high perinatal mortality rate have shown improved survival with fetal surgery. NIH-funded, prospective trials have been performed for CDH and TTTS. Current clinical trials include evaluations for the efficacy of fetal intervention for MMC, hydrops, and CCAM, and reversible tracheal occlusion for CDH. In order to maximize the benefit to the fetus while minimizing the risk to the mother, fetal interventions were initially reserved for fetuses with lethal anomalies. MMC represents the first nonlethal anomaly that has been evaluated.

As minimal access techniques improve, and the maternal risks are further reduced, indications for fetal intervention may continue to broaden. New areas of investigation include tissue engineering, and stem cell and gene therapy. Maternal safety must remain paramount, and the risk to the mother should be minimized at all times. The study of these emerging techniques should occur initially with animal models and then in humans under the rubric of prospective, clinical trials.

## FOREIGN BODIES

Joseph L. Lelli Jr., MD

Infants and young children are naturally curious about their environment. It is this childhood inclination for exploration that results in the serious problems of aspiration, insertion, and ingestion of foreign bodies (FBs). The complications of FBs in the upper and lower airway, the gastrointestinal tract, and the ears carry a significant morbidity and mortality.

FB aspiration has been the cause of 160 annual deaths in children younger than the age of 14 years in the United States.<sup>1</sup> In 2007, the Annual Report of the American Association of Poison Control Centers noted 127,777 cases of ingestion of an FB by a minor. More than 70% of these cases (95,754) involved a child younger than age 6 years.<sup>2</sup> The Centers for Disease Control and Prevention (CDC) reported an estimated 15,653 children, 14 years of age or younger, who were treated in emergency departments in 2007 for choking-related episodes.<sup>3</sup> Although many of these events are benign, significant complications arise from FB entrapment, including but not limited to infection, obstruction, corrosion, fistula formation, hemorrhage, and nerve injury. FBs may be a secondary sign of underlying disorders such as pica, otalgia, rhinitis, neurologic dysfunction, and even child abuse. Despite significant advances in prevention, first aid, and intervention, FBs in the pediatric patient will remain a problem as long as children remain naturally curious.

Other factors contribute to ingestion and aspiration of FBs besides age. Contributing factors include the male gender, immature coordination of swallowing, lack of molars before age 4 years, neurologic impairment, seizure disorders, anatomic or functional esophageal disorders, immature laryngeal sphincter control, and an unsafe environment.<sup>4,5</sup> Children who are neglected or abused have been found to have an increased risk for FB indigestion or aspiration. The suspicion of child abuse should be raised if a very young child has a history of multiple previous episodes or is found to have multiple FBs on evaluation.<sup>6,7</sup>

Prior to 1930, the mortality rate associated with FBs was 24%. Owing in large part to the work of Chevalier Jackson,<sup>8</sup> the mortality rate was reduced to 2%. Jackson has been credited with the development of appropriate preparation of the patient and optimal

positioning, as well as the equipment that made endoscopic removal of the FBs safe and successful.<sup>9</sup> In 1968, Harold Hopkins made the next significant evolution in endoscopy.<sup>10,11</sup> The Hopkins rod-lens telescope was added to the endoscope, bringing vastly improved illumination and visualization. As extraction devices evolved, the visualization during removal improved. Also, the incidence of complications began to decrease.<sup>12</sup>

Food items compose 50% to 80% of FBs removed by endoscopy from children's aerodigestive tracts.<sup>13-16</sup> In the 2007 CDC annual report, 60% of choking episodes treated in emergency departments were due to food substances, with 30% due to a nonfood substance.<sup>3</sup> Sixty-five percent of food-based choking episodes were due to candy or gum. The list of foods causing choking injury was similar in many published reports: hot dogs, nuts, seeds, and vegetable or fruit pieces.<sup>14-17</sup> Coins account for a significant portion of nonfood substances causing choking events in children.<sup>1,16,18,19</sup> Sixty-eight percent of the deaths in children younger than age 14 years reported to the Consumer Product and Safety Commission (CPSC) between 1972 and 1992 were due to nonfood items.<sup>16</sup> The cause of fatal choking was often balloons, balls, and other toys intended for children's use. The remaining 32% of causes of fatal choking episodes were household items. Two deaths in the CPSC database were due to choking on latex examination gloves given to children in clinicians' offices. The majority of choking deaths occurred in children 3 years of age and older with balloons and other conforming objects.<sup>16</sup>

The diagnosis of an FB in the aerodigestive tract may be challenging because of the difficulty in obtaining a reliable history from the child. The timely recognition of aspiration or ingestion relies heavily on clinical suspicion. Symptoms are mild or even absent in 40% to 60% of patients. Eighty percent of the asymptomatic patients have normal findings on physical examination. Twenty to 25 percent of FB events are not witnessed.<sup>18,20,21</sup> In one report, 15% of children evaluated by an emergency medicine physician for choking were not recognized as FB victims.<sup>21</sup> FBs persisted undetected in these children for 7 or more days, not

suspected by caretakers, parents, or the physician. The clinician has a limited amount of data available when evaluating these patients. Therefore, a high index of suspicion for FB ingestion and aspiration must always be maintained.

## AIRWAY FOREIGN BODIES

Approximately 75% of FB aspiration events in the pediatric age group occur in children younger than age 3 years. Boys are affected twice as frequently as girls. There are a number of factors that make young children more susceptible to aspiration. Children younger than age 3 years often cry, shout, and run with objects in their mouths and have immature coordination of swallowing and airway protection. They are also at an oral exploration stage of development when everything they hold tends to go into their mouths. These factors combine to make the child younger than age 3 years susceptible to FB aspiration (Table 11-1).

Most FBs are small enough to pass through the larynx and enter the trachea. The narrowest point in the child's airway is the cricoid ring. The 1% to 7% of airway FBs that become lodged in the laryngeal inlet are mostly seen in infants younger than 1 year of age (Fig. 11-1). Because the trachea is relatively large compared with the cricoid, FBs that lodge within it account for only an additional 3% to 12% of cases. These usually occur in cases of tracheomalacia, in the patient who has poor respiratory effort, or when previous postoperative stricture has occurred. In the majority of cases, the FB will pass easily through the trachea and lodge in the primary or secondary bronchi. A predominance of right bronchial involvement is somewhat dependent on age (Fig. 11-2). The prevalence for right-sided FBs is due to the greater diameter of the right bronchus, a smaller angle of divergence from the tracheal axis, greater air flow to the right lung, and the position of the carina to the left of the midline. In one anatomic study, the position of the carina was believed to be the only determining factor in the distribution of the FB.<sup>22</sup> The angle of the left bronchus and, therefore, the position of the carina is determined by the development of the aortic knob. The aortic knob reaches adult size by the age of 15 years, at which time it displaces the left main-stem bronchus downward. This creates a more obtuse angle at the carina, changing the more symmetric bronchial angles in young children. This may explain the increased propensity for right bronchus

**Table 11-1** Factors that Make Young Children Susceptible to Aspiration

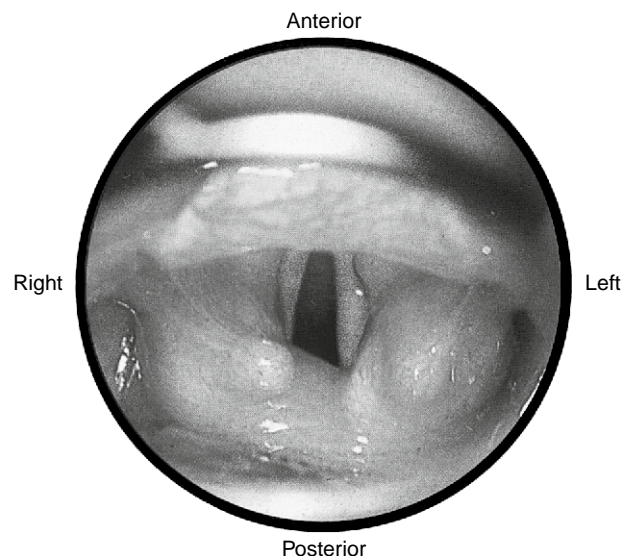

Age younger than 3 years
Male gender
Often cry, shout, run, and play with objects in their mouths
Do not have molars to chew certain foods adequately
Immature coordination of swallowing and airway protection
Oral exploration of their environment
Immature laryngeal sphincter control

FBs in young children compared with those in older children and adults.

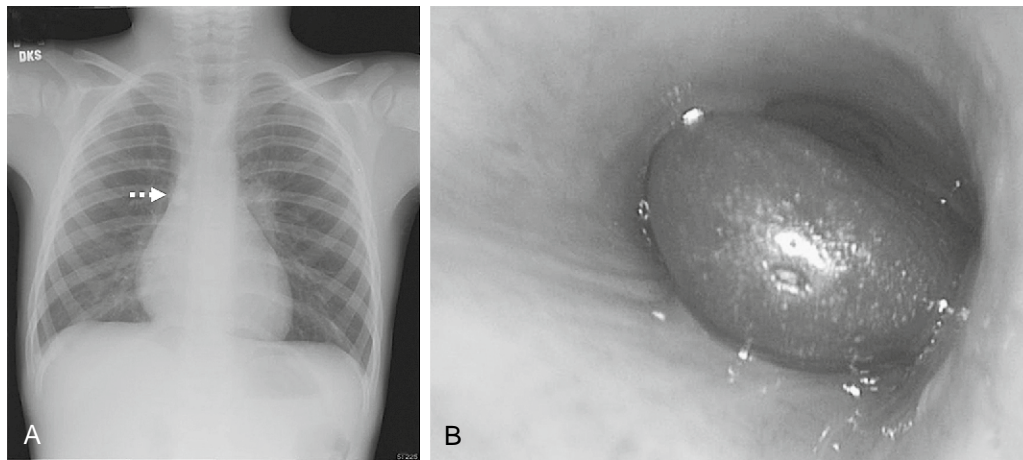

The type of airway FB varies from generation to generation and country to country. For instance, in the United States, as diapers became disposable, the incidence of aspirated safety pins declined dramatically. Fifty years ago, a safety pin, usually opened, was an extremely common FB, but now it accounts for less than 5% in most reports. Small plastic products are now significant items in childhood FB aspiration. The CPSC mandates federal choking prevention standards. The standards use a small parts cylinder to determine if the small part on a toy is a choking hazard. When reviewing airway injuries and fatalities from FBs, 23% of fatalities were from toys with small parts that met the CPSC guidelines for size and 90% of all FBs found in the airway met the standard for being considered "safe." Nevertheless, food matter is still the most commonly aspirated FB for all generations and nations (Table 11-2).

The most important factor in evaluating a child who possibly aspirated an FB is an accurate history. The common signs and symptoms will be present in 50% to 90% of children who aspirate an FB. In a series of 100 FB aspiration cases, a choking crisis occurred in 95% and was the most sensitive clinical parameter.<sup>23</sup> FBs that lodge in the larynx and trachea can be completely obstructive, causing sudden death. Partial obstruction by an FB can lead to a sufficient inflammatory reaction in the surrounding tissue to produce total, or near total, obstruction. A history of choking without initial physical findings of reduced air exchange requires a high degree of suspicion if a timely diagnosis is to be made.<sup>24</sup> The larynx, trachea, and bronchi can initially accommodate FBs with minimal physical findings. This may account for the fact that 20% to 50% of FBs are detected more than 1 week after aspiration.<sup>25</sup>

The complications that develop as a result of aspiration are obstruction due to granulation tissue formation

**Figure 11-1.** In this young infant, a coin became lodged anteriorly between the tongue and epiglottis in the vallecula.

**Figure 11-2.** This 6-year-old had a rock in his mouth, tripped, and aspirated the rock. **A**, On the chest radiograph, it is lodged in the right main-stem bronchus (arrow). **B**, The rock is seen at bronchoscopy. It was difficult to remove this rock because it was quite large, but it was able to be wedged between a Fogarty catheter and the bronchoscope and retrieved in this manner.

Table 11-2 Commonly Aspirated Foreign Bodies	
Food Products	Nonfood Products
Candy/gum	Coins
Peanuts and other nuts	Toy parts
Seeds	Crayons

Meat matter	Screws
Fish bones	

or strictures, atelectasis, bronchiectasis, pneumonia, empyema, lung abscess, perforation with pneumothorax, and systemic sepsis. Clinical findings that develop in a previously asymptomatic patient include croup, persistent cough, hemoptysis, fever, malaise, and respiratory compromise.<sup>21,25,26</sup> Because an unwitnessed choking event may not produce initial symptoms or physical findings, radiographic evaluation is essential for timely diagnosis and treatment.

Radiographic examination consists of anteroposterior and lateral views of the extended neck and chest. Chest radiographs in inspiration and expiration are beneficial in demonstrating unilateral air trapping that is present in up to 62% of patients when the bronchial FB acts as a one-way valve.<sup>27</sup> Air moves past the FB as the bronchus expands during inhalation, but the air is trapped, producing obstructive emphysema. Hyperinflation of the obstructed lobe or lung produces mediastinal shift to the contralateral or unobstructed side. For evaluation in the young patient who cannot cooperate with inspiration and expiration radiographs, left and right lateral decubitus radiographs may be helpful because the obstructed lung will not deflate while in the dependent position (Fig. 11-3). Although 56% of patients will have a normal chest radiograph within 24 hours of aspiration, others will demonstrate

mediastinal shift (55%), consolidation (47%), pneumonia (26%), atelectasis (18%), or a radiopaque object (3%).<sup>28</sup> FBs that are present for a long time will develop complete obstruction and atelectasis secondary to a local inflammatory reaction.

A radiolucent FB is often evident only because of the ball-valve effect. The benefit of the radiographic assessment is dependent on the location of the FB. Laryngotracheal FBs can be evaluated radiographically with about a 90% yield. In cases of bronchial FBs, chest radiography is less diagnostic, with a sensitivity and specificity of 65% to 75%.<sup>14,26-29</sup> Radiographic evaluation is helpful in evaluating the patient with a choking history, but the definitive diagnostic assessment remains bronchoscopy.

General anesthesia provides a controlled environment for removal of most airway FBs. Only in the small group of patients with laryngeal FBs can removal be accomplished at times without anesthesia. Spontaneous ventilation, with the patients generating their own negative intrathoracic pressure, is the preferred technique. Positive-pressure ventilation is avoided because it can force the FB farther into the airway or may produce complete occlusion. However, assisted ventilation may be necessary for either oxygen desaturation or inadequate depth of anesthesia for the procedure. As in any standard operation, induction is performed with precautions taken to minimize secretions, laryngospasm, and hypoxia. After induction, the patient's head is extended and placed in the "sniffing" position. A laryngoscope is used to expose the larynx for insertion of the bronchoscope and to ensure that the FB is not within easy grasp of a McGill forceps. When the laryngeal inlet is deemed clear, the endoscopy is performed.

Endoscopic extraction of FBs from children requires a gentle, experienced hand. Great care is taken to protect the eyes, lips, teeth, tongue, and other laryngeal structures with insertion of the bronchoscope. The tongue is always swept to the left side with the laryngoscope to expose the glottis. The bronchoscope is inserted into the upper trachea and ventilation is

**Figure 11-3.** Radiographic evaluation in the young patient with a suspected foreign body aspiration can be difficult because inspiratory/expiratory chest radiographs may not be possible. Therefore, left and right lateral, decubitus films may be helpful because the obstructed lung will not deflate while in the dependent position. **A**, Radiograph with the child in a left lateral decubitus position. Note that the dependent left lung deflates appropriately. **B**, In the right lateral decubitus position, the right lung does not deflate, indicating a possible foreign body in the right main-stem bronchus. This was confirmed at bronchoscopy.

performed through the side arm. The tracheobronchial tree is then completely inspected, and the FB is removed.

The rigid bronchoscope is the primary instrument for evaluating the tracheobronchial tree for an FB. The instruments most commonly used are the Doesel-Huzly bronchoscope with Hopkins rod-lens telescope (Karl Storz Endoscopy, Tuttlingen, Germany) and the Holinger ventilating fiber-illuminated bronchoscope (Pilling Weck, Inc., Markham, ON). Both have the benefit of good exposure and the ability to shield FBs within the tube during extraction. The rigid instruments also allow the use of a diverse number of forceps. The length and diameter of the endoscope is dictated by the patient's age and size. In general, one should use the largest scope possible that will not cause trauma. The forceps used in most pediatric surgery practices are the positive-action, "center-action," or the passive-action forceps. The combination optical/illumination system with the forceps allows the greatest visibility.

Standard flexible bronchoscopy is being performed with increasing frequency in children older than age 12 years utilizing conscious sedation.<sup>30</sup> Older children can tolerate a larger and more versatile bronchoscope owing to their larger trachea. Additionally, the utilization of laryngeal mask anesthesia with a flexible bronchoscope passed through a side port in the mask has been used in younger as well as older children.

The primary causes of unsuccessful FB removal are inexperience, an impacted FB obscured by granulation tissue, and inadequate equipment. Many endoscopists describe the use of a Fogarty catheter for extraction of FBs inaccessible to grasping instruments. Removal may be limited by poor visualization associated with bleeding, granulation tissue, and edema. In cases with

significant granulation tissue and bleeding or multiple FB fragments that migrate distally and become impacted, a second endoscopy may be required. Post-instrumentation laryngeal edema may require respiratory therapy intervention before the second procedure. The post-instrumentation edema responds well to inhaled epinephrine and intravenous corticosteroid treatment.<sup>31,32</sup> The second procedure may include repeated endoscopy or thoracotomy with bronchotomy, segmentectomy, or lobectomy as required.

In an attempt to minimize the complications associated with a delay in diagnosis of FB aspiration in young children, bronchoscopy based on a history of choking alone has been advocated.<sup>12,14,17,21,25</sup> A negative bronchoscopy rate of 10% to 15% has been deemed acceptable to prevent the morbidity associated with delayed diagnosis.<sup>33</sup> Individual patient circumstances, including access to expert care, will enter into decisions for this more aggressive approach.

## ESOPHAGEAL FOREIGN BODIES

The esophagus is a muscular tube that has two shallow curves as it descends through the diaphragm to its termination at the gastric cardia. It is the narrowest portion of the alimentary tract and is protected at its upper end by the cricopharyngeus muscle where many ingested FBs lodge. The esophagus is narrowed somewhat at the aortic arch, left main-stem bronchus, and the diaphragm, areas where FBs will be trapped (Table 11-3).

Once they pass the cricopharyngeus, most swallowed objects will pass into the stomach. Congenital and acquired esophageal anomalies may contribute

**Table 11-3** Level of Retention of Aspirated Esophageal Foreign Bodies

Cricopharyngeus muscle	63%–84%
Aortic crossover mid-esophagus	10%–17%
Lower esophagus sphincter	5%–20%

From Stack LB, Munter DW. Foreign bodies in the gastrointestinal tract. *Emerg Med Clin North Am* 14:493, 1996.

to FB obstruction of the esophagus. The middle and lower esophageal motility is abnormal in patients born with esophageal atresia. Also, it is relatively common for young children to swallow soft, rubbery foods and have them lodge firmly near the area of the esophageal anastomosis. FB obstruction may be seen in patients with an unsuspected vascular ring, ectopic salivary glands, cartilaginous rests, middle mediastinal mass, an esophageal stricture, achalasia, or duplication cyst. Twenty-two percent of patients older than age 5 years with esophageal FBs were noted to have anatomic abnormalities.<sup>34,35</sup> In a series of patients with an impacted esophageal food bolus, up to 70% had esophageal abnormalities.<sup>36</sup> In most cases in which the level is reported, ingested FBs lodge at the normal anatomic narrowing of the cricopharyngeus muscle or the level of the aortic arch (see Table 11-3).

Coins and smooth blunt objects are the most commonly ingested items in large pediatric series. The patients are most commonly between 18 and 48 months of age.<sup>37</sup> In one review of almost 200 patients, 89% of FBs were coins.<sup>38</sup> There is a well-documented cultural and geographic difference in the types of FBs ingested. In a review of 343 Chinese children, 42% had ingested fish bones and only 39% had ingested coins.<sup>35</sup> In a report from Belgium, only 89 (27%) of 325 patients were found to have ingested coins, but 16% had ingested sharp objects, a significantly higher percentage when compared with other nations. In older children, food boluses and school supplies—parts of pencils and pens—are most common.

The ingestion of an FB is often unrecognized and asymptomatic, as the FB passes uneventfully through the gut. Although swallowed FBs are not considered as dangerous as aspirated FBs, up to 1500 deaths per year have been documented from esophageal FB ingestion.<sup>39</sup> Clinical symptoms of a patient with an FB that obstructs the esophagus include the sudden onset of acute and severe coughing, pain in the pharyngeal or retrosternal region, gagging, poor feeding, and drooling, among others. Periesophageal inflammation from an unsuspected esophageal FB can cause airway symptoms such as wheezing, stridor, and coughing. Significant respiratory symptoms can be seen with an esophageal FB as the esophageal dilation can result in airway impingement.

The ingestion of small batteries creates a different set of serious problems. Batteries have been found in less than 2% of esophageal FBs historically but are being increasingly seen with the rise of small batteries in children's toys.<sup>40</sup> A 7-year review reported 2320 cases of battery ingestion, but only 9.9% of these patients

**Figure 11-4.** This infant accidentally swallowed a lithium battery. The battery was removed within a few hours of its ingestion. However, 1 week later, the patient developed respiratory distress and bronchoscopy revealed this tracheoesophageal fistula (arrow).

were symptomatic.<sup>41</sup> Batteries can cause unique injuries not seen with other FBs. These include direct caustic injury, pressure necrosis, tissue necrosis from electrical discharge, and toxin release (mercury poisoning). The main chemical ingredients of disc batteries include alkaline corrosive agents or heavy metals. Battery size and type may affect management and outcome. Disc batteries can cause corrosive injury to the esophagus within 4 hours.<sup>42</sup> Lithium batteries cause more adverse effects due to their greater size and voltage. A review of reported cases showed that batteries less than 15 mm almost never become lodged in the esophagus, whereas those that are larger than 20 mm account for most of the reported esophageal injuries.<sup>43</sup> A 3-volt lithium battery is enough to cause cellular electrolyte flux, releasing intracellular potassium, and can result in cell death and tissue necrosis. Complications caused by esophageal impaction of button batteries include tracheoesophageal fistula (Fig. 11-4), esophageal burn with and without perforation, aorto-esophageal fistula, esophageal stricture, and death. Emergency endoscopy must be performed for batteries retained in the esophagus because of the high propensity of early mucosal injury.<sup>44</sup>

Radiologic evaluation for possible FB ingestion must include a lateral view and an anteroposterior view of both the neck and chest (Fig. 11-5). The radiologic evaluation of a child with a history of possibly swallowing a coin or a radiopaque object is highly sensitive and specific. In a review of the preoperative radiographs of 182 children with a history of FB ingestion (primarily coins), 96.7% had a positive radiographic finding confirmed by endoscopy.<sup>37</sup> Objects that are only faintly radiopaque such as bones or small items of aluminum are often seen on lateral views because

**Figure 11-5.** This infant was seen in the emergency department for swallowing difficulty and drooling. **A**, Anteroposterior radiograph shows a coin in the upper esophagus. **B**, However, on the lateral view, there are actually four coins superimposed on one another. The lateral view is very helpful for the purpose of determining whether more than one coin has been ingested.

the “end-on” view increases their radiodensity. Totally radiolucent FBs such as plastic beads or toys present a much more difficult radiographic challenge. In these cases, suspicion must be high enough to use contrast studies for the diagnosis. An esophagogram may demonstrate a radiolucent FB as a filling defect and may also reveal anomalies as compression by a vascular ring or an intrinsic stricture. Even though preoperative radiographic evaluation is accurate in demonstrating an FB in a child, the clinical situation should dictate the decision to perform esophagoscopy. Small coins, for example, lodged at the gastroesophageal junction, are likely to pass if given a chance. In an attempt to minimize the complications associated with the delay in diagnosis, endoscopy for suspicious cases with or without radiologic confirmation has been advocated. A negative esophagoscopy rate of 6.2% has been quoted as acceptable to prevent the morbidity associated with the missed diagnosis of an esophageal FB.<sup>37</sup>

Rapid diagnosis and treatment of FBs in the esophagus will decrease morbidity. Studies have been performed, however, to evaluate “watchful waiting” of asymptomatic esophageal coins. In a prospective randomized study, up to 30% of coins passed spontaneously within 8 to 16 hours of observation. Spontaneous passage appears to be associated with increasing age of the patient.<sup>45,46</sup> Watchful waiting, however, failed 70% of the time and was associated with an increased length of hospitalization.<sup>46</sup> Attempts at using glucagon to stimulate passage have proven to be ineffective.<sup>47</sup>

Three common techniques for FB removal from the esophagus are Foley catheter extraction, bougienage to push the FB into the stomach, and endoscopic retrieval. Foley catheter retrieval is generally easy and successful for removing smooth objects in the upper two thirds of the esophagus. The procedure is cost efficient and can be performed without anesthesia and usually under fluoroscopic guidance (Fig. 11-6). The risks of the procedure are potential airway compromise, esophageal injury, inability to visualize the esophageal reaction to the FB, and the discomfort of the awake

**Figure 11-6.** This radiograph shows the Foley catheter technique for removing a coin lodged in the upper esophagus. Under fluoroscopy, the Foley catheter is advanced past the coin and the balloon is filled with barium (asterisk). Under fluoroscopy, the catheter is then removed, bringing the coin with it. Care must be taken to ensure the patient does not aspirate the coin during its removal. This is a very cost-efficient way to remove coins in the upper esophagus in young children.

child. The success rate of 84% to 96% with Foley catheter extraction is less than with endoscopy.<sup>48-51</sup> Objects that have been retained in the esophagus for longer than 24 hours may have produced significant tissue reaction that significantly increases the risk of catheter extraction as well as the risk of failure for retrieving the FB. On occasion, the Foley catheter insertion itself has resulted in pushing FBs into the stomach.

Bougienage has been shown to be successful in selected cases. The patient has usually ingested a single coin within 24 hours of presentation, is stable, and has

**Figure 11-7.** This coin was lodged in the esophagus of a 2-year-old child. It was unclear how long the coin had been in the esophagus. Therefore, rigid esophagoscopy was performed. **A**, The coin is seen through the esophagoscope. **B**, The optical graspers are being used to grasp the coin and remove it. The safety and success rate for rigid esophagoscopy and coin removal approaches 100% with minimal complications. This is usually a safe and successful way to remove a coin in the esophagus of children in whom the Foley catheter technique is not appropriate.

no history of esophageal abnormalities or FB aspiration. Blunt-tipped, weighted esophageal bougies are introduced to advance the coin or other smooth object into the stomach with the expectation the object will be passed per rectum. Roughly 90% to 95% of these objects will be evacuated spontaneously.<sup>52</sup> The concern with bougienage is that the nonevacuated FBs can lead to obstruction or perforation of the small intestine, requiring more difficult endoscopic retrieval or surgical exploration.

Rigid endoscopy is the most reliable and successful method used in retrieval of esophageal FBs (Fig. 11-7). The safety and success rate with rigid endoscopy has approached 100% with minimal complications. The procedure is performed in a controlled environment with the same precautions that apply to the use of the rigid bronchoscope. The patient is placed in the supine position with the head in the neutral sniffing position. The cervical spine is straight, allowing for passage of the endoscope over the cervical kyphosis. Esophagoscopes differ from the bronchoscopes in that they have a smooth, flared leading edge. This difference allows the endoscopist to lift the larynx with minimal trauma to expose and open the cricopharyngeus “sphincter.” The appropriate size is the largest that can be accommodated without forcing the esophagoscope.

## GASTROINTESTINAL FOREIGN BODIES

The vast majority of FBs that are ingested by children are not retained in the esophagus. In one study, 60% of patients who were evaluated for FB ingestion were found to have the FB in their stomach at the time of evaluation.<sup>53</sup> With the exception of sharp objects and batteries, most gastric FBs do not have to be removed because they are eliminated spontaneously.<sup>44,54,55</sup> In a study of 1481 children, 97% of ingested FBs that passed through the esophagus on radiographic study were spontaneously evacuated. The incidence of operative retrieval of ingested FBs found initially to be in the stomach is 1%, whereas the rate

for ingested sharp objects is 15% to 30%. Some surgeons recommend early endoscopic retrieval of sharp FBs.<sup>56</sup> Commonly ingested sharp FBs include bones, nails, safety pins, needles, sharp toys, and toothpicks. Toothpick and bones are the most commonly ingested objects that require retrieval. If either of these objects becomes impacted in the intestinal mucosa, erosion may develop, which then can lead to perforation and peritonitis. Objects larger than 2 cm or longer than 3 cm that are swallowed by infants have been shown to have difficulty traversing the pyloric channel. In older children and adults, objects thicker than 2 cm and longer than 5 cm tend to have difficulty passing through the duodenal loop, causing functional gastric outlet obstruction. These objects also warrant endoscopic retrieval. Rarely, FBs become lodged distal to the ligament of Treitz. Although the ileocecal valve is the only natural narrowing in the lower intestinal tract, it is rarely the site for FB retention. Disc battery ingestion requires removal if lodged in the esophagus. Once the battery is in the stomach, it can be managed conservatively with spontaneous passage expected without complications.<sup>57</sup>

Ingestion of multiple magnets usually causes minimal initial physical findings. Late complications, however, include bowel perforation, volvulus, ischemia, and enteroenteral fistulas. Removal of magnets is recommended when there are more than one and while they are still in the stomach. Once they are distal to the stomach, observation is necessary to ensure that they all pass per the rectum.<sup>58</sup>

Bezoars are FBs that have accumulated over time in the alimentary tract. These can cause obstructive symptoms, bleeding, failure to thrive, weight loss due to early satiety, abdominal pain, anorexia, halitosis, and nausea. Common concentrations include plant and vegetable matter (phytobezoar), hair (trichobezoar), persimmons (disopyrobesoar), and neonatal casein curd (proteinaceous) aggregations.

Trichobezoars can extend a long tail from the stomach down through the entire intestinal tract to or even beyond the ileocecal valve where they then cause an

**Figure 11-8.** A 10-year-old girl was admitted to the hospital with decreasing oral intake, vomiting, and weight loss. **A**, An abdominal CT scan was performed that showed a large gastric bezoar (*asterisk*) in the stomach. Laparoscopic extraction of the trichobezoar was performed. **B**, The stomach was opened and the bezoar was visualized. The trichobezoar was extracted and placed in a bag which was then exteriorized through the umbilical incision. **C**, After extraction of the bezoar, the gastrotomy was closed with the endoscopic stapler. **D**, The incisions used for laparoscopic removal of the trichobezoar are seen in the postoperative photograph.

obstruction. Children with extensive trichobezoars causing this type of obstruction are referred to as having the Rapunzel syndrome.<sup>59</sup> Trichotillomania is a psychosomatic entity in which there is a desire to pull out one's hair and ingest it. Patients suffering from this disorder feel instant release of tension, a sense of relief, and security. This process can lead to the formation of trichobezoars.<sup>60</sup> Most cases of trichotillomania in children are considered "habit disorders" that are amenable to psychotherapy. Bezoars may be retrieved endoscopically or eliminated by enzymatic fragmentation. Laparotomy or laparoscopy may be warranted with large obstructing bezoars such as in the Rapunzel syndrome (Fig. 11-8).

## EAR AND NOSE FOREIGN BODIES

FBs may be the cause of mouth breathing and rhinorrhea in children. Identification and removal require appropriate suspicion and adequate instrumentation. Although most FBs recently inserted are easily removed from the nose, those of long standing may not be as simple to remove. Nasal mucosal reaction with edema and granulation tissue develops rather quickly. The mucosal lining of the nose is a dynamic

surface that requires uninterrupted mucociliary flow to remain free of crusting and inflammation. Interruption of the flow patterns by an FB readily produces inflammation and infection. FBs placed in the anterior nares can be inert or reactive. Common objects placed in the nares are dried beans, plastic objects, buttons, metals, food, erasers, nuts, seeds, and button batteries. Presenting signs and symptoms with nasal FBs include rhinorrhea, crusting, air flow obstruction, rhinitis, sinusitis, lymphadenopathy, epistaxis, otitis media, and adenoiditis.

Otitis media is a potential sequela of a posterior nasal reaction from an FB, causing eustachian tube obstruction. Plastic and other inert materials may be tolerated for long intervals, but granulation tissue develops to produce an obstruction. Button batteries may lead to septal perforation and destruction of cartilage, leading to a saddle-nose deformity. The site of maximal damage from button batteries has been shown to correspond to the negative pole of the battery.

Successful removal of a nasal FB in a child requires visualization and appropriate instrumentation. Usually this is a simple bedside procedure. The primary or emergency physician using tweezers, cerumen curet, or a cotton-tipped applicator can remove most FBs. Long-standing objects may be more complicated,

requiring assistance from a surgical specialist. Tools that can be helpful in visualizing the object are the Frazier tip suction, the optic headlight, and the nasal speculum. The Hartmann forceps, wire loop, flexible cerumen curet, alligator forceps, and a right-angled hook are tools that increase the likelihood of recovering the FB. It is beneficial to place the instrument alongside or behind the object for successful removal. Great care must be taken not to impact the FB or to push it through the nose and risk aspiration.

The external ear canal is another orifice of interest to the curious child. The child can place a multitude of FBs in the ear canal. Symptoms may vary depending on the nature of the FB, the size of the FB, and the duration that the FB has been present. Local trauma

can occur with bleeding and difficulty with hearing. The child may describe a fullness sensation. Complications can arise with inflammatory changes. Secondary infection may cause canal wall skin to bleed and slough, producing otorrhea and severe granulation tissue formation. The presence of a secondarily infected ear canal from an FB may mimic a chronic mastoid infection that will not respond to antibiotics. Disc batteries, as in the nose and gastrointestinal tract, are extremely caustic and can cause extensive damage to the external auditory canal, tympanic membrane, and middle ear. The removal of an FB requires that the patient be extremely cooperative. Therefore, the use of general anesthesia may be necessary to minimize iatrogenic injury.

# BITES

Gary S. Wasserman, DO • Jennifer Lowry, MD • D. Adam Algren, MD

A wide variety of bites are seen in children. It is estimated that more than 1 million children are treated annually for bites (Table 12-1).<sup>1</sup> In this chapter we concentrate on bites of interest to the surgeon. The reader is referred elsewhere for discussions of management of venomous stings and injuries from marine life and general details of wound management.

## TETANUS

The gram-positive anaerobic organism *Clostridium tetani* is the causative agent for tetanus, a severe and often fatal disease. According to the 2006 report of the Department of Health and Human Services Centers for Disease Control and Prevention (CDC), there were a total of 41 cases (27 females) reported in the United States.<sup>2</sup> Only two cases were reported in the age group younger than 15 years old, with six cases in the 15- to 24-year age group. No neonatal cases were described.

There has been a low incidence of tetanus since a peak of 102 cases in 1975. Mortality from tetanus is associated with co-morbid conditions such as diabetes and intravenous drug usage and occurs in the elderly,

especially when vaccination status is unknown. Infection can occur weeks after a break in the skin, even after a wound has seemed to heal. The ideal anaerobic surroundings allow spores to germinate into mature organisms producing two neurotoxins: tetanolysin and tetanospasmin.<sup>3</sup> The latter is able to enter peripheral nerves and travel to the brain, causing the clinical manifestations of uncontrolled muscle spasms and autonomic instability. The incubation period varies from as short as 2 days to as long as months, with most cases occurring within 14 days.<sup>4</sup> In general, the shorter the incubation period, the more severe the disease and the higher the fatality risk.

Initially, the diagnosis must be made clinically because wound cultures are often negative and serum antitoxin antibodies have a long turn-around time. So-called “dirty” wounds—lacerations treated after 24 hours, abscesses, ulcers, gangrene, and wounds with nonviable tissue—are the most common injuries that become infected. However, a history of acute trauma is not necessary.

All wounds should be cleaned and debrided. Symptomatic and supportive care includes medications, such as benzodiazepines, to control tetanic spasms and antimicrobials for infections. Metronidazole (oral

**Table 12-1** “Bites and Envenomations” to Humans—Calls to Poison Centers in 2006

Animal	Total Calls	Age < 6 yr	Age 6-19 yr	All Ages Treated at Facility	Severe Outcome/Death
Bat	647	84	135	392	0/0
Cat	797	97	136	452	0/0

Spiders	14,613	1,469	2,284	3,509	51/1

n = 2,403,539 total human poisoning calls; n = 82,133 in the category of bites and envenomations.

Data from Bronstein AC, Spyker DA, Cantilena LR, et al (eds): 2006 Annual Report of the American Association of Poison Control Centers' National Poison Data System (NPDS). Clin Toxicol 45:815-917, 2007.

Table 12-2 Wound Tetanus Prophylaxis Guideline		
Vaccination History (Td)	Clean/Minor Wounds	All Other Wounds
? or < 3 doses	Td or Tdap—No TIG	Td or Tdap—TIG
≥ 3 doses	Td or Tdap—No TIG if ≥ 10 yr since last dose	Td or Tdap—No TIG if ≥ 5 yr since last dose

Td, adult type diphtheria and tetanus toxoids vaccine; TIG, tetanus immune globulin (human); Tdap, booster tetanus toxoid, reduced diphtheria toxoid, and cellular pertussis.

From American Academy of Pediatrics: Tetanus (lockjaw), bite wounds. In Pickering LK, Baker CJ, Long SS, McMillan JA (eds): Redbook: 2006 Report of the Committee on Infectious Diseases, 27th ed. Elk Grove Village, IL, American Academy of Pediatrics, 2006, pp 191-195, 648-653.

or intravenous, 30 mg/kg/day, divided into four daily doses, maximum 4 g/day) is the antibiotic of choice because it decreases the number of vegetative forms of *C. tetani*.<sup>5</sup> An alternate choice is parenteral treatment with penicillin G (100,000 U/kg/day every 4 to 6 hours, not to exceed 12 million units/day) for 10 to 14 days. Human tetanus immune globulin (TIG) is administered to adults and adolescents as a one-time dose of 3000 to 6000 units intramuscularly. Some experts recommend that children receive 250 to 500 units to decrease discomfort from injection.<sup>5</sup> Infiltrating part of the dose locally is controversial.

Prevention in a potentially exposed patient depends on the nature of the wound and history of immunization with tetanus toxoid as recommended by the CDC. One should consult an infectious disease expert for the most updated therapy or the CDC's website: [www.cdc.gov/vaccines/](http://www.cdc.gov/vaccines/) (Table 12-2).<sup>5</sup>

## CAT, DOG, HUMAN, AND OTHER MAMMALIAN BITES

Children are frequent victims of mammalian bites. The most common complication from bites is infection: cats, 16% to 50%; dogs, 1% to 30%, and humans, 9% to 18%.<sup>6</sup> When the bite is from a cat, dog, or other mammal, the most common infectious organisms to consider include (but are not limited to) *Streptococcus*, *Staphylococcus*, *Actinomyces*, *Pasteurella* species, *Capnocytophaga* species, *Moraxella* species, *Corynebacterium* species, *Neisseria* species, *Eikenella corrodens*, *Haemophilus* species, anaerobes, *Fusobacterium nucleatum*, and *Prevotella melaninogenica*.<sup>5,7,8</sup> Human bites are a potential source not only for bacterial contamination but also for hepatitis B and, possibly, human immunodeficiency virus (HIV) infection.<sup>9</sup>

Recommendations for bite wound management are presented in Table 12-3. Evidence-based medicine studies concerning the closure of bite wounds are not conclusive. Distal extremity wounds, especially hand/fist to teeth, are at higher risk for infection. Whether minimal risk wounds require prophylactic antimicrobial

therapy is controversial. Antibiotics started within 8 to 12 hours of the bite and continued for 2 to 3 days may decrease infection rate.<sup>5</sup> The oral drug of choice is amoxicillin clavulanate. For penicillin-allergic patients, an extended-spectrum cephalosporin (5%-15% of penicillin-allergic people are also hypersensitive to cephalosporins) or trimethoprim-sulfamethoxazole plus clindamycin should be given.<sup>5</sup>

## RABIES AND POSTEXPOSURE PROPHYLAXIS

Rabies is a viral disease usually transmitted through the saliva of a sick mammal (i.e., dogs, cats, ferrets, raccoons, skunks, foxes, bats, and most other carnivores). Most reported cases in the United States are caused by raccoons, skunks, foxes, mongooses, and bats.<sup>2</sup> Small rodents such as rats, mice, squirrels, chipmunks, hamsters, guinea pigs, and gerbils (also lagomorphs such as rabbits and hares) are almost never infected with rabies. Over the past decade, cats have been the most common domestic animal with rabies. In 2006, there were three cases of human rabies identified in the United States and all were fatal. This was a decline from a peak of seven cases in 2004 (with records dating back to 1975).<sup>2</sup> The rabies virus enters the central nervous system and causes an acute, progressive encephalomyelitis from which survival is extremely unlikely. The human host has a wide range for the incubation period from days to years (most commonly weeks to months).

Prophylactic treatment for humans potentially exposed to rabies includes immediate and thorough wound cleansing followed by passive vaccination with human rabies immune globulin (HRIG) and cell culture rabies vaccines, either human diploid (HDCV) or purified chick embryo (PCECV).<sup>10-12</sup> (Consult [www.cdc.gov/vaccines/](http://www.cdc.gov/vaccines/) for the most up-to-date information.)

Table 12-3 Components of Bite Wound Management

- Obtain detailed history of injury.
- Evaluate injury and re-examine in 24-48 hours.
  - Check for foreign bodies and possible deep structure injury in small children.
- Evaluate for risk of tetanus, rabies, hepatitis B, human immunodeficiency virus.
- Perform meticulous cleansing and irrigation.
  - Irrigation of puncture wounds is controversial.
- Obtain wound culture as indicated.
  - Culture is recommended if wound appears infected or is of late presentation.
- Debride necrotic tissue or contaminants not removed by irrigation.
- Perform exploratory surgery as indicated.
- Primary closure is sometimes performed for dog bites but not recommended for human or cat bites.
- Consider antimicrobial therapy.

Many factors help determine the risk assessment in deciding which patient benefits from postexposure prophylaxis and which regimen should be given. The risk of infection depends on the type of exposure, surveillance, epidemiology of animal rabies in the region of contact, species of animal, animal behavior causing it to bite, and availability of the animal for observation or laboratory testing for rabies virus. The final decision for treatment with vaccines is complex. Therefore local, state, or CDC experts are available for assistance.

## SPIDER BITES

There are about 40,000 species of spiders that have been named and placed in about 3000 genera and 105 families.<sup>13</sup> Families with over 100 genera are Salticidae (jumping spiders), Linyphiidae (dwarf or money spiders, sheet web weavers), Araneidae (common orb spiders), Theridiidae (cobweb weavers), Lycosidae (wolf spiders), Gnaphosidae (ground spiders), and Thomisidae (crab spiders). New species are constantly being discovered while others are becoming extinct. In regard to medically relevant spiders, few are known to cause significant clinical effects. In 2006, over 14,000 calls were made to U.S. Poison Control Centers (PCC) regarding spider bites.<sup>1</sup> Although PCC data are biased with over 85% of calls originating from the general public (see Table 12-1), one third of these cases were evaluated in a health care facility with 51 cases having a severe outcome with one death. Although it is unknown if surgical intervention was required in these cases, it is rare that a spider bite requires surgical care. Few spiders have been shown to have the ability to bite humans because their fangs cannot pierce our skin. The two most medically important spiders in the United States are Sicariidae (brown spiders) and Latrodectus (widow spiders).

## Brown Spiders

Loxoscelism is a form of cutaneous-visceral (necrotic-systemic) arachnidism found throughout the world with predilection for North and South America.<sup>14</sup> There are four species of brown spiders within the United States that are known to cause necrotic skin lesions (*Loxosceles deserta*, *L. arizonica*, *L. rufescens*, and *L. reclusa*). *L. deserta* and *L. arizonica* can be found in the southwestern United States. *L. rufescens* is found sporadically all over the United States in very circumscribed infestations (typically one building). *L. reclusa* can usually be found in the South central United States, especially Missouri, Kansas, Oklahoma, Arkansas, Tennessee, and Kentucky.<sup>15</sup> Spiders can be transported out of their natural habitat but very rarely cause arachnidism in nonendemic areas. *L. reclusa* is tan to brown with a characteristic dark, violin-shaped marking on its dorsal cephalothorax, giving it the nickname "fiddleback spider." The spider can measure up to 1 cm in total body length with a 3 cm or longer leg span (Fig. 12-1) and only three pairs of eyes.

The incidence of *L. reclusa* bites predominantly occurs from April through October in the United States. The venom of the brown recluse spider contains at least 11 protein components. Most are enzymes with cytotoxic activity.<sup>16</sup> Sphingomyelinase D is believed to be the enzyme responsible for dermonecrosis and activity on red blood cell membranes.<sup>17-19</sup> In addition to the local effects, the venom has activity against neutrophils and the complement pathway that induces an immunologic response.<sup>19-21</sup> The resulting effect is a necrotic dermal lesion with the possibility of a systemic response that can be life threatening.

The prevalence of brown recluse spider envenomations is unknown. The victim may not feel the bite or may only feel a mild pinprick sensation. Many victims are bitten while they sleep and may be unaware of the

**Figure 12-1.** *Loxosceles reclusa* (brown recluse, "fiddleback") spider showing the classic violin-shaped marking on the back (dorsal side) of the cephalothorax. Note the long slender legs and oval body segment with short hairs. The arrow is pointing toward the classic violin marking. (From Ford M, Delaney K, Ling L, Erickson T: Clinical Toxicology. Philadelphia, Elsevier, 2001.)

**Figure 12-2.** A, A 3-year-old girl hospitalized on the third day after a brown recluse spider bite for severe hemolytic anemia, hemoglobinuria, and ecchymosis (note the vast expansion of the ecchymosis secondary to hyaluronidase “spreading factor” in the venom). There is no necrosis or ischemia, but a small bleb/blister is present over the right clavicle that, although not pathognomonic, is often present early in lesion progression. Also note that the cutaneous lesion is mild in comparison with this patient’s systemic presentation. B, On the 15th day after envenomation, the lesion measures 5 × 2 cm. Multiple small areas of necrosis have become apparent in the past week. The largest area indicates the original bite size. The lesion’s edges have begun to involute with healing, and the ischemia is fading. C, Nine months after the bite, the necrotic wound has healed with no significant scarring.

envenomation until a wound develops. The majority of victims do not see the spider at the time of the bite.<sup>22</sup> Typically, the bite progressively begins to itch, tingle, and become ecchymotic, indurated, and edematous within several hours.<sup>23</sup> Often within hours, a characteristic bleb or bullae will form. The tissue under a blister is more likely to become necrotic, but the extent of necrosis is not predictable. As the wound ischemia and inflammation progresses, it becomes painful and may blanch or become erythematous, forming a “target” or “halo” design. Inflammation, ischemia, and pain increase over the first few days of the bite as enzymes spread. Over hours to weeks, an eschar forms at the site of the bite. Eventually, this eschar sloughs, revealing an underlying ulcer that may require months to heal, usually by secondary intention (Fig. 12-2). On very rare occasions, the ulcer does not heal and may require surgical intervention.

The need for hospitalization occurs if the patient develops systemic symptoms. Two studies documented that 14% to more than 50% of patients developed systemic symptoms, with fever being the most common symptom.<sup>10</sup> Other common symptoms include a maculopapular rash, nausea and vomiting, headache, malaise,

muscle/joint pain, hepatitis, pancreatitis, and other organ toxicity. Life-threatening systemic effects include hemolysis (intravascular and/or extravascular), coagulopathy, and multiple organ system failure. Secondary effects include sepsis, necrotizing fasciitis, and shock.<sup>24-26</sup> Hemolysis usually manifests within the first 96 hours. However, late presentations can occur. When hemolysis does develop, it can take 4 to 7 days (or longer) to resolve. Complications such as cardiac dysrhythmias, coma, respiratory compromise, pulmonary edema, congestive heart failure, renal failure, and seizures can occur.

The diagnosis of a brown recluse spider envenomation is largely one of exclusion as it is rare to see or identify the spider. While the wound can look classic for an envenomation, other etiologies must be considered (Table 12-4). Certain laboratory findings can be consistent with a brown recluse spider envenomation but are not specific in making the diagnosis (Table 12-5).

Controversy surrounds the treatment of dermal and systemic symptoms of loxoscelism. Medications such as dapsone, nitroglycerin, and tetracycline have been used. Also, hyperbaric oxygen (HBO) therapy has been advocated as has surgical excision of the necrotic wound. However, none of these has shown consistently to be effective in treating or preventing the ulcer development. In South America, an antivenom has been developed and used in the treatment of *Loxosceles* envenomations. Unfortunately, the usual long delay in seeking medical care often leads to ineffective use of antivenom.<sup>27</sup> An antivenom is not available in North America.

Use of dapsone, a leukocyte inhibitor, has been advocated in case reports and animal studies.<sup>28-30</sup> However, other animal studies have shown no benefit from this treatment. In an animal study,<sup>31</sup> piglets received venom and were randomized to receive one of four treatments: no treatment, HBO, dapsone, or dapsone with HBO. Neither dapsone, HBO, nor the combination treatment reduced necrosis compared with controls. A second study compared the use of HBO, dapsone, or cyproheptadine against no treatment in decreasing

**Table 12-4** Differential Diagnosis of Brown Recluse Spider Envenomations

Acquired hemolytic anemias
Bites from other creatures (e.g., snakes, spiders, insects) that can result in cutaneous lesions
Dermatologic conditions (e.g., pyoderma gangrenosum)
Hereditary hemolytic anemias
Infectious causes (e.g., Lyme disease, infection with <i>Streptococcus</i> , <i>Staphylococcus</i> , or <i>Clostridium</i> species)
Medical conditions causing necrotic lesions:
Emboli
Frostbite or thermal injuries
Ischemic injuries
Neoplastic wounds (e.g., ecthyma gangrenosum)
Trauma

**Table 12-5** Laboratory Findings Consistent with Systemic Effects of *Loxosceles* Envenomations

Hemoglobinemia
Hemoglobinuria or hematuria
Elevated plasma free hemoglobin or decreased free haptoglobin
Leukocytosis
Anemia
Thrombocytopenia
Coagulopathy (elevated prothrombin time, decreased fibrinogen, elevated D-dimer, decreased antithrombin III)
Inflammatory markers (elevated C-reactive protein, elevated erythrocyte sedimentation rate, elevated liver and/or pancreatic enzymes)
Immunology (positive antiglobulin tests: direct or indirect Coombs; decreased total serum complement or components; interference with blood screening or crossmatching)

the necrotic wound after envenomation with *L. deserta* venom. No statistical difference was seen with respect to lesion size, ulcer size, or histopathologic ranking.<sup>32</sup> In addition, the use of dapsone is not without risk, especially hypersensitivity reactions.<sup>33</sup> Therapeutic doses of dapsone are associated with hemolytic anemia, methemoglobinemia, and other hematologic effects in patients with and without glucose-6-phosphate dehydrogenase deficiency and may complicate the clinical picture in treating these patients.

Topically applied nitroglycerin as a vasodilator had been advocated but is not effective in preventing necrosis. A randomized, blinded, controlled study was performed on rabbits envenomated with *Loxosceles* venom and showed that skin necrosis developed in all animals.<sup>34</sup> In addition, there was no difference in regard to the area of necrosis, amount of edema, and increase in creatinine phosphokinase (CPK) concentration. Alternatively, rabbits were inoculated with *Loxosceles* venom and randomized to receive topical doxycycline, topical tetracycline, or placebo.<sup>35</sup> Those who received topical tetracycline had reduced progression of the dermal lesion. However, treatment was started early at 6 hours after envenomation, which may not be realistic after a human bite. In addition, the agents used for this research study are not commercially available in the United States. Further studies need to be performed before topical tetracycline can be recommended.

As previously mentioned, HBO has been advocated for wound treatment to prevent progression of the necrotic wound. The initial use of HBO was based on the belief that tissue hypoxia was partially responsible for the subsequent necrosis seen after a bite. As mentioned previously, no statistical differences were noted in animal studies that compared dapsone and HBO.<sup>31,32</sup> Similar results have been seen in animal studies assessing the effect of HBO alone.<sup>36,37</sup> However, a randomized, controlled trial of HBO in a rabbit model in which standard HBO was used showed a significantly reduced wound diameter at 10 days.<sup>38</sup> No significant change in blood flow at the wound center or 1 to 2 cm

from the wound center was seen. HBO is expensive and not without complications. At the present time, much of the literature contradicts the benefit of HBO for brown recluse spider envenomations. As such, it is not currently recommended as a first-line therapy for these bites but may be helpful in patients with underlying/preexisting vascular compromise such as sickle cell anemia or diabetes.

Early surgical intervention is not helpful because the venom diffuses rapidly throughout the soft tissues surrounding a bite.<sup>39</sup> In addition, patients may be more at risk for delayed wound healing and objectional scarring if surgery occurs within the first 72 hours of the bite.<sup>40,41</sup> Debridement of enlarging blebs is proposed with the theory that toxins exist within the blister fluid. However, necrosis almost always occurs beneath the blisters.<sup>42</sup> The question is whether surgical intervention should be advocated late after envenomation. The wound from the brown recluse spider may take 2 to 3 months to heal. Thus, skin grafting of a nonhealing necrotic area should be delayed up to 12 weeks to allow for neovascularization of the demarcated area.<sup>43</sup> Imaging studies of soft tissue areas are incorrectly interpreted as being "cellulitis" because of the noninfected inflammatory reaction within the tissue layers. This is especially noted in the head and neck regions as well as extremities.

Treatment of systemic signs and symptoms are largely symptomatic and involve supportive care. Patients should be monitored closely for hemolysis (and children hospitalized) if systemic symptoms such as fever and rash develop. Systemic corticosteroids seem to suppress hemolysis and may be needed for 5 to 10 days with a subsequent tapering dose.<sup>43</sup> Methylprednisolone can be administered as a 1.0- to 2.0-mg/kg intravenous loading dose (no maximum) followed by a 0.5 to 1.0 mg/kg maintenance dose every 6 hours. Hydration, to maintain good urine output, is required to prevent acute renal tubular necrosis if hemolysis or hematuria occurs. Antibiotics are not generally required early in the care of these patients because the spider does not inoculate humans with bacteria. However, secondary infections can occur and lead to sepsis, toxic shock syndrome, and necrotizing fasciitis. These complications require close observation and antibiotic therapy to cover anaerobic, staphylococcal, and streptococcal infections.

## Black Widow Spider

The black widow spider (*Latrodectus mactans*) is found throughout North America except for areas of extreme cold.<sup>44</sup> They can usually be found outdoors in warm, dark places or in a garage or basement. They are web-making spiders and usually strike when their web is disturbed. The female spider is readily recognized as she is a black spider with a red marking on her abdomen in the shape of an hourglass. Widow spiders have a neurotoxic venom that is responsible for clinical effects. The venom,  $\alpha$ -latrotoxin, acts on the neuromuscular junction to cause depletion of acetylcholine at motor endings and catecholamines at the postganglionic sympathetic synaptic sites followed by complete

blockade of the neuromediator release.<sup>45</sup> Because the venom does not have cytotoxic properties, dermal effects including significant local pain are not seen.

In the majority of cases, a pinprick sensation may be felt at the time of a bite. A “halo” lesion may be present, but this tends to disappear within 12 hours of envenomation. Significant symptoms may present within 1 to 12 hours after the bite. Within several hours, tenderness may be felt in the regional lymph nodes and the affected extremity or surrounding tissues. Depending on where the bite occurs, pain migrates to large muscle groups in the thigh, buttock, and abdomen or to the chest. The most common presenting complaint to emergency departments is intractable abdominal, chest, back, or leg pain, depending on the site of the bite.<sup>46</sup> Board-like rigidity of the abdomen, shoulders, and back may develop that may lead to misdiagnosis of surgical abdomen or other etiology. The pain generally peaks at 2 to 3 hours but can last up to 72 hours.

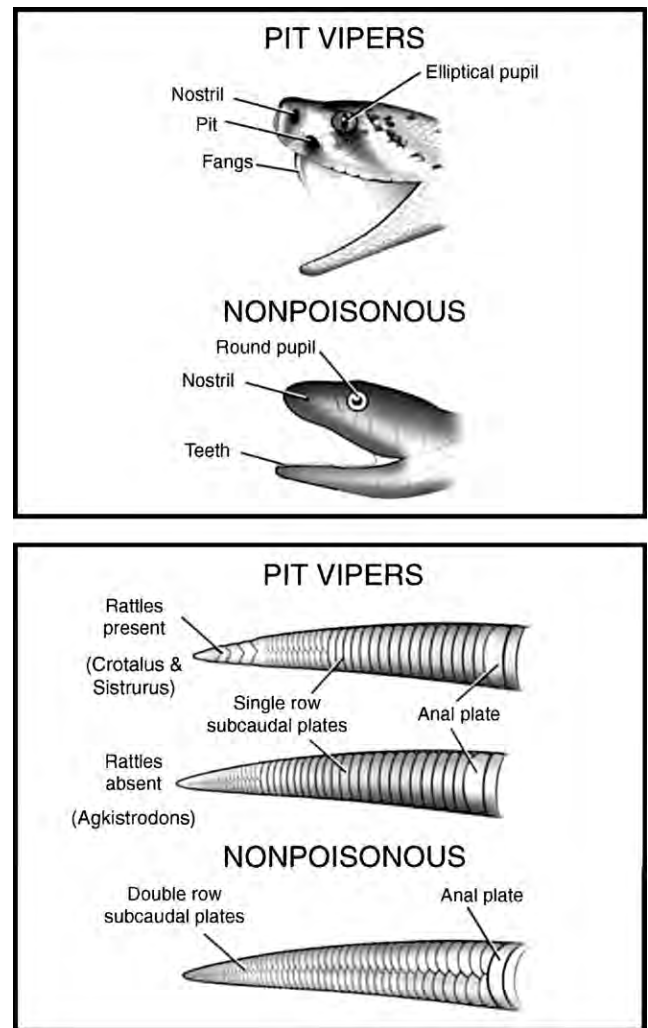

Because the venom affects the autonomic nervous system, patients may present with symptoms of dysautonomia that include hypertension (sometimes severe), tachycardia, weakness, ptosis, eyelid edema, pruritus, nausea and vomiting, diaphoresis, hyperreflexia, difficulty breathing, and excessive salivation. Fatalities are rare but have been reported. Children are more at risk to develop systemic symptoms.

Treatment is largely symptomatic and supportive. For the most part, treatment is focused on analgesia. For those with mild pain, oral medications are appropriate. Patients may present with severe pain requiring opioids and benzodiazepines as adjunctive therapy. Calcium gluconate has been advocated in the past. However, it is not recommended because of lack of consistent effects in alleviating the symptoms. Antivenom is available and generally reserved for patients who have life-threatening symptoms or pain that is not relieved by opioids and benzodiazepines. Because it is an equine product, it has increased risk for anaphylaxis and serum sickness and it is not readily available in most hospital settings.

## CROTALID SNAKE ENVENOMATIONS

In the United States, there are two major classes of poisonous snakes: crotalids and elapids. Crotalids, otherwise known as pit vipers, are indigenous to almost every state and account for the vast majority of poisonous snakebites in the United States annually. Most snakebites occur during the warm summer months when both snakes and humans are more active and thus more likely to come into contact with each other. It is generally thought up to 20% of snakebites are “dry bites” and do not result in envenomation.<sup>47</sup>

Crotalids can be classified into three major groups: rattlesnakes, cottonmouths (water moccasins), and copperheads. Copperheads are responsible for the majority of crotalid envenomations. In general, these bites are less severe and rarely result in systemic toxicity.<sup>48,49</sup> Rattlesnake envenomations more commonly produce coagulopathy and systemic toxicity.

**Figure 12-3.** Identifying characteristics of pit vipers and nonpoisonous snakes. The presence or absence of a single row of subcaudal plates may be the only identifying feature in a decapitated snake. (From Ford M, Delaney K, Ling L, Erickson T: *Clinical Toxicology*. Philadelphia, Elsevier, 2001.)

Crotalids have several physical features that can help distinguish them from nonpoisonous snakes (Fig. 12-3). Crotalids have triangular heads and elliptical pupils. Nonpoisonous snakes have round heads and pupils. Crotalids have a single row of subcaudal plates/scales distal to the anal plate, whereas nonpoisonous snakes have a double row of subcaudal plates. Most importantly, crotalids have two retractable fangs and the characteristic heat-seeking pit located between the nostril and the eye. Nonpoisonous snakes have short, pointy teeth but no fangs.

## Crotalid Venom Pharmacology/ Pathophysiology

Crotalid venom is a complex mixture of proteins, including metalloproteinases, collagenase, hyaluronidase, and phospholipase.<sup>50</sup> These enzymes act to destroy tissue at the site of envenomation. Damage to the vascular endothelium and basement membranes

leads to edema, ecchymosis, and bullae formation. Concurrently with local tissue destruction, venom is absorbed systemically and can result in shock and coagulopathy. The potency of venom varies with the species of the snake, age, diet, and time of year.<sup>47</sup> Even within the same snake the composition and potency of venom can vary substantially based on these factors.

## Clinical Effects

In questioning the patient, one should ascertain the circumstance and timing of the bite as well as any first aid methods that were used. Knowing what prehospital measures were instituted can be extremely helpful. Certain therapies such as incision, excision, and suction may result in significant local trauma and act to confound the assessment of local injury. The clinician should determine if the patient has previously received antivenom because sensitization can occur, thereby placing the patient at higher risk for an allergic reaction. Health care providers should be cautious regarding the reliability of victim identification of the offending snake. It is often assumed that rattlesnakes will rattle their tails before biting. However, this is not always the case. Also, rattles may be absent from rattlesnakes due to shedding or trauma. Victims occasionally trap or kill the snake and bring it to the emergency department. Vigilance is necessary when examining these snakes because they are capable of biting again. Even dead snakes have been known to bite reflexively for up to an hour after they are killed.<sup>47</sup>

Envenomations can result in significant local pain and swelling. The patient typically has two fang marks at the location of the bite. Often, there is mild bleeding or oozing from the wound. Swelling typically develops within 1 to 2 hours, and ecchymosis or bullae (some hemorrhagic) formation may appear. Several different models have been developed to grade the severity of snakebites.<sup>47,51</sup> The minimal, moderate, severe model is a simple tool that can help assess severity and determine the need for antivenom (Table 12-6).

Serial measurements of the extremity are required to detect any progression of swelling. Local effects have traditionally been documented by drawing a line demarcating the progression of the swelling. This

**Figure 12-4.** A 15-year-old boy was bitten on his right hand by a timber rattlesnake. Note the significant swelling of the arm. Serial limb circumference measurements documented progression of the swelling. The patient did well after treatment with Fab antivenom.

technique requires subjective interpretation. Measurement of the limb circumference is more objective and can be easily repeated to determine any progression (Fig. 12-4). These measurements should be recorded every 15 minutes for the first 2 hours and then less frequently (every 30-60 minutes). In addition to measuring the limb circumference, serial neurovascular examinations can identify any ischemia or evidence of compartment syndrome.

Compartment syndrome is rare (<1%-2%) after snake envenomation because it is unusual for a snake's fangs to penetrate the muscle fascia. The true incidence is difficult to ascertain from the literature because many of the older case series report the use of prophylactic fasciotomies without measuring the compartment pressure.<sup>52,53</sup> Although swelling may be severe, it is almost always localized to the subcutaneous tissue. If there is concern for compartment syndrome in the setting of severe pain and swelling, measurement of compartment pressures is necessary. Even if elevated compartment pressures are found, treatment with antivenom is usually sufficient to alleviate the elevated pressures and reverse the compartment syndrome.<sup>52-55</sup> Given the efficacy and safety of the newer crotalid antivenom routine, prophylactic fasciotomies are not indicated in the setting of an envenomation.<sup>56</sup> Recent evidence has shown that prophylactic fasciotomies worsen local effects and do not improve clinical outcomes.<sup>57,58</sup> If compartment pressures are elevated, they should be re-measured after antivenom administration and repeat antivenom can be given, if required. If the pressures remain elevated for more than 4 hours despite antivenom, then fasciotomy is indicated (Fig. 12-5). Measurement of finger compartment pressures is not possible. If significant concern exists about the viability of the finger, a digit dermatomy is indicated.<sup>58</sup>

Systemic manifestations present in a variable fashion after envenomation. Nonspecific symptoms and

**Table 12-6** Grading of Snake Envenomations

<b>Minimal</b>	Mild local swelling without progression; no systemic or hematologic toxicity
<b>Moderate</b>	Local swelling with proximal progression and/or mildly abnormal laboratory parameters (e.g., decreased platelets, prolonged coagulation studies)
<b>Severe</b>	Marked swelling with progression and/or significant systemic toxicity (shock, compartment syndrome) or laboratory abnormalities (severe thrombocytopenia/coagulopathy)

Adapted from Gold BS, Dart RC, Barish RA: Bite of Venomous Snakes. *N Engl J Med* 347:347-356, 2002.

**Figure 12-5.** The need for fasciotomy for compartment syndrome may be suggested by excessive swelling in the soft tissue, but compartment pressures are rarely elevated significantly. Prophylactic fasciotomy is based on the belief that it protects against compartment syndrome. Such practices are unnecessary and can be catastrophic in venom-defibrinated patients. (From Brent J, Wallace K, Burkhart K, et al: *Critical Care Toxicology: Diagnosis and Management of the Critically Poisoned Patient*. Philadelphia, Elsevier, 2005.)

signs include nausea, vomiting, diaphoresis, and metallic taste. Hypotension and shock can occur in severe cases. Severe rattlesnake envenomations often develop coagulopathy with a disseminated intravascular coagulation-like syndrome. Thrombocytopenia has been noted to be severe and prolonged after timber rattlesnake envenomations.<sup>59</sup> Canebrake rattlesnake envenomations have been associated with significant rhabdomyolysis.<sup>60</sup> It should be noted that although crotalid envenomations have characteristic findings, there is one exception. The Mojave rattlesnake, native to California and Arizona, is able to produce neurologic symptoms, including weakness and respiratory failure. Its venom has evolved and contains a neurotoxin that inhibits the release of acetylcholine from the presynaptic neuron in the neuromuscular junction.

## Management

After a crotalid bite, the victim should avoid exertion and have the involved extremity immobilized. These actions may act to decrease venom absorption into the systemic circulation. Rings, jewelry, and other constrictive clothing should be removed. Most importantly, the victim should be rapidly transported to the nearest emergency department.

Historically, different procedures and therapies have been advocated in the prehospital and in-hospital management of snakebites. Treatments such as cryotherapy and electric shock are associated with significant complications and are not recommended.<sup>61</sup> It is commonly thought that tourniquets should be applied to the affected extremity. However, their use has not been found to improve outcomes and evidence suggests they may worsen local toxicity.<sup>62-64</sup> Therefore, their use should be discouraged. Given the short transport times of most patients, the morbidity associated with tourniquet application (limb ischemia) outweighs any potential benefit.

In those situations in which the victim is in a remote location that is hours away from an emergency department, the use of a constriction band can be considered. There are limited data to suggest that constriction bands decrease the rate of systemic venom absorption.<sup>62</sup> Constriction bands differ from venous tourniquets in that they serve to impede lymphatic return rather than blood flow. When placed correctly, two fingers should easily slip under a constriction band.

Pressure immobilization is another modality commonly recommended for snakebites worldwide. It involves wrapping the entire limb in an elastic compression bandage and then immobilizing the limb in extension with a splint. Although likely effective in cases of elapid envenomations,<sup>65</sup> their use in cases of crotalid envenomation should be discouraged. An animal model of crotalid envenomation demonstrated pressure immobilization slightly prolonged the time to death but was associated with a significant increase in extremity compartment pressures.<sup>66</sup>

Suction therapy with an extractor device has been previously suggested. A commercially available device is widely obtainable from sporting goods retailers. The general assertion is that when applied shortly after a bite occurs, the suction generated by the device would pull the venom out of the wound. However, it has been demonstrated that these devices are not efficacious and remove less than 1% of injected venom.<sup>67</sup> These devices may actually increase the amount of local tissue destruction.<sup>68</sup> Therefore, use of extractor devices in the prehospital or hospital setting is not recommended.

Incision therapy, often combined with suction, gained favor in the early 20th century. This procedure entailed making several parallel incisions longitudinally along the affected extremity. While early animal models demonstrated some survival improvement, subsequent human studies have failed to show any change in clinical outcomes.<sup>69</sup> Incising the wound also risks injury to underlying tendons, nerves, and blood vessels and increases infection rates.<sup>69-71</sup>

In-hospital management should initially focus on assessing and supporting the airway, breathing, and circulation. Anaphylactic reactions have been reported after envenomation.<sup>72</sup> The initial evaluation should assess the patient for evidence of shock and hypoperfusion. Hypotension mandates aggressive resuscitation with crystalloid fluid, antivenom (see later), and vasopressors, if required. If the patient arrives in the emergency department with a tourniquet in place, it should be slowly loosened and removed over 20 to 30 minutes. Rapid removal of a tourniquet could result in delivery of a venom bolus to the central circulation, resulting in decompensation of the patient.<sup>62</sup> Intravenous access should be obtained in the noninjured extremity, with placement of a second access line in those with significant envenomation. Opioids are often required for management of pain. The patient's tetanus should be updated, if needed. Prophylactic antibiotics are not warranted because the risk of infection resulting from snakebites is less than 5%.<sup>73</sup> Although snakes do carry pathogenic bacteria in their mouths,

a majority of infections are secondary to the victim's normal skin flora.

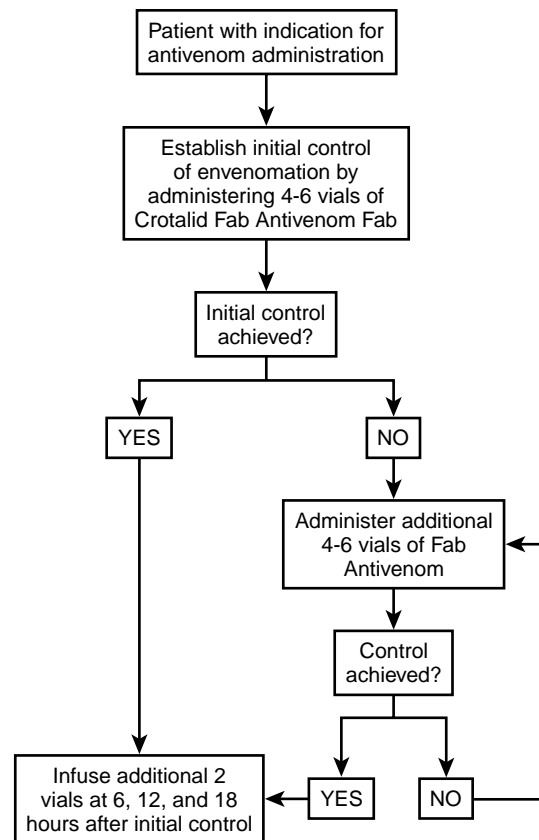

The antivenom supplies of the hospital should be assessed in all cases of snakebites, even those cases in which antivenom administration does not appear to be indicated. This is prudent because the patient's clinical condition can change rapidly in the first several hours after envenomation. It is important for the clinician to arrange for procurement of antivenom or hospital transfer while the patient is stable and not in immediate need of antivenom. A complete blood cell count, chemistries, coagulation studies, fibrinogen, and creatine kinase are indicated in all cases of snakebites to assess systemic toxicity. Medical toxicologists and regional poison centers (1-800-222-1222) can serve as valuable resources to clinicians who are unfamiliar with the management of snake envenomations.

Antivenom is indicated for envenomations displaying more than minimal local effects (Table 12-7). The older Wyeth (Collegeville, PA) polyvalent antivenom that was introduced in the United States in 1954 is no longer manufactured. This product was a crudely purified, equine-derived IgG antibody directed against the venom of several crotalids. Because it contained foreign proteins and the highly immunogenic Fc portion of the antibody, the incidence of immediate hypersensitivity reactions was high. Approximately 50% of recipients developed urticaria or signs of anaphylactic shock.<sup>74</sup> This mandated that patients be observed in a critical care setting and have an epinephrine infusion at the bedside. Serum sickness, a delayed immunologic reaction to the foreign proteins, is another adverse effect associated with antivenom. This reaction typically occurs 1 to 3 weeks after antivenom administration and manifests clinically as a fever, rash, arthralgias, myalgias, and occasionally glomerulonephritis and pericarditis. It is generally self-limited and can be treated with corticosteroids and antihistamines. Serum sickness was common after polyvalent antivenom use, with an incidence of more than 50% if more than 5 vials were administered.<sup>74</sup>

Fortunately, a new polyvalent immune Fab antivenom (CroFab, Protherics, Inc., Brentwood, TN) is available that is much safer and associated with significantly fewer adverse reactions. It is a highly purified product that contains the Fab fragments of IgG antibodies. The product is sheep derived and is effective against all North American crotalid species. The incidence of immediate hypersensitivity reactions is less than 5% to 10%.<sup>75-79</sup> Many of the hypersensitivity reactions are mild (urticaria) and do not prevent further antivenom administration. Anaphylaxis is uncommon. Likewise, the incidence of serum sickness is also less

**Table 12-7** Indications for Crotalid Antivenom

Shock
Coagulopathy and/or thrombocytopenia
Compartment syndrome
Significant swelling/progression of local effects
Neurotoxicity (Mojave rattlesnake)

**Figure 12-6.** This schematic depicts management of the patient who needs crotalid polyvalent immune Fab antivenom.

than 5%.<sup>78,79</sup> The dosing of polyvalent immune Fab is based on the clinical severity and response of the patient to the antivenom (Fig. 12-6). The dosing is not weight based. Therefore, the dosing in children is the same as in adults. Skin testing is not required. Clinical trials have demonstrated improved outcomes when regular follow-up doses of antivenom were given for recurrence (see later) of local and systemic toxicity in those who received a single dose of antivenom. This resulted in the development of the currently recommended dosing schedule. Multiple studies have demonstrated that the polyvalent immune Fab antivenom is efficacious in ameliorating the local and systemic venom toxicity. Recent analysis of pediatric data also demonstrates excellent efficacy and safety in treating children as young as 18 months of age. There were no cases of anaphylaxis in pediatric patients (>100 cases) reported in five case series.<sup>80-84</sup> Liberal use should be considered for bites involving the hands or feet because these envenomations are associated with significant morbidity and prolonged recovery.<sup>85</sup>

Recurrence is defined as worsening of local and/or systemic toxicity after a period of improvement with antivenom therapy. This results from the pharmacokinetic differences between the antivenom and venom.<sup>86</sup> The Fab components have a low molecular weight and are small enough to be freely filtered by the kidney. This results in an elimination half-life of Fab antivenom of about 15 to 20 hours versus venom that has a half-life

of approximately 40 hours.<sup>86,87</sup> Multiple reports have documented progression of swelling or worsening hematologic toxicity after antivenom therapy.<sup>75,78,88</sup> Those patients who develop hematologic toxicity during initial treatment are at highest risk for recurrence. Administration of antivenom is usually effective in treating further local progression. Although hematologic toxicity does not typically result in clinically significant bleeding, further antivenom administration is not effective in completely normalizing hematologic abnormalities.<sup>78,89</sup> Close monitoring is indicated, and treatment can be resumed in those with bleeding or markedly abnormal laboratory parameters.<sup>89</sup> A new Fab<sub>2</sub> immune antivenom (Anavip, Pharmasil, Inc., Columbia, MD) is currently in premarketing trials in the United States with the hope that it will have improved pharmacokinetics, thus potentially decreasing the incidence and severity of recurrence.

The disposition of patients who are bitten is dependent on the severity of the envenomation. Discharge after a 6- to 8-hour observation can be considered in those circumstances in which it is thought that no significant envenomation occurred (dry bite). There should be no appreciable local swelling, and results of initial laboratory studies and repeat laboratory studies before discharge should be normal. All patients with significant local swelling or evidence of systemic toxicity should be admitted for further evaluation and management. Rattlesnake bite victims from those areas in which the Mojave rattlesnake is endemic should be monitored for neurotoxicity.

## CORAL SNAKE ENVENOMATION

The coral snake is the only poisonous elapid snake native to the United States. While there are several species of coral snakes in the United States, the species

of greatest concern is found only in Florida and southern Georgia. These snakes are brightly colored and have bands in a distinctive pattern (black, yellow, red). This order gives rise to the common phrases, “red on yellow, kill a fellow” and “red on black, venom lack,” that can help to differentiate a coral snake from the nonpoisonous king snake. Unlike crotalids, coral snakes have round heads and pupils. Instead of fangs they have short teeth. It has been described that these snakes have to be removed from the victim similar to removing Velcro. Up to 25% of bites do not result in significant envenomation.<sup>90</sup>

Unlike crotalids that produce local tissue destruction and coagulopathy, venom from elapids is associated with neurotoxicity. The resulting toxicity is likely related to an acetylcholinesterase present in the venom. After a bite, local effects tend to be mild. Of greater concern is the risk of progressive weakness and resulting respiratory failure. Neurologic symptoms (cranial nerve palsies, weakness) typically develop within 2 hours but may be delayed up to 13 hours.<sup>90</sup> Given the lack of significant local effects, surgical management is not indicated.

All patients with suspected coral snake bites should be admitted for observation. Treatment is supportive with close monitoring for respiratory compromise and antivenom administration. Coral snake antivenom is an equine-derived IgG. It should be administered in all cases of suspected coral snake bites, even if the victim is asymptomatic. This is recommended because antivenom only prevents progression of symptoms and does not reverse any neurologic signs that have occurred. The recommended dose is 3 to 5 vials in asymptomatic patients, followed by another 5 vials in those who develop symptoms. In the largest series of U.S. coral snake envenomations, immediate hypersensitivity reactions occurred in 15% of patients, whereas serum sickness was reported in 10%.<sup>90</sup>

# BURNS

Dai H. Chung, MD • David N. Herndon, MD

For the past several decades, there have been major advances in the care of burns, resulting in significant improvement in the survival for patients with extensive burn injury. The development of the Lund and Browder burn diagram in 1944<sup>1</sup> allowed for assessment of the percent of the total body surface area (TBSA) burned. Other advances such as the determination of appropriate fluid resuscitation to treat burn shock and the introduction of topical antimicrobials (silver nitrate, mafenide acetate, silver sulfadiazine) have made significant impact as well. More recently, a better understanding of and further refinements in the areas of fluid resuscitation, infection control, support of the hypermetabolic response, treatment of inhalation injury, and early surgical excision and grafting of deep burn injuries have all contributed to a 50% decline in burn-related deaths and hospital admissions in the United States.<sup>2,3</sup>

Nearly 2 million burn injuries occur each year in the United States, with about half of these injuries occurring in children. Although a significant percentage of burn injuries are minor, approximately 50,000 patients suffer moderate to severe burns requiring hospitalization for treatment. Of these cases, approximately half are in children younger than 15 years of age. Children younger than the age of 5 account for 12% of burn-related hospital admissions. Moreover, nearly 40% of hospital admissions involve burns that affect more than 10% TBSA. The current mortality rate for burn patients is 5.6%, with burn injuries responsible for nearly 2500 deaths in children each year.<sup>4</sup>

Scald burns remain the most common cause of burn injury in children younger than 5 years of age. The majority of scald burns in infants and toddlers are from hot foods and liquids. Hot grease spills are notorious for causing deep burns to the involved areas. Hot tap water burns, which can easily be prevented by installing special faucet valves so that water does not leave the tap at a temperature above 120°F, frequently result in burns of larger areas to children. Children also frequently suffer product-related contact burns to their hands and faces from curling irons, ovens, steam irons, and fireworks. Contact with electrical outlets

and electric cords also causes a significant percentage of electrical injuries.

Child abuse also represents a significant cause of burns in children. Burns with a bilaterally symmetric distribution, a stocking-glove distribution, burns to the dorsum of hands, and delay in seeking medical attention should all raise the suspicion for possible child abuse. In the adolescent age group, flame burns are more common, frequently occurring as a result of experimenting with fire and volatile agents.

## PATHOPHYSIOLOGY

As the largest organ of the body, the skin guards against harmful environmental insults, prevents entry of microorganisms, and maintains fluid and electrolyte homeostasis. Skin is also important for thermoregulation, metabolism of vitamin D, and processing neurosensory inputs. The surface area of skin ranges from 0.2 to 0.3 m<sup>2</sup> in an average newborn to 1.5 to 2.0 m<sup>2</sup> in an adult. The epidermis is composed primarily of epithelial cells, specifically keratinocytes. The cells from the basal layer of keratinocytes (the stratum germinativum) divide and migrate outward to the stratum spinosum, granulosum, lucidum, and eventually the stratum corneum. These cells then eventually desquamate. This entire process of epidermal maturation from the basal layer to desquamation generally takes 2 to 4 weeks. The basement membrane at the dermoepidermal junction is composed of mucopolysaccharides rich in fibronectin and functions as a barrier to the passage of macromolecules. The dermis is made up of fibroblasts producing collagen and elastin and is subdivided into a superficial papillary dermis and a deep reticular dermis. The papillary and reticular dermis are separated by a plexus of nerves and blood vessels. The reticular dermis and fatty layer contain skin appendages such as hair follicles, sweat glands, and sebaceous glands.

Thermal injury produces coagulation necrosis of the epidermis and a varying depth of injury to the underlying tissue. The extent of burn injury depends on the

temperature, duration of exposure, skin thickness, tissue conductance, and specific heat of the causative agent. For example, the specific heat of lipid is higher than that of water. Therefore, grease burns often result in much deeper burns than a scald burn from water with the same temperature and duration of exposure. Thermal energy is easily transferred from high-energy molecules to those of lower energy during contact through the process of heat conduction. The skin generally provides a barrier to the transfer of energy to the deeper tissues. Therefore, much of the burn injury is confined to this layer. However, local tissue response to the zone of initial burn injury can lead to progression of the burn injury to surrounding tissue.

The area of cutaneous burn injury is divided into three zones: coagulation, stasis, and hyperemia (Fig. 13-1). The *zone of coagulation* comprises the initial burn eschar where cells become irreversibly damaged at the time of injury. The area immediately surrounding the necrotic area is called the *zone of stasis*. In this zone, most cells are initially viable but tissue perfusion becomes progressively impaired from the local release of inflammatory mediators, such as thromboxane  $A_2$ , arachidonic acid, oxidants, and cytokines.<sup>5</sup> Their influence on the microcirculation results in the formation of platelet thrombus, neutrophil adherence, fibrin deposition, and vasoconstriction, all of which lead to cell necrosis. Thromboxane  $A_2$  inhibitors can significantly improve the dermal blood flow to decrease the zone of stasis.<sup>6</sup> Antioxidants as well as bradykinin antagonists also improve local blood flow.<sup>7,8</sup> Inhibition of neutrophil adherence to endothelium with anti-CD18 or anti-intercellular monoclonal antibodies improves tissue perfusion in animal models.<sup>9,10</sup> The *zone of hyperemia* is characterized by vasodilation with increased blood flow as part of the inflammatory response. This zone lies peripheral to the zone of stasis.

The burn-induced inflammatory response is not limited to the local burn wound. A massive systemic release of thromboxane  $A_2$ , along with other inflammatory mediators (bradykinin, leukotrienes, catecholamines, activated complements, and vasoactive amines) induces a significant physiologic burden on the cardiopulmonary, renal, and gastrointestinal organ systems.<sup>11</sup> Decreased plasma volume due to increased capillary permeability and subsequent plasma leak into the interstitial space can lead to depressed cardiac

function. As a result of low cardiac output, renal blood flow can decrease, leading to a diminished glomerular filtration rate. Activation of other stress-induced hormones and mediators, such as angiotensin, aldosterone, and vasopressin, can further compromise renal blood flow, resulting in oliguria.<sup>12</sup> If not promptly recognized and treated, this condition can progress to acute tubular necrosis and subsequent renal failure, which contribute to poor outcome for burn patients.<sup>13</sup>

Burn injury can also affect remote organ systems such as the gastrointestinal tract. A rapid onset of atrophy of the small bowel mucosa occurs as a result of increased epithelial apoptosis and decreased epithelial proliferation.<sup>14-16</sup> Intestinal permeability to macromolecules, which are normally repelled by an intact mucosal barrier, increases after burns.<sup>17</sup> Transient mesenteric ischemia is thought to be an important contributing factor to an increase in intestinal permeability. This results in bacterial translocation and subsequent endotoxemia. Burn injury also causes a global depression of immune function. Macrophage production is decreased. Neutrophils are impaired in terms of diapedesis, chemotaxis, and phagocytosis; and cytotoxic T lymphocyte activity is decreased. These impaired functions of neutrophils, macrophages, and T lymphocytes contribute to an increased risk for infectious complications after burns.<sup>18,19</sup>

## INITIAL MANAGEMENT

The burned patient must be immediately removed from the thermal source of injury, obviously including burning clothes and metal jewelry. Immediate cooling, such as pouring cold water on the wound, can minimize the depth of burn injury, but it must be used with extreme caution only in a small BSA because it can result in systemic hypothermia. In case of chemical burns, victims should be quickly removed from the continued exposure to the causative chemical agent(s) and the wounds irrigated with copious amounts of water, taking care not to spread the responsible chemical agent(s) to adjacent uninvolved skin areas. Attempts to neutralize causative chemicals are contraindicated because this process may produce additional heat and further add insult to the initial burn injury.

**Figure 13-1.** Three zones of burn injury: coagulation, stasis, and hyperemia.

As with any trauma patient, burn patients are quickly assessed through primary and secondary surveys. Airway, breathing, and circulation status are assessed, and any potential life-threatening conditions should be promptly identified and intervention initiated. Respiratory symptoms such as wheezing, tachypnea, and hoarseness should alert impending major airway problems. Therefore, the airway should be rapidly secured with 100% oxygen support. Oxygen saturation is monitored using pulse oximetry, and chest expansion is observed to ensure adequate and equal air entry. Circumferential full-thickness burns to the chest can significantly impair respiratory functions by constricting the chest wall and preventing adequate chest expansion. If necessary, escharotomy should be performed to allow better chest expansion and subsequent ventilation. Blood pressure may be difficult to obtain in burned patients with charred extremities. A change in the pulse rate is a sensitive indicator for intravascular volume status. The presence of tachycardia should prompt aggressive fluid resuscitation.

The burn depth is categorized according to the depth of the injury: epidermis, papillary dermis, reticular dermis, subcutaneous fat, and underlying structures. *First-degree* burns are confined to the epidermis. The epidermis appears intact and erythematous and is painful to touch. Therapy is targeted toward symptomatic relief. This typically involves application of a topical ointment containing aloe vera along with a nonsteroidal anti-inflammatory agent. *First-degree* burns (e.g., sunburn) heal spontaneously without scarring in 7 to 10 days. *Second-degree* burns are divided into superficial and deep, based on the depth of dermal involvement. Superficial second-degree burns are defined as burn injury limited to the papillary dermis and are typically erythematous and painful with blister formation. Superficial second-degree burns also heal spontaneously with the re-epithelialization process taking place in 10 to 14 days. Slight skin pigment discoloration is usually the only significant sequela. Deep second-degree burns extend into the reticular layer of the dermis. The deep epidermal appendages allow some of these wounds to slowly heal over several weeks, usually with significant scarring. However, in general, deep second-degree burn injury requires surgical debridement and skin grafting for more rapid recovery and shorter hospitalization. *Third-degree* burns involve full-thickness injury and result in complete destruction of the epidermis, dermis, and dermal appendages. These burns are characterized by a dry, leathery eschar that is insensate to any stimuli. Without any residual epidermal or dermal appendages, burn wounds can heal by re-epithelialization from the burn wound edges. However, this process is slow, requiring prolonged hospitalization with the risk for burn wound infection. *Fourth-degree* burns involve organs beneath the layers of the skin, such as muscle and bone.

Accurate and rapid determination of burn depth is vital to the proper management of the injury. In particular, the distinction between superficial and deep dermal burns is critical because this dictates whether the burns can be managed with or without excision

and grafting. Evaluation by an experienced burn surgeon as to whether an apparent deep dermal burn will heal in 3 weeks is only about 50% accurate. Early excision and grafting provides better results than non-operative therapy for such "indeterminate" burns. More precise objective methods to determine the burn depth include techniques such as using a multisensor heatable laser Doppler flowmeter and fluorescein to determine blood flow, ultrasonography to detect denatured collagen, and light reflectance of the wound.<sup>20,21</sup> Ultimately, burn wound biopsy seems to be the most precise diagnostic tool.<sup>22</sup> However, it is not clinically practical because it is invasive and provides only a static evaluation of the burn wound. It also requires an experienced pathologist to interpret the histologic findings. Although clinical examination by an experienced burn surgeon remains the most reliable method of determining the burn depth, other diagnostic tools such as laser Doppler imaging and videomicroscopy (visualizing intact dermal capillaries) are gaining popularity for routine clinical use.<sup>23</sup>

Full-thickness circumferential burns to the extremities produce constricting eschar, which can result in vascular compromise to the distal tissues. Accumulation of tissue edema beneath the nonelastic eschar impedes venous outflow first and eventually affects arterial flow. When distal pulses are absent by palpation or on Doppler imaging, escharotomies should be performed to avoid vascular compromise of the limb tissues. With the use of either the scalpel or electrocautery unit, escharotomies can be performed at the bedside along the lateral and medial aspects of the involved extremities (Fig. 13-2). When the hands are involved, incisions are carried down onto the thenar and hypothenar eminences and along the dorsolateral aspects of the digits. Because of the full-thickness burn depth, minimal bleeding is encountered. With

**Figure 13-2.** Escharotomies. The incisions are made on the medial and lateral aspects of the extremity. Hand escharotomies are performed on the medial and lateral digits and on the dorsum of the hand. (From Eichelberger MR [ed]: *Pediatric Trauma: Prevention, Acute Care, Rehabilitation*. St. Louis, Mosby, 1993.)

prolonged tissue vascular compromise, reperfusion after an escharotomy may cause reactive hyperemia and further edema formation in the muscle compartments. Ischemia-reperfusion injury also releases free oxygen radicals, resulting in transient hypotension. If increased compartment pressures are noted, fasciotomy should be performed immediately to avoid permanent ischemic injuries to the nerves, muscles, and other soft tissues.

Intravenous access should be established immediately to deliver lactated Ringer's solution according to the resuscitation guidelines. Peripheral intravenous access is preferred, but femoral venous access is an ideal alternative in patients with massive burns, particularly involving extremities. When achieving vascular access is problematic in small children (<6 years of age) with burned extremities, intraosseous access is an alternative route of fluid and medication administration. However, proper technique must be used to avoid potential injury to bone growth plate. A nasogastric tube is introduced in all patients with major burns in anticipation of a gastric ileus and potential vomiting. In addition, almost immediate implementation of enteral nutrition via a transpyloric feeding tube can effectively eliminate burn-induced small bowel ileus. A urinary catheter should be inserted to accurately monitor urine output as a measure of end-organ perfusion. Admission laboratory tests should include complete blood cell count, type and crossmatch, chemistry profile, urinalysis, coagulation profile, and chest radiograph. Whenever inhalation injury is suspected,

arterial blood gas analysis with carboxyhemoglobin level should also be obtained.

The size of the burn is generally assessed by the "rule of nines" in adolescents and adults. Each upper extremity and head represent 9% of the TBSA and the lower extremities and the anterior and posterior trunks are 18% each. The perineum, genitalia, and neck each measures 1% of the TBSA. A quick rough estimate of the burn size can also be assessed by the use of the patient's palm, which represents 1% TBSA. However, the general use of this rule can be misleading in children because of different body proportions. Children have a relatively larger portion of their BSA in the head and neck and a smaller surface area in the lower extremities. For example, an infant's head constitutes 19% of TBSA compared with 9% in an adult. Thus, the modified "rule of nines" based on the anthropomorphic difference of infancy and childhood is generally used to assess pediatric burn size (Fig. 13-3).

### Fluid Resuscitation

Appropriate fluid resuscitation should begin immediately after securing intravenous access. Peripheral intravenous access is sufficient in the majority of small to moderate size burns. Saphenous vein cutdowns are useful in cases of difficult intravenous access in larger patients. In children, percutaneous femoral central venous access may be easier and more reliable when dealing with a difficult peripheral intravenous access situation. Many guidelines exist as fluid resuscitation

**Figure 13-3.** Modified "rule of nines" for pediatric burn patients. (Adapted from Lee J, Herndon DN: The pediatric burned patient. In Herndon DN [ed]: Total Burn Care, 3rd ed. Philadelphia, WB Saunders, 2007, p 487.)

Table 13-1 Formulas for Body Surface Area (BSA)	
<b>Dubois Formula</b>	$BSA (m^2) = \text{height (cm)}^{0.725} \times \text{weight (kg)}^{0.425} \times 0.007184$
<b>Jacobson Formula</b>	$BSA (m^2) = [\text{height (cm)} + \text{weight (kg)} - 60]/100$

formulas, delivering various concentrations of colloid and crystalloid solutions. The Parkland formula (4 mL of lactated Ringer's per kilogram of body weight per percentage of TBSA burned) is most widely used, but the child's fluid resuscitation formula should be based on his or her BSA because of the disparity of BSA to weight. Children have greater BSA relative to their body weight. As a result, weight-based formulas can under-resuscitate children with minor burns and may grossly over-resuscitate children with extensive burns.<sup>24</sup> TBSA can also be assessed from height and weight using standard nomograms or calculated using formulas (Table 13-1). The Shriners-Galveston formula utilizes 5000 mL/m<sup>2</sup> BSA burn plus 2000 mL/m<sup>2</sup> BSA of lactated Ringer's solution given over the first 24 hours after burn injury. Half of this volume is administered during the first 8 hours and the remaining half over the following 16 hours (Table 13-2).

The primary goal of fluid resuscitation is to achieve adequate organ and tissue perfusion regardless of which guidelines are used. Fluid administration should be titrated to maintain a urine output of 1 mL/kg/hr. Approximately 50% of administered fluid is sequestered in nonburned tissues in 50% TBSA burn patients due to increased capillary permeability that occurs particularly in the first 6 to 8 hours after injury.<sup>25</sup> During this period, large molecules leak into the interstitial space to increase the extravascular colloid osmotic pressure. Therefore, to maintain adequate intravascular osmotic pressure, albumin is added 12 hours after the injury. After the first 24 hours, 3750 mL/m<sup>2</sup> BSA burn is given to replace evaporative fluid loss plus 1500 mL/m<sup>2</sup> BSA per 24 hours for maintenance. Dextrose-containing solutions, such as 5% dextrose with 0.25 to 0.5 normal saline, are used as the primary solution. Children younger than 2 years of age are susceptible to hypoglycemia due to limited glycogen stores. Therefore, lactated Ringer's solution with 5% dextrose is given during the first 24 hours in these patients.

Table 13-2 Burn Resuscitation Formulas		
Formula	First 24 Hours	Fluid Solution
Parkland	4 mL/kg per %TBSA burn	Lactated Ringer's (LR)
Brooke	1.5 mL/kg per %TBSA burn	LR + colloid 0.5 mL/kg per %TBSA burn
Shriners-Galveston	5000 mL/m <sup>2</sup> burned + 2000 mL/m <sup>2</sup> total	LR + 12.5 g albumin

TBSA, total body surface area.

Children often do not exhibit clinical signs of hypovolemia until more than 25% of their circulating volume is depleted and complete cardiovascular collapse is imminent. Tachycardia reflects a compensatory response to hypovolemia, but caution should be used not to overinterpret this finding, because a reflex tachycardia owing to postinjury catecholamine response is also common. A lethargic child with decreased capillary refill and cool, clammy extremities needs prompt attention. Measurement of the arterial pH and base deficit can help interpret the adequacy of fluid resuscitation. Hyponatremia is also a frequent complication in pediatric burn patients after aggressive fluid resuscitation. Frequent monitoring of serum chemistry with appropriate correction is required to avoid severe electrolyte imbalance. A serious complication such as central pontine myelinolysis can occur as a result of rapid correction of hypernatremia.<sup>26</sup>

Hypertonic saline resuscitation can be beneficial in treating burn-induced shock.<sup>27</sup> This hypertonic fluid maintains intravascular volume more effectively by removing fluid from the interstitial space by osmosis, resulting in a decrease in generalized tissue edema. However, it is not widely used because of its potential risks for hypernatremia, hyperosmolarity, renal failure, and alkalosis.<sup>11</sup> Some favor the use of a modified hypertonic solution by adding one ampule of sodium bicarbonate to each liter of lactated Ringer's solution during the first 24 hours of resuscitation.<sup>28</sup> Burn units with experienced multidisciplinary team members are best prepared to handle major burns. Patients who sustain a major burn injury (Table 13-3) should be transferred promptly to a nearby burn center for their care.

The ideal target for fluid resuscitation should be to maintain adequate visceral organ perfusion while minimizing soft tissue edema as a result of the diffuse capillary leak. Over-resuscitation during the first 24 hours post burn has been shown to be associated with an increased incidence of pneumonia, bloodstream infection, acute respiratory distress syndrome, multiple-organ failure, and death.<sup>29</sup> "Permissive hypovolemia" during burn fluid resuscitation has been shown to improve multiple-organ dysfunction scores,<sup>30</sup> further suggesting that this is a safe and beneficial approach during acute burn resuscitation.

Table 13-3 Major Burn Injury Criteria (American Burn Association)	
Second-degree burns > 10% TBSA in patients younger than 10 yr	
Third-degree burns > 5% TBSA

Burns with significant preexisting medical disorders	

TBSA, total body surface area.

## INHALATION INJURY

Inhalation injury remains the major contributor to mortality in burn patients. The mortality rate of children with isolated cutaneous burns is 1% to 2%, but this significantly increases to approximately 40% in the presence of inhalation injury.<sup>31</sup> Inhalation injury is caused primarily by inhaled toxins such as fumes, gases, and mists. Although the supraglottic region can be injured by both thermal and chemical insults, tracheobronchial and lung parenchymal injuries rarely occur as a result of direct thermal damage because the heat disperses so rapidly in the larynx. Hypoxia, increased airway resistance, decreased pulmonary compliance, increased alveolar epithelial permeability, and increased pulmonary vascular resistance can be triggered by the release of vasoactive substances (thromboxanes A<sub>2</sub>, C<sub>3a</sub>, and C<sub>5a</sub>) from the damaged epithelium.<sup>32</sup> Neutrophil activation plays a critical role in this process. Pulmonary function has been shown to improve with the use of a ligand binding to E-selectins (inhibiting neutrophil adhesion) and anti-interleukin-8 (inhibiting neutrophil chemotaxis). Another significant respiratory tract pathology is sloughing of ciliated epithelial cells from the basement membrane, resulting in exudate formation. These exudates, consisting of lymph proteins, coalesce to form fibrin casts. These fibrin casts are frequently resistant to routine pulmonary toilet and can create a “ball-valve” effect in localized areas of lung. This eventually causes barotrauma.

The diagnosis is usually made on clinical history and physical findings at the initial evaluation. Victims trapped in a house fire with excessive smoke and fumes are likely to have sustained severe inhalation injury. Facial burns with singed hair and carbonaceous sputum suggest inhalation injury. Hoarseness and stridor should alert significant airway obstruction and the airway should immediately be secured with endotracheal intubation. Patients who present with disorientation and obtundation are likely to have an elevated carbon monoxide level (carboxyhemoglobin > 10%). Fiberoptic bronchoscopy remains the gold standard for diagnosing the presence of inhalation injury. It can demonstrate inflammatory changes in the tracheal mucosa such as edema, hyperemia, mucosal ulceration, and sloughing. A ventilation scan with xenon-133 can also identify regions of inhalation injury by assessing respiratory exchange and excretion of xenon by the lungs.<sup>33</sup> The use of these complementary diagnostic tools, bronchoscopy and xenon-133 scanning, is over 90% accurate in the diagnosis of inhalation injury. However, bronchoscopic examination of the airway at the bedside, without having to transport critically ill burn patients to nuclear medicine, is frequently sufficient to confirm the diagnosis of inhalation injury.

The treatment of inhalation injury begins at the scene of the burn accident. The administration of 100% oxygen rapidly decreases the half-life of carbon monoxide. The airway must be secured with intubation in patients with signs and symptoms of imminent respiratory failure. In the intensive care unit, inhalation treatment protocols have been effective in improving the

**Table 13-4** Inhalation Injury Treatment Protocol

Treatment	Interval/Dosage
Suction and lavage	Every 2 hours
Bronchodilators (Albuterol)	Every 2 hours
Nebulized heparin	5000-10,000 units with 3 mL NS every 4 hours
Nebulized acetylcysteine	20%, 3 mL q4h
Hypertonic saline	Induces effective coughing
Racemic epinephrine	Reduces mucosal edema

NS, normal saline.

clearance of tracheobronchial secretions and decreasing bronchospasm (Table 13-4). Aggressive pulmonary toilet with physiotherapy and frequent suctioning is important to prevent serious respiratory complications. The patient is frequently turned side to side along with chest physiotherapy every 2 hours. When physiologically stable, the patient is positioned out of bed in a chair as well as assisted to ambulate. Humidified air is delivered at high flow, and bronchodilators and racemic epinephrine are used to treat bronchospasm. Intravenous heparin has been shown to reduce tracheobronchial cast formation, minute ventilation, and peak inspiratory pressures after smoke inhalation. Inhalation treatments such as 20% acetylcysteine nebulized solution along with nebulized heparin is effective in improving the clearance of tracheobronchial secretions and minimizing bronchospasm and significantly improving reintubation rates and mortality.<sup>34</sup>

The presence of inhalation injury generally requires an increased amount of fluid resuscitation, up to 2 mL/kg/% TBSA burn more than would be required for an equal size burn without an inhalation injury. In fact, pulmonary edema that is associated with inhalation injury is not prevented by fluid restriction. Rather, inadequate resuscitation may increase the severity of pulmonary injury by sequestering neutrophils.<sup>35</sup> Corticosteroids have not been shown to be beneficial in inhalation injury. Prophylactic intravenous antibiotics are not indicated but are started with the clinical suspicion of pneumonia. Early pneumonia is usually the result of gram-positive organisms such as methicillin-resistant *Staphylococcus aureus*. Later infection is usually caused by gram-negative organisms, such as *Pseudomonas*. Antibiotic therapy should be guided by serially monitored sputum cultures and bronchial washings.

A recent report suggests that there is a distinct cytokine profile in pediatric burn patients with inhalation injury as an early predictor for high mortality.<sup>36</sup> Early alterations in serum levels of interleukin (IL)-6, IL-7, and IL-10 were found to be useful markers of high mortality in burned children with inhalation injury. Increased IL-6 and IL-10 as well as decreased IL-7 serum levels were associated with a greater risk for mortality, thus suggesting a valuable role for these diagnostic tools in the evaluation of severe pediatric burn patients with concomitant inhalation injury.

## WOUND CARE

The appropriate wound care is generally determined by an accurate assessment of the burn depth and size (Table 13-5). First-degree burns require no particular dressing, but the involved areas should be kept out of exposure to direct sunlight. They are generally treated with topical ointments for symptomatic pain relief. Superficial second-degree burns are treated with daily dressing changes with topical antimicrobial agents. They can also be treated with simple application of petroleum gauze or synthetic dressings to allow for rapid spontaneous re-epithelialization. Deep second- and third-degree burn wounds eventually require excision of the eschar with skin grafting.

## Antimicrobial Agents

Various topical antimicrobial agents have been used for management of burn wounds. None of these agents effectively prevent colonization of organisms that commonly harbor in the eschar, but they serve a purpose of maintaining bacterial quantity at less than  $10^2$  to  $10^5$  colonies/g of tissue. Routine punch quantitative wound biopsies of burned areas can document impending burn wound sepsis.

Silver sulfadiazine (Silvadene, Monarch Pharmaceuticals, Inc., Bristol, TN) is the most commonly used topical antimicrobial agent for burn wound dressings. Although it does not penetrate eschar, it has a broad spectrum of efficacy and soothes the pain associated

**Table 13-5** Burn Wound Dressings

Dressings	Advantages	Disadvantages
<b>Antimicrobial Salves</b>		
Silver sulfadiazine (Silvadene)	Painless; broad-spectrum; rare sensitivity	Leukopenia; some gram-negative resistance; mild inhibition of epithelialization
Mafenide acetate (Sulfamylon)	Broad-spectrum; penetrates eschar; effective against <i>Pseudomonas</i>	Painful; metabolic acidosis; mild inhibition of epithelialization
Bacitracin/Neomycin/Polymyxin B Nystatin	Ease of application, painless, useful on face Effective in inhibiting fungal growth; use in combination with Silvadene, Bacitracin	Limited antimicrobial property Cannot use in combination with mafenide acetate
Mupirocin (Bactroban)	Effective against <i>Staphylococcus</i> , including MRSA	Cost; poor eschar penetration
<b>Antimicrobial Soaks</b>		
0.5% Silver nitrate	Painless; broad-spectrum; rare sensitivity	No eschar penetration; discolors contacted areas; electrolyte imbalance; methemoglobinemia
Povidone-iodine (Betadine)	Broad-spectrum antimicrobial	Painful; potential systemic absorption; hypersensitivity
5% Mafenide acetate	Broad-spectrum antimicrobial	Painful; no fungal coverage; metabolic acidosis
0.025% Sodium hypochlorite (Dakin's solution)	Effective against most organisms	Mildly inhibits epithelialization
0.25% Acetic acid	Effective against most organisms	Mildly inhibits epithelialization
<b>Silver-impregnated</b>		
Aquacel, Acticoat	Broad-spectrum antimicrobial; no dressing changes	Cost
<b>Synthetic Dressings</b>		
Biobrane	Provides wound barrier; minimizes pain; useful for outpatient burns, hands (gloves)	Exudate accumulation risks invasive wound infection; no antimicrobial property
OpSite, Tegaderm	Provides moisture barrier; minimizes pain; useful for outpatient burns; inexpensive	Exudate accumulation risks invasive wound infection; no antimicrobial property
Transcyte	Provides wound barrier; accelerates wound healing	Exudate accumulation risks invasive wound infection; no antimicrobial property
Integra, Alloderm	Complete wound closure, including dermal substitute	No antimicrobial property; expensive; requires training, experience
<b>Biologic Dressings</b>		
Allograft (cadaver skin), Xenograft (pig skin)	Temporary biologic dressings	Requires access to skin bank; cost
Amniotic membrane	Minimizes dressing changes	Not widely used

MRSA, methicillin-resistant *S. aureus*.

with second-degree burns. Silver sulfadiazine on fine mesh gauze can be used separately or in combination with other antimicrobial agents, such as nystatin (Teva Pharmaceutical Industries, USA). The combination of Silvadene with nystatin has significantly reduced the incidence of *Candida* infection in burned patients.<sup>37</sup> The most common side effect is leukopenia. However, this is generally caused by margination of white blood cells and is usually transient.<sup>38</sup> When the leukocyte count falls below 3000 cells/mm<sup>3</sup>, changing to another topical antimicrobial agent typically resolves this side effect.

Mafenide acetate (Sulfamylon, UDC Laboratories, Inc., Rockford, IL) is more effective in penetrating eschar and is frequently used in third-degree burns. Fine-mesh gauze impregnated with Sulfamylon (10% water-soluble cream) can be applied directly onto the burn wound. Sulfamylon has a much broader spectrum of efficacy, including *Pseudomonas* and *Enterococcus*. It is also available in a 5% solution to soak burn wounds, eliminating the need to perform frequent dressing changes. Sulfamylon is a potent carbonic anhydrase inhibitor and can therefore cause metabolic acidosis. This side effect can usually be avoided by limiting the use of Sulfamylon to only 20% TBSA at any given time and rotating application sites every several hours with another topical antimicrobial agent. In addition, the application of Sulfamylon can be painful, which limits its practical use in an outpatient setting, especially in children.

In addition to 5% Sulfamylon solution, other agents are available as a soak solution. These include 0.5% silver nitrate and 0.025% sodium hypochlorite (Dakin's solution). These soak solutions are generally poured onto the gauze dressings, avoiding frequent dressing changes with potential loss of grafts or healing cells. Silver nitrate is painless on application and has broad coverage, but its side effects include electrolyte imbalance (hyponatremia, hypochloremia) and dark gray or black stains. A new commercially available dressing containing biologically active silver ions (Aquacel, ConvaTec Ltd., UK; Acticoat, Smith & Nephew, London, UK) holds promise for retaining the effectiveness of silver nitrate but without its side effects. Dakin's (0.025%) solution is effective against most microbes, including *Pseudomonas*. However, it requires frequent dosing because of the inactivation of hypochlorite on contact with protein. Moreover, it can also retard healing.<sup>39</sup> Petroleum-based antimicrobial ointments, such as polymyxin B and bacitracin (Polysporin), are painless and transparent, allowing easier monitoring of the burn wounds. These agents are mostly effective against gram-positive organisms. Their use is limited to facial burns, small areas of partial-thickness burns, and healing donor sites. As with Silvadene, these petroleum-based agents can also be used in combination with nystatin to suppress skin *Candida* colonization.

The use of silver-impregnated antimicrobial dressings (Aquacel, Acticoat) has gained popularity in recent years. Aquacel Ag is a silver-impregnated hydrocolloid dressing that becomes adherent to the wound within 24 hours after application and can be left on for up to 2 weeks without change. The antimicrobial activity is

equivalent to other silver-containing compounds.<sup>40</sup> A recent report demonstrated a shorter length of hospitalization as a result of reducing the complexity and number of dressing changes in pediatric burn patients when compared with treatment with silver sulfadiazine.<sup>41</sup>

The use of perioperative intravenous antibiotics has significantly contributed to an overall improvement in the survival of major burn patients during the past 2 decades. Bacteria colonized in the burn eschar can potentially shed systemically at the time of eschar excision and contribute to sepsis. It is our general practice to administer intravenous antibiotics against *Streptococcus*, *S. aureus*, and *Pseudomonas* perioperatively until quantitative cultures of the excised eschar are finalized. The antibiotic regimen should be guided by culture results and used appropriately for indicated clinical conditions.

## Burn Wound Dressings

Superficial second-degree burns can be managed using various methods. A topical antimicrobial dressing using Silvadene is most commonly used, but synthetic dressings, such as Biobrane (UDL Laboratories, Rockford, IL) and OpSite (Smith & Nephew, London, UK), offer unique advantages of eliminating frequent painful dressing changes and potential tissue fluid loss. The general principle behind these synthetic products is to provide sterile coverage of superficial second-degree burn wounds to allow rapid spontaneous re-epithelialization of the involved areas.

Biobrane is a bilaminate thin membrane composed of thin semipermeable silicone bonded to a layer of nylon fabric mesh that is coated with a monomolecular layer of type I collagen of porcine origin. This dressing provides a hydrophilic coating for fibrin ingrowth that promotes wound adherence. It is supplied in simple sheets or preshaped gloves for easy application (Fig. 13-4).<sup>42</sup> After being placed onto clean fresh superficial second-degree burn wounds using Steri-strips and bandages, the Biobrane dressing dries and becomes well adherent to burn wounds within 24 to 48 hours. Once adherent, the covered areas are kept open to air and examined closely for the first few days to detect any signs or symptoms of infection. As the

**Figure 13-4.** This burned right forearm and hand have been placed in a biobrane glove.

epithelialization occurs beneath the Biobrane sheet, it is easily peeled off the wound. Sterile aspiration of serous fluid underneath the Biobrane can preserve its use. However, if a foul-smelling exudate is detected, it should be removed and a topical antimicrobial dressing applied. The use of Biobrane has become widespread in the management of superficial second-degree burns because it has been shown to reduce pain and fluid and electrolyte loss, thereby allowing for application in an outpatient setting. Alternatively, OpSite or Tegaderm (3M Pharmaceuticals, St. Paul, MN) can also be used to cover superficial second-degree burn wounds. Commonly used as a postoperative dressing, it is easy to apply and provides an impervious barrier to the environment. It is also relatively inexpensive, and its transparent nature allows for easier monitoring of second-degree burn wounds. Despite lacking any special biologic factors (collagen and growth factors) to enhance wound healing, it promotes spontaneous re-epithelialization. Biobrane and OpSite are preferred to topical antimicrobial dressings when dealing with small superficial second-degree burn wounds, especially in the outpatient setting.

Synthetic and biologic dressings are also available for coverage of full-thickness burn wounds. Integra (Integra LifeSciences Corp., Plainsboro, NJ) consists of an inner layer made of a porous matrix of bovine collagen and the glycosaminoglycan chondroitin-6-sulfate, which facilitates fibrovascular ingrowth.<sup>43</sup> The outer layer is polysiloxane polymer with vapor transmission characteristics similar to normal epithelium. Integra serves as a matrix for the infiltration of fibroblasts, macrophages, lymphocytes, and capillaries derived from the wound bed and promotes the rapid neodermis formation for the treatment of full-thickness burn wounds (Fig. 13-5). After the collagen matrix engrafts into the wound in approximately 2 weeks, the outer silicone layer is replaced with epidermal autografts. Epidermal donor sites heal rapidly without significant morbidity. Moreover, Integra-covered wounds have less scarring. However, they are also susceptible to wound infection and must be monitored carefully. The use of Integra for children with large TBSA burns was recently evaluated for short- and long-term follow-up.<sup>44</sup> Burned

children treated with Integra demonstrated significantly decreased resting energy expenditure as well as increased bone mineral content and density, along with improved scarring at 24 months after burn injury, thus validating the use of this dermal substitute in the management of pediatric burned patients. Interestingly, Integra has also been successfully used as a dermal matrix host for the dispersal of keratinocytes as a novel skin-grafting technique.<sup>45</sup>

Alloderm (LifeCell Corp., Branchburg, NJ) is another dermal substitute with decellularized preserved cadaver dermis. This synthetic dermal substitute has a tremendous potential for minimizing scar contractures and improving the cosmetic and functional outcome. Biological dressings, such as xenografts from swine and allografts from cadaver donors, can also be used to cover full-thickness burn wounds as a temporary dressing. Particularly useful when dealing with large TBSA burns, biological dressings can provide immunologic and barrier functions of normal skin. The areas of xenograft and allograft are eventually rejected by the immune system and sloughed off, leaving healthy recipient beds for subsequent autografts. Although extremely rare, the transmission of viral diseases from the allograft is a potential concern.

Human amniotic membranes can also be used as an alternative burn wound dressing. Amnion has been used in the past for the treatment of burns. A recent prospective study compared the use of amnion as a biological dressing for pediatric facial burn patients to standard topical treatment.<sup>46</sup> Although patients in the amnion group had significantly fewer dressing changes, the overall time to healing, length of stay, and hypertrophic scarring were not different between the two treatment groups. Importantly, the use of amnion was not associated with an increased risk of infection, thus indicating the safe use of amnion as an alternative dressing for superficial second-degree burns.

## Excision and Grafting

Early excision with skin grafting has been shown to decrease operative blood loss and length of hospitalization and ultimately to improve overall survival of

**Figure 13-5.** Synthetic and biological dressings are available for coverage of full-thickness burn wounds. When left on for 2 weeks, Integra serves as a matrix for neovascularization in the treatment of full-thickness burns. It can be used on the face (A) or in other locations (B). At 2 weeks, a nonmeshed epidermal split-thickness skin graft (.006 to .008 inch) can be applied with good cosmetic results.

**Figure 13-6.** Tangential excision of eschar. The excision of eschar is performed to the depth of a viable, bleeding tissue plane. (From Herndon DN [ed]: *Total Burn Care*, 2nd ed. Philadelphia, WB Saunders, 2002, plate 2.)

burn patients.<sup>3,47</sup> Typically, tangential excision of the full-thickness burn wound is performed 1 to 3 days after burn injury when relative hemodynamic stability has occurred. Eschar is sequentially shaved using a powered dermatome and/or knife blades until a viable tissue plane is achieved (Fig. 13-6). Early excision of eschar (usually < 24 hours after burns) generally decreases operative blood loss due to the vasoconstrictive substances, such as thromboxane and catecholamines, in the burn wounds. Once the burn wounds become hyperemic 48 hours after burns, bleeding at the time of excision of the eschar can be excessive. Tourniquet and subcutaneous injections of epinephrine-containing solution can lessen the blood loss, but these techniques can potentially hinder the surgeon's ability to differentiate viable from nonviable tissues.<sup>48</sup> Topical hemostatic agents such as thrombin can also be used, but they are expensive and not very effective in preventing excessive bleeding from open wounds. In patients with deep full-thickness burns, electrocautery is useful to rapidly excise eschar with minimal blood loss. More importantly, the earlier the excision, the less blood loss occurs in burns greater than 30% TBSA.<sup>49</sup> However, scald burns are more difficult to assess the exact burn depth initially. Therefore, these burns require a more conservative approach with delayed excision. A recent innovative technique, Versajet hydrosurgery (Smith & Nephew, London, UK), utilizes streaming of water for tissue excision. This technique could eliminate significant bleeding associated with "traditional" tangential excision. In a prospective randomized trial, the Versajet technique was shown to produce a more precise and faster excision of burn wounds.<sup>50</sup>

Ideally, the excised burn wound is covered with autograft. Burn wounds less than 20% to 30% TBSA can be covered at one operation with split-thickness autografts. Split-thickness autografts are harvested

and the donor sites are dressed with petroleum-based gauze, such as Xeroform (Kendall Healthcare, Miami, FL) or Scarlet-red (Tyco Healthcare, Mansfield, MA). OpSite can also be used to cover donor sites. It is preferable to use sheet autografts for better long-term aesthetic outcome, but narrowly meshed autografts (1:1 or 2:1) have the advantages of limiting the total surface area of donor harvest and allowing better drainage of fluid at the grafted sites. With massive burns, the closure of burn wounds is achieved by a combination of widely meshed autografts (4:1 to 6:1) with allograft (2:1) overlay (Fig. 13-7). Repeat grafting is required for large burns with sequential harvesting of split-thickness autograft from limited donor sites until the entire burn wound is covered. As the meshed autografts heal, the allografts slough. However, the formation of significant scar remains the major disadvantage of this technique. Therefore, the use of widely meshed graft is avoided on the face and functionally important areas. Full-thickness grafts that include both dermal and epidermal components provide the best outcome for wound coverage with diminished contracture and better pigment match. However, its use is generally limited to small areas owing to the lack of abundant full-thickness donor skin.

The limitation of donor sites in patients with burns over massive areas is partially addressed with the use of systemic recombinant human growth hormone (rHGH). Administration of rHGH has resulted in accelerated donor site healing, allowing more frequent donor site harvest in a given period of time.<sup>51,52</sup> Use of rHGH decreased donor site healing time by an average of 2 days, which ultimately improved the overall length of hospitalization from 0.8 to 0.54 days per percentage of TBSA burned.<sup>51</sup> These effects from rHGH are thought to be due to stimulation of insulin-like growth factor (IGF)-1 release and induction of IGF-1 receptors in the burn wound.<sup>52</sup> Given alone, insulin has been shown to decrease donor site healing time from 6.5 to 4.7 days.<sup>53</sup> The decrease in donor site healing by 1 day between each harvest can significantly impact overall length of hospital stay in patients with massive burns who require multiple grafting procedures. The administration of rHGH in burned children was associated with a 23% reduction in total cost of hospital care for a typical 80% TBSA burn.<sup>51</sup>

**Figure 13-7.** Schematic diagram of wound covering with 4:1 meshed autograft with 2:1 meshed allograft overlay. (From Eichelberg MR [ed]: *Pediatric Trauma: Prevention, Acute Care, Rehabilitation*. St. Louis, Mosby, 1993, p 581.)

The use of cultured keratinocytes from the patient's own skin has generated considerable interest as a potential solution for massively burned patients with limited donor sites.<sup>54,55</sup> This concept of using cultured skin to provide complete coverage is appealing, but there are several problems to overcome. First, cultures of keratinocytes grow slowly. Once grafted, they are very susceptible to mechanical trauma, with successful results in only 50% to 70%. Also, a significantly longer hospital stay has been reported with the use of cultured epithelial grafts in patients with burns of more than 80% TBSA.<sup>56</sup> However, this technology may hold promise in treating massive burns in the near future. Recently, the ReCell technique,<sup>57</sup> a new process of skin grafting that separates keratinocytes from small split-thickness skin grafts and disperses them for spraying onto the excised wound, has gained considerable interest. This technique results in the need for smaller donor sites and is associated with less pain.

## HYPERMETABOLIC RESPONSE

Burn injury produces a hypermetabolic response that generally increases with increasing burn size and reaches a plateau at a 40% TBSA burn.<sup>58</sup> This response is characterized by increased energy expenditure, oxygen consumption, proteolysis, lipolysis, and nitrogen losses. These physiologic changes are induced by upregulation of catabolic agents such as cortisol, catecholamines, and glucagon, which act synergistically to increase the production of glucose, a principal fuel during acute inflammation.<sup>59</sup> Cortisol stimulates gluconeogenesis and proteolysis and sensitizes adipocytes to lipolytic hormones. Catecholamines stimulate the rate of glucose production through hepatic gluconeogenesis and glycogenolysis and also promotes lipolysis and peripheral insulin resistance. Thus, serum insulin levels are elevated but the cells are resistant.<sup>60</sup> This increase in glucagon, which is stimulated by catecholamines, further promotes gluconeogenesis.

A significant protein catabolism occurs in severe burns. Cortisol is catabolic and is partially responsible for the loss of tissue protein and a negative nitrogen balance. In addition, burn injury is associated with decreased levels of anabolic hormones such as growth hormone and IGF-1, which contributes significantly to net protein loss. The synthesis of protein, which is essential for the production of collagen for wound healing and antibodies and leukocytes for the immune response, requires a net positive nitrogen balance. Exogenous administration of rHGH, which increases protein synthesis, has been shown to improve nitrogen balance, preserve lean muscle mass, and increase the rate of wound healing.<sup>52</sup> However, the use of rHGH is associated with hyperglycemia along with increased free fatty acids and triglycerides, which limit its clinical applicability.

Excessive catecholamines in post-burn patients also contribute to persistent tachycardia and lipolysis. The consequences of these physiologic changes are cardiac failure and fatty infiltration of the liver. Propranolol

lowers resting heart rate and left ventricular work and decreases peripheral lipolysis without adversely affecting cardiac output or the ability to respond to cold stress.<sup>61-63</sup> Therefore, a combination use of rHGH and propranolol appears ideal. A recent prospective randomized controlled trial showed efficacy in rHGH and propranolol treatment in attenuating hypermetabolism and inflammation in severely burned children.<sup>64</sup> In this study, patients receiving rHGH (0.2 mg/kg/day) and propranolol (to decrease heart rate by 15%) for more than 15 days demonstrated significantly decreased percent predicted resting energy expenditure, C-reactive protein, cortisone, aspartate aminotransferase, alanine aminotransferase, free fatty acid, IL-6, IL-8, and macrophage inflammatory protein-1 $\beta$  when compared with controls. Other markers, such as serum IGF-1, IGF-binding protein-3, growth hormone, prealbumin, and IL-7 increased in rHGH/propranolol-treated burned patients. These findings further validate the beneficial role of combination treatment with rHGH and a  $\beta$  blocker in pediatric burn patients.

Another anabolic agent of recent interest in the management of severe burns has been oxandrolone. Oxandrolone (Upsher-Smith Laboratories, Inc., Minneapolis, MN), an oral synthetic derivative of testosterone with a lower androgenic/anabolic ratio, has been safely used to improve lean body mass and weight gain in severely burned adults and children.<sup>65</sup> A large prospective double-blind randomized study involving 235 severely burned children (TBSA > 40%) showed that oxandrolone treatment significantly increased lean body mass along with serum total protein, prealbumin levels, and mean muscle strength.<sup>66</sup> Interestingly, the oxandrolone-treated group also had a shorter hospital stay.

## NUTRITION

The metabolic rate of patients with burns significantly increases (1.5  $\times$  normal rate in a patient with 25% TBSA burns to 2  $\times$  in 40% TBSA burns).<sup>67</sup> Children are particularly vulnerable for protein-calorie malnutrition because of their proportionally less body fat and smaller muscle mass in addition to increased metabolic demands. This malnutrition is associated with dysfunction in various organ systems, including the immune system, and delayed wound healing. Feeding tubes are generally positioned in the duodenum under fluoroscopy immediately after the initial burn evaluation and enteral nutrition is started within hours after the injury. Early enteral feedings have been shown to decrease the level of catabolic hormones, improve nitrogen balance, maintain gut mucosal integrity, and decrease the incidence of sepsis and overall hospitalization.<sup>68-70</sup> Hyperalimentation in burn patients has clearly been shown to be associated with deleterious effects on the immune function, small bowel mucosal atrophy with an increased incidence of bacterial translocation, and a decrease in survival.<sup>71,72</sup>

Several formulas are used to calculate caloric requirement in burn patients. Both the Curreri

**Table 13-6** Nutritional Requirements for Burned Children (Shriners Burn Hospital–Galveston)

Age Group	Daily Caloric Requirements
Infant and toddler	2100 kcal/m <sup>2</sup> total + 1000 kcal/m <sup>2</sup> burn
Child	1800 kcal/m <sup>2</sup> total + 1300 kcal/m <sup>2</sup> burn
Adolescent	1500 kcal/m <sup>2</sup> total + 1500 kcal/m <sup>2</sup> burn

(25 kcal/kg plus 40 kcal/% TBSA burned) and modified Harris-Benedict (calculated or measured resting metabolic rate times injury factor) formulas use the principle of providing maintenance caloric needs plus the additional caloric needs related to the burn size. Similar to fluid resuscitation formulas, a caloric requirement formula based on total and burned BSA is more appropriate for pediatric burn patients (Table 13-6).<sup>73-75</sup> The exact nutrient requirements of burn patients are not clear, but it is generally accepted that maintenance of energy requirement and replacement of protein losses are vital. The recommended enteral tube feedings should have 20% to 40% of the calories as protein, 10% to 20% as fat, and 40% to 70% as carbohydrates. Milk is one of the least expensive and best tolerated nutritional substances, but sodium supplement may be needed when milk is used in a large quantity to avoid dilutional hyponatremia. There are also numerous commercially available enteral formulas, such as Vivonex (Nestle-Nutrition, Switzerland) or PediaSure (Abbott Laboratories, Abbott Park, IL).

One recent report evaluated the efficacy of an anti-inflammatory, pulmonary enteral formula in the treatment of pediatric burn patients with respiratory failure.<sup>76</sup> Based on evidence that the inclusion of dietary lipids (e.g., omega-3 fatty acid, eicosapentaenoic acid) known to modulate the inflammatory response and the addition of antioxidants may improve cardiopulmonary function and respiratory gas exchange, this study evaluated the role of a specialized pulmonary enteral formula (SPEF) containing anti-inflammatory and antioxidant-enhanced components in pediatric burn patients. The use of SPEF was shown to be safe in pediatric patients and resulted in an improvement in oxygenation and pulmonary compliance in burn patients with acute respiratory distress syndrome (ARDS).

## PAIN MANAGEMENT

Burn wound treatment and rehabilitation therapy produce pain for patients of all age groups. Infants and children do not express their pain in the same way as adults and may display pain through behaviors of fear, anxiety, agitation, tantrums, depression, and withdrawals. In older children, allowing the child to participate in providing wound care can help the child to have some control and alleviate fear and pain. Various combinations of analgesics with antianxiety

medications are used effectively during procedures and wound dressing changes. Successful pain management of burned children requires understanding by the entire burn team members of how the pain is associated with burn depth and the phase of wound healing. Pain management protocols should be tailored to control background pain as well as specific procedure-related painful stimuli such as dressing changes, vascular access placement, and physical therapy. Scheduled administration of acetaminophen can often address background pain. Morphine sulfate or fentanyl is frequently used to manage postoperative pain. The intravenous use of ketamine (0.5-2.0 mg/kg) is quite effective and ideal for short procedures, such as dressing changes and vascular access placements. For burned children requiring deeper sedation and analgesia, a combination strategy with propofol and ketamine has also been shown to be effective.<sup>77</sup> Advanced pain management protocols can be administered safely by those experienced with the use of conscious sedation. Physical therapy, which is vital to optimize good functional outcome, can more effectively be employed if there is appropriate pain control. However, caution must be exercised to prevent any potential injury due to overmedication at the time of exercise therapy. Burn injury is extremely traumatic for affected children as well as their families.

## NONTHERMAL INJURIES

### Chemical Burns

Children accidentally come in contact with various household cleaning products. Treatment of chemical burns involves the immediate removal of the causative agent and lavage with copious amounts of water with caution for potential hypothermia. Fluid resuscitation is started, and care should be taken to ensure that the effluent does not contact uninjured areas. After completion of the lavage, the wounds should be covered with a topical antimicrobial dressing and appropriate surgical plans made. The rapid recognition of the offending chemical agent is crucial for proper management.<sup>78</sup> When there is doubt, the local poison control center should be contacted for identification of the product's chemical composition. The common offending chemical agents can be classified as alkali or acid. Alkalis, such as lime, potassium hydroxide, sodium hydroxide, and bleach, are among the most common agents involved in chemical injury. Mechanisms of alkali-induced burns are saponification of fat resulting in increased cell damage from heat, extraction of intracellular water, and formation of alkaline proteinates with hydroxyl ions. These ions induce further chemical reaction into the deeper tissues. Attempts to neutralize alkali are not recommended because the chemical reaction can generate more heat and add to the injury. Acid burns are not as common. Acids induce protein breakdown by hydrolysis and result in eschar formation. Therefore, these burns do not penetrate as deeply as the alkaline burns. Formic acid

injuries are rare but can result in multiple systemic organ failures such as metabolic acidosis, renal failure, intravascular hemolysis, and ARDS. In general, hydrofluoric acid burns are managed differently from other acid burns.<sup>79</sup> After copious local irrigation with water, fluoride ion must be neutralized with topical application of 2.5% calcium gluconate gel. If not appropriately treated, free fluoride ion causes liquefaction necrosis of the affected soft tissues, including bones. Because of potential hypocalcemia, patients should be closely monitored for prolonged QT intervals.

## Electrical Burns

Three to 5 percent of all admitted burn patients are injured from electrical contact. Fortunately, electrical burns are rare in children. Electrical burns are categorized into high- and low-voltage injuries. High-voltage injuries are characterized by a varying degree of local burns with destruction of deep tissues.<sup>80</sup> The electrical current enters part of the body and travels through tissues with the lowest resistance (nerves, blood vessels, and muscles). Heat generated by the transfer of the current damages deep tissues. This damage may not be easily visualized. Skin is mostly spared due to the high resistance to electrical current. Primary and secondary surveys, including electrocardiography, should be completed. If the initial electrocardiogram is normal, no further monitoring is necessary. However, any abnormal findings require continued monitoring for 48 hours and appropriate treatment of dysrhythmias when detected.<sup>81</sup> The key to managing electrical burns lies in the early detection and proper treatment of injuries to deep organs and tissues. Edema formation and subsequent vascular compromise is common to extremities. Fasciotomies are frequently necessary to avoid potential limb loss. If myoglobinuria develops, vigorous hydration with sodium bicarbonate and mannitol is indicated. Low-voltage injury is similar to thermal injury without transmission of the electrical current to deep tissues and usually only requires local wound care.

## OUTPATIENT BURN CARE

The majority of all pediatric burns are minor, often resulting from scald accidents and affecting less than 10% TBSA, or from thermal injuries isolated to the hands from touching hot curling irons. Such injuries are usually limited to partial thickness of the skin and can be treated as an outpatient. After an initial assessment, the burn wound is gently washed with water and a mild bland soap with appropriate measures taken for pain control. Blisters are left intact, especially on the palms of the hand, because they can provide a natural barrier against the environment and help to avoid the need for daily dressing changes. Spontaneous resorption of the fluid occurs in approximately 1 week with the re-epithelialization process. Larger areas of blisters should be debrided and topical antimicrobial dressings applied. Silvadene is most commonly used with the fewest side effects. However,

because silver sulfadiazine can impede epithelialization, its use should be discontinued when healing partial-thickness wounds are devoid of necrotic tissue and evidence of re-epithelialization is noted. Alternatively, antimicrobial dressings with triple antibiotic ointment (neomycin, bacitracin, and polymyxin B sulfate) and Polysporin are commonly used. Neither has any negative effects on epithelialization. For small superficial partial-thickness burns, nonmedical white petrolatum-impregnated fine mesh or porous mesh gauze (Adaptic, Johnson & Johnson Gateway, LLC, Piscataway, NJ) or fine mesh absorbent gauze impregnated with 3% bismuth tribromophenate in a nonmedicinal petrolatum blend (Xeroform) is usually sufficient without the need for topical antimicrobial agents.

Superficial burns to the face can be treated by applying triple antibiotic ointment only without any dressings. The frequency of dressing change varies from twice daily to once a week, depending on the size, depth of burns, and drainage. Those who advocate twice-daily dressing changes base their care on the use of topical antimicrobial agents whose half-life is 8 to 12 hours. Others who use petrolatum-based or bismuth-impregnated gauze recommend less frequent dressing changes of once every 3 to 5 days. The use of synthetic wound dressings (e.g., Biobrane) is also ideal for the treatment of superficial partial-thickness burns on an outpatient basis (see Fig. 13-4).<sup>82</sup> Although daily dressing changes are eliminated, Biobrane-covered wounds should still be monitored closely for signs of infection.

## REHABILITATION

Rehabilitation therapy is a vital part of burn care. During the acute phase of burn care, splints are used to prevent joint deformities and contractures. By using thermoplastic materials, which are amendable to heat manipulation, splints can be fitted individually to each patient. Application of splints at all times, except during the exercise period, can potentially prevent severe contractures that occur in large burns. Patients are mobilized out of bed immediately after graft take, and aggressive physical therapy is encouraged. After the acute phase, hypertrophic scar formation is a major concern. Burn depth, patient's age, and genetic factors all play an important role in hypertrophic scar formation. In general, deep second-degree burns, requiring 3 weeks or more to heal, will produce hypertrophic scarring. Children are more prone to hypertrophic scar formation than adults, probably because of the high rate of cell mitosis associated with growth. Constant pressure, 24 hours per day, is the most effective way to decrease the incidence of hypertrophic scar formation. Pressure garments should be worn until scars mature. Scar maturation usually occurs 6 to 18 months after injury. In younger patients, scars mature at a much slower rate. In addition to splints and pressure garments, exercise therapy is a crucial component of rehabilitation therapy. Families should be thoroughly instructed on a program of range of motion exercises and muscle strengthening.

# EARLY ASSESSMENT AND MANAGEMENT OF TRAUMA

Arthur Cooper, MD, MS

**T**rauma is the leading cause of mortality and morbidity in children from ages 1 to 14 years. It results in more death and disability than all other childhood diseases combined.<sup>1</sup> It is defined as forceful disruption of bodily homeostasis. Moreover, this term encompasses those injuries whose severity poses a demonstrable threat to life, which corresponds to an Injury Severity Score (ISS) of 10 or higher in children or a Pediatric Trauma Score (PTS) of 8 or lower.<sup>2</sup>

The term *first trauma* refers to the anatomic and physiologic disruption that results from acute injury. The term *second trauma*, defined and described by the American Trauma Society, refers to the social and familial dislocation associated with first trauma, which is often considerable in pediatric patients. Pediatric trauma remains a major public health problem in the United States, killing more than 10,000 pediatric patients annually nationwide<sup>1</sup> and causing some 10% of all pediatric hospitalizations,<sup>3</sup> about 15% of all pediatric intensive care unit admissions,<sup>4</sup> approximately 25% of pediatric emergency department visits,<sup>5</sup> and 50% or more of all pediatric ambulance runs.<sup>6</sup> Moreover, it also represents nearly 20% of all hospitalizations for serious injury among all age groups.<sup>7</sup>

## TRAUMA EPIDEMIOLOGY

The incidence of serious traumatic injury, with hospitalization as the indicator of injury severity, is approximately 420/100,000.<sup>8</sup> Although the hospital-based fatality rate is 2.4/100,000, the population-based mortality rate is 11.8/100,000, indicating that 78% of lethally injured children die before hospital admission and demonstrating the need for effective injury prevention and prehospital care. The population-based mortality rate for pediatric injuries serious enough to require hospitalization is 3.2%.<sup>7</sup> Intracranial injuries are the cause of most pediatric trauma deaths because of the untoward effects of traumatic coma on airway patency, breathing control, and cerebral perfusion. Conversely,

intrathoracic and intra-abdominal injuries are the cause of few pediatric trauma deaths, because they are infrequently associated with hypotensive shock.<sup>9</sup>

Most blunt trauma in childhood is sustained unintentionally (during the course of family, play, or sports activities), but 7% of serious injuries are due to intentional physical assault (of which nearly half, or 3%, are due to physical abuse).<sup>10</sup> Blunt injuries outnumber penetrating injuries in children by a ratio of 12:1, a ratio that has decreased significantly in recent years. While blunt injuries are more common, penetrating injuries are more lethal. Still, the leading killer of children is the motor vehicle, responsible for approximately 75% of all childhood deaths, which are evenly split between those resulting from pedestrian trauma and those resulting from occupant injuries (Table 14-1).

## INJURY RISKS

Lack of adequate or appropriate supervision of children during play involving possible injury hazards is recognized by all caretakers as a major risk factor for unintentional injury in pediatric patients, but drug and alcohol use, obesity, poverty, and race also influence injury rates. Toxicology screens are reportedly positive in 10% to 40% of injured adolescents, while obese children and adolescents, despite less severe head injuries, appear to have more complications and require longer stays in the intensive care unit.<sup>11-14</sup> For reasons poorly understood, race and ethnicity may also affect injury risk independent of socioeconomic status, particularly among African-American children, whose rate of death from preventable injuries, head injuries, and child abuse is three to six times higher than that of white children.<sup>15-17</sup> Improper use of motor vehicle restraints may contribute to the increased fatality rates of African-American children, who are only one half as likely to be restrained as white children involved in motor vehicle accidents and only one third as likely to be placed in car seats during such events.<sup>18</sup>

<b>Table 14-1 Incidence and Mortality of Pediatric Trauma</b>		
<b>By Injury Mechanism</b>	<b>Incidence (%)</b>	<b>Mortality (%)</b>

\*Collective mortality of these seven categories.

†Collective mortality of these two categories.

From Discala C: National Pediatric Trauma Registry Annual Report.

Boston, Tufts University Rehabilitation and Childhood Trauma Research and Training Center, 2002, with permission.

Analysis of the Crash Injury Research Engineering Network (CIREN) database has recently yielded valuable information about the pattern of childhood injuries after motor vehicle accidents: (1) child victims of frontal crashes were more likely to suffer severe spine and musculoskeletal injuries; (2) those of lateral crashes were more likely to suffer head and chest injuries; (3) those in front seats sustained more injuries to the chest, abdomen, pelvis, and axial skeleton than those in the rear seats; (4) seat belts were especially

protective against pelvic and musculoskeletal injuries; (5) children involved in high-severity, lateral-impact crashes typically sustained injuries characterized by higher Injury Severity Scores (ISSs) and lower Glasgow Coma Scale (GCS) scores.<sup>19,20</sup> Special attention has also been directed toward appreciation of injuries suffered by seat belt-restrained, rear-seat child passengers. A “concussion cluster” is sustained by about 10%, an “abdominal/spine cluster” by about 55%, and a “mixture cluster” by the remainder.<sup>21</sup> Restraint devices have also been subjected to careful analysis in recent years: (1) they do not appear to protect young victims of motor vehicle accidents as well as older victims; (2) car seats may not significantly affect injury outcome; (3) improper application may predispose to abdominal injuries, even in low-severity crashes; (4) the presence of abdominal wall bruising in restrained children, although rare, is strongly indicative of intra-abdominal injury.<sup>22-25</sup> Direct impact from a bicycle handlebar remains highly predictive of the need for operation.<sup>26</sup>

## INJURY OUTCOMES

In recent years, much effort has been devoted to outcomes research in pediatric trauma with the hope that benchmarking of treatment results may lead to better care for injured children. Both historical studies and contemporary investigations indicate that children survive more frequently and recover more fully in hospitals that specialize in pediatric trauma than in other hospitals. The availability of pediatric subspecialty and nursing support, as well as pediatric equipment, resources, and facilities, appears to matter far more than whether care is (1) provided in a children’s hospital or a general hospital committed to treatment of injured children or (2) directed by a pediatric surgeon or an adult surgeon with a special interest in pediatric trauma care.<sup>27-44</sup> No less important than survival outcome is functional outcome, for which several studies now indicate improved outcomes in hospitals that specialize in pediatric trauma care. However, they also suggest that whereas children may recover from injury more quickly than adults, physical function may not fully normalize.<sup>33-45</sup> Even so, self-perceived long-term quality of life among seriously injured children may not be adversely affected, justifying an aggressive approach to pediatric trauma resuscitation.<sup>46</sup>

Perhaps the most important recent development for outcomes research in pediatric trauma has been the expansion of the National Trauma Data Bank™ (NTDB™) of the American College of Surgeons to fully embrace children. The NTDB™ annual report is based on the most recent 5 years of case records submitted to the NTDB™, which approximates 250,000 total pediatric reports (<http://www.ntdb.org>).<sup>47</sup> Although currently designed as a simple case repository, efforts are underway to develop a representative national sample from the NTDB™ to provide population estimates of severe pediatric injury, as well as benchmarks for quality of pediatric trauma care. Preliminary data suggest that such benchmarks perform as well as existing measures.<sup>48</sup>

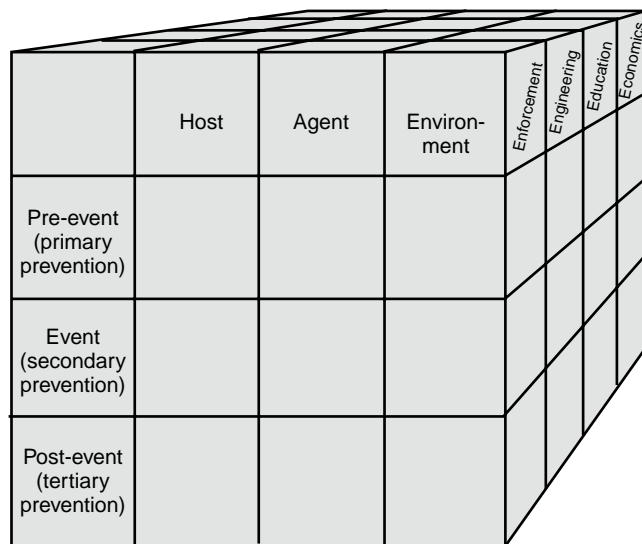

## INJURY PREVENTION

Injuries are not accidents but rather are predictable events that respond to risk- and harm-reduction strategies similar to those applied to other diseases. The Haddon Factor Phase Matrix neatly depicts these in graphic form (Fig. 14-1).<sup>49</sup> It demonstrates how strategies to lessen the burden of injury can be applied to the host, agent, and environment before, during, and after the traumatic event using enforcement, engineering, education, and economics as techniques to minimize the adverse impact of each factor.

Effective injury-prevention programs are community based and require extensive collaboration with civic leaders, governmental agencies, and neighborhood coalitions. Programs such as the National Safe Kids Campaign (<http://www.safekids.org>) and the Injury Free Coalition for Kids (<http://www.injuryfree.org>) have proven highly successful in reducing the burden of childhood injury in many communities.<sup>50,51</sup> Such programs require ongoing collaboration between trauma programs and local public health entities so the incidence of injury can be tracked by locality and specific plans made to target high-frequency risks, which can be precisely quantified using tools such as the Injury Prevention Priority Score (IPPS).<sup>52,53</sup>

## INJURY MECHANISMS

The effects of injury on the pediatric patient are related to the laws of physics and biomechanics. The kinetic energy transferred is equal to one half of the mass of the impacting object times its velocity squared. However, because the child's body is smaller, it is compacted into a smaller

**Figure 14-1.** The Haddon Factor Phase Matrix, as modified and refined to include a third strategic dimension, integrates all phases of injury control into a single system. (Adapted from Haddon W: Advances in the epidemiology of injuries as a basis for public policy. Public Health Rep 95:411-421, 1980; and Runyan CW: Using the Haddon Matrix: Introducing the third dimension. Inj Prev 4:302-307, 1998).

space. In blunt trauma, the forces of impact are dependent on factors such as the size and speed of the vehicle or the vertical displacement after a fall. These impact forces can be mitigated through use of design elements such as roll bars and crumple zones in automobiles; active and passive restraint devices such as lap belts, shoulder harnesses, air bags, and age-specific and properly fitted infant car seats or child booster seats for young passengers; helmets for bicycle riders; safety surfaces beneath playground equipment; and window guards in medium- and high-rise buildings. In penetrating trauma, the forces of violation are dependent on the weapon used (specifically, the size of the missile it discharges and the muzzle velocity with which it is delivered).

Injury mechanism is the main predictor of injury pattern. Motor vehicle pedestrian trauma results in the Waddell triad of injuries to the head, torso, and lower extremity: pelvis, femur, or tibia (Fig. 14-2). Motor vehicle occupant injuries may cause head, face, and neck injuries in unrestrained passengers. Cervical spine injuries, bowel disruption or hematoma, and Chance fractures occur in restrained passengers (Fig. 14-3). Bicycle trauma results in head injury in unhelmeted riders as well as upper extremity and upper abdominal injuries, the latter the result of contact with the handlebar (Fig. 14-4). Low falls, the most common cause of childhood injury, rarely produce significant trauma, but high falls from the second story or higher are associated with serious head injuries, with the addition of fractures of long bones if falling from the third story. Intrathoracic and intra-abdominal injuries result from falls from the fifth story (the height from which 50% of children can be expected to die after a high fall) (Table 14-2).<sup>54</sup>

## INJURY PATTERNS

The injured child is subject to different mechanisms of injury than the adult. The body regions most frequently injured in major childhood trauma are the lower extremities, head and neck, and abdomen. In minor childhood injury, soft tissue and upper extremity injuries predominate. Because most pediatric trauma is blunt trauma involving the head, it is primarily a disease of airway and breathing rather than of circulation, bleeding, and shock. Even so, although neuroventilatory derangements (abnormalities in GCS score and respiratory rate) are five times more common than hemodynamic derangements, the latter are twice as lethal as the former.<sup>9</sup>

Injuries to specific body regions give rise to specific anatomic diagnoses (see Table 14-1). Because multiple injuries usually involve the head and neck, brain injury constitutes a major cause of injury mortality in childhood. Precise estimates of injury mortality by anatomic diagnosis cannot presently be calculated, owing to lack of population-based databases and the inability to determine with accuracy the relative contribution of individual diagnoses to injury mortality in multisystem trauma. Despite these constraints, brain injuries are directly (primary tissue injury) or indirectly (secondary

**Figure 14-2.** The Waddell triad of injuries to head, torso, and lower extremity is depicted. (From Foltin G, Tunik M, Cooper A, et al [eds]: Teaching Resource for Instructors of Prehospital Pediatrics. New York, Center for Pediatric Emergency Medicine, 1998. Accessed at <http://www.cpem.org>.)

**Figure 14-3.** The mechanism for the development of intestinal and vertebral injuries from lap belts is shown. (From Foltin G, Tunik M, Cooper A, et al [eds]: Teaching Resource for Instructors of Prehospital Pediatrics. New York, Center for Pediatric Emergency Medicine, 1998. Accessed at <http://www.cpem.org>.)

hypoxic injury due to respiratory failure and shock) responsible for 75% of childhood trauma deaths.<sup>55-57</sup>

## Head

Head injuries are potentially more dangerous in children than in adults for several reasons. First, developing neural tissue is delicate. The softer bones of the

skull allow impacting forces to be transmitted directly to the underlying brain, especially at points of bony contact. Second, intracranial bleeding in infants in whom the fontanelles and sutures remain open may, on rare occasions, be severe enough to cause hypotensive shock. Third, the proportionately larger size of the head, when coupled with the injury mechanisms commonly observed in children, virtually guarantees that most serious blunt trauma in childhood will involve the brain and produce loss of consciousness. As a consequence, the voluntary muscles of the neck lose their tone, promoting development of soft tissue obstruction in the upper airway (which leads to hypoxia). It follows that diffuse brain injuries, particularly cerebral swelling (which results chiefly from cerebral hypoxia, loss of cerebral pressure autoregulation, and subsequent cerebral hyperemia, instead of vasogenic edema), are more common in childhood than in later years. Focal areas of cerebral contusion or laceration may occur adjacent to bony prominences in a coup-contrecoup pattern (typically in the frontal and temporal lobes), but major intracranial hemorrhage is uncommon and usually does not warrant surgical evacuation. Bilateral subdural hematomas in infants are indicative of child abuse (particularly when associated with retinal hemorrhages) and result from tearing of the bridging meningeal veins associated with the whiplash shaken impact syndrome.

## Neck

Cervical spine injury is an uncommon event in pediatric trauma, occurring at a rate of 1.8/100,000 population, in contrast to closed-head injury, which occurs at a rate of 185/100,000 population.<sup>58</sup> When such injury does occur, it is more frequent at levels (C2, C1, and

**Figure 14-4.** Children riding bicycles can sustain blunt abdominal trauma after contact with handlebars or head trauma from falling off the bicycle. (From Foltin G, Tunik M, Cooper A, et al [eds]: Teaching Resource for Instructors of Prehospital Pediatrics. New York, Center for Pediatric Emergency Medicine, 1998.)

the occipitoatlantal junction) above those whose nerve roots give rise to diaphragmatic innervation (C4), predisposing the child to respiratory arrest as well as muscular paralysis. The increased angular momentum produced by movement of the proportionately larger head, the greater elasticity of the interspinous ligaments, and the more horizontal apposition of the cervical vertebrae are responsible for this spectrum of injuries. Subluxation without dislocation causes spinal cord injury without radiographic abnormality (SCIWORA), from lateral shearing or axial stretching, despite the fact the stability of the cervical spine does not appear to be so affected as to warrant bracing. SCIWORA accounts for up to 20% of pediatric spinal cord injuries as well as a number of prehospital deaths previously attributed to head trauma.<sup>59-61</sup>

The greater elasticity of the interspinous ligaments also gives rise to a normal anatomic variant known as pseudosubluxation, which affects up to 40% of children younger than age 7 years. The most common finding is a short (2 to 3 mm) anterior displacement of C2 on C3, although anterior displacement of C3 on C4 also may be seen. The condition is accentuated when the pediatric patient is placed in a supine position, which forces the cervical spine of the young child into mild flexion because of the forward displacement of the head by the more prominent occiput. The greater

elasticity of the interspinous ligaments also is responsible for the increased distance between the dens and the anterior arch of C1 that is found in up to 20% of children.

## Chest

Serious intrathoracic injuries occur in 6% of pediatric blunt trauma victims<sup>62</sup> and require thoracostomy in about 50%. Thoracotomy is seldom needed. Lung injuries (52%), pneumothorax and hemothorax (42%), and rib and sternal fractures (32%) occur most frequently (Table 14-3). Injuries to the heart (6%), diaphragm (4%), great vessels (2%), bronchi (<1%), and esophagus (<1%) occur least frequently. Because blunt trauma is nearly 10 times more deadly when associated with major intrathoracic injury, this condition serves as a marker of injury severity, even though it is the proximate cause of death in less than 1% of all pediatric blunt trauma.<sup>63</sup>

The child compensates poorly for respiratory derangements associated with serious thoracic injury because of (1) a larger oxygen consumption but smaller functional reserve capacity (which makes the child more susceptible to hypoxia), (2) lesser pulmonary compliance yet greater chest wall compliance (which dictate chiefly a tachypneic response to hypoxia), and

Table 14-2 Common Injury Mechanisms and Corresponding Injury Patterns in Childhood Trauma		
Injury Mechanism		Injury Pattern
Motor vehicle injury: occupant	Unrestrained	Head/neck injuries Scalp/facial lacerations

(3) horizontally aligned ribs and rudimentary intercostal musculature (which make the small child a diaphragmatic breather). The thorax of the child usually escapes major harm because the pliable nature of the cartilaginous ribs allows the kinetic energy associated with forceful impacts to be absorbed without significant injury, either to the chest wall itself or to underlying structures. Pulmonary contusions are the typical result but seldom are life threatening. Pneumothorax and hemothorax, due to lacerations of the lung parenchyma and intercostal vessels, occur less commonly but place the child in grave danger of sudden, marked ventilatory and circulatory compromise as the mediastinum shifts.

## Abdomen

Serious intra-abdominal injuries occur in 8% of pediatric blunt trauma victims<sup>62</sup> and are caused by crushing the solid upper abdominal viscera against the vertebral column, sudden compression and bursting of hollow upper abdominal viscera against the vertebral column, or shearing of the posterior attachments or vascular supply of the upper abdominal viscera after rapid deceleration (see Table 14-3).<sup>64</sup> Injuries to the liver (27%), spleen (27%), kidneys (25%), and gastrointestinal tract (21%) occur most frequently and account for most of the deaths from intra-abdominal injury. Injuries to the great vessels (5%), genitourinary

tract (5%), pancreas (4%), and pelvis (<1%) occur less frequently and account for few of the deaths that result from intra-abdominal injury. Most solid visceral injuries are successfully treated nonoperatively, especially those involving kidneys (98%), spleen (95%), and liver (90%).<sup>65-67</sup>

The abdomen of the child is vulnerable to injury for several reasons. Flexible ribs cover only the uppermost portion of the abdomen. Thin layers of muscle, fat, and fascia provide little protection to the large solid viscera. Also, the pelvis is shallow, lifting the bladder into the abdomen. Moreover, the overall small size of the abdomen predisposes the child to multiple rather than single injuries as energy is dissipated from the impacting force. Finally, gastric dilatation due to air swallowing (which often confounds abdominal examination by simulating peritonitis) leads to ventilatory and circulatory compromise by (1) limiting diaphragmatic motion, (2) increasing the risk of aspiration, and (3) causing vagally mediated dampening of the normal tachycardic response to hypovolemia.

## Skeleton

Although they are the leading cause of disability, fractures are rarely an immediate cause of death in blunt trauma. They are reported to occur in 26% of serious blunt-injury cases and constitute the principal anatomic diagnosis in 22%.<sup>10</sup> Upper extremity fractures outnumber lower extremity fractures by 7:1, although, in serious blunt trauma, this ratio is 2:3. The most common long-bone fractures sustained during childhood pedestrian/motor vehicle accidents are fractures of the femur and tibia. Falls typically are associated with

both upper and lower extremity fractures if the fall height is significant (from the window of a high-rise dwelling or the top of a bunk bed, but not from falls from standard beds or down stairs).<sup>54,68-70</sup> Because isolated long-bone and pelvic fractures are rarely associated with significant hemorrhage,<sup>71</sup> a diligent search must be made for another source of bleeding if signs of hypotensive shock are observed. This source is usually found in the abdomen.

The pediatric skeleton is susceptible to fractures because cortical bone in childhood is highly porous, whereas the periosteum is more resilient, elastic, and vascular. This results in higher percentages both of incomplete (torus and greenstick) fractures and complete but nondisplaced fractures. Long-term growth disturbances also may complicate childhood fractures. Diaphyseal fractures of the long bones cause significant overgrowth, whereas physeal (growth plate) fractures can cause significant undergrowth.

### PREHOSPITAL CARE

Basic life support of the pediatric trauma patient consists of oxygen administration, airway adjuncts, bleeding control, and spine stabilization, providing assisted ventilation and fracture immobilization as needed. Spinal immobilization requires both neutral positioning (which cannot be achieved without placing a thin layer of padding beneath the torso from shoulders

to hips)<sup>72</sup> and careful strapping (because forced vital capacity may be decreased by 4% to 59%).<sup>73</sup> One study suggested that cervical spine immobilization can be safely avoided in most pediatric trauma patients with minor injuries, but caution was urged in view of the known risks of SCIWORA and atlantoaxial instability.<sup>74</sup> Advanced life support of the pediatric trauma patient theoretically adds endotracheal intubation and volume resuscitation to this armamentarium, but neither intervention appears to improve outcome.<sup>75-79</sup>

Field triage of pediatric trauma patients to pediatric trauma centers is now well established. Regional protocols should direct ambulance transports to such centers where available. Although both the PTS<sup>80</sup> and the Revised Trauma Score (RTS)<sup>81</sup> reliably predict the need for pediatric trauma care, neither is optimally sensitive nor specific (Table 14-4). Good results also have been achieved by using checklists to identify anatomic, physiologic, and mechanistic criteria rather than calculated scores (Table 14-5).

**EMERGENCY CARE****Primary Survey**

Early management of childhood trauma begins in the field and continues in the emergency department.<sup>82,83</sup> Attention is first directed to the ABCDEs of trauma care: a “primary survey” of the Airway, Breathing, Circulation, and neurologic Disabilities, the purpose of which is to identify and correct deficits in ventilation, oxygenation, perfusion, and mentation, as well as conditions of the thorax and abdomen (e.g., tension pneumothorax and gastric dilatation) that pose an immediate threat to life (Table 14-6). The primary survey continues with complete Exposure of the patient to ensure that no injuries are missed, taking care to avoid hypothermia (through the use of blankets, over bed radiant warmers, and warmed intravenous fluids). It concludes with placement of adjuncts, such as a urinary and gastric catheter (unless contraindicated, respectively, by evidence of pelvic, or basilar skull or oromaxillofacial fractures). Together with other adjuncts (e.g., pulse oximetry and the trauma series of plain chest, pelvic, and lateral cervical spine radiographs that is obtained for all seriously injured patients), these steps facilitate the early recognition and treatment of immediate threats to vital functions.

**Resuscitation**

Resuscitation of the child trauma victim is conducted concurrent with the primary survey in a continuous cycle of assessment, intervention, and reassessment. An airway obstructed by soft tissues and secretions is opened while taking proper cervical spine precautions, then cleared (by using a large-bore Yankauer-type suction device) before its patency can be confirmed and assessment can proceed to the next step (Table 14-7).

**Table 14-7** Airway/Cervical Spine

**Open:** jaw thrust/spinal stabilization  
**Clear:** suction/remove particulate matter  
**Support:** oropharyngeal/nasopharyngeal airway  
**Establish:** orotracheal/nasotracheal intubation\*  
**Maintain:** primary/secondary confirmation†  
**Bypass:** needle/surgical cricothyroidotomy

\*Rapid sequential intubation technique: etomidate, then succinylcholine.

Abnormalities of breathing (ventilation and oxygenation) are next addressed with supplemental oxygen or assisted ventilation, if needed. Finally, the integrity of the circulation is assured through control of bleeding and administration of fluid.

Any child initially seen with major trauma should receive breathing support with high-concentration oxygen by the most appropriate means (Table 14-8). For the child with simple respiratory distress (increased work of breathing), a non-rebreather mask normally will suffice, provided the airway is open and breathing is spontaneous. For the child with frank respiratory failure (labored or inadequate work of breathing), assisted ventilation via face mask or an endotracheal tube attached to a bag-valve device should be initiated in preparation for endotracheal intubation. Orotracheal intubation with rapid-sequence induction techniques (etomidate and succinylcholine are now the preferred pharmacologic agents) and uncuffed endotracheal tubes (equivalent in diameter to the size of the naris or tip of the small finger, selected by using either a length-based resuscitation tape<sup>84</sup> or the formula 4 + age in years/4) is mandatory for all cases of respiratory failure.

The first step in management of the circulation is hemorrhage control. Direct pressure using sterile dressings is therefore applied to all actively bleeding external wounds. Blind clamping is avoided, owing to the potential risk of injury to neurovascular bundles.

**Table 14-8** Breathing/Chest Wall

**Ventilation:** chest rise/air entry/effort/rate  
**Oxygenation:** central color/pulse oximetry

Military experience suggests that commercial arterial tourniquets, and topical hemostatic agents such as chitosan granules or powder, zeolite granules, and kaolin clay, are effective respectively, in stopping major arterial hemorrhage, and massive arteriolar, venular, and capillary oozing from large open wounds. However, because no results of their use in children have been reported to date, no recommendation can be made regarding their use in children.

The child with major trauma will require volume resuscitation if signs of hypovolemic shock are present (Table 14-9). This is best carried out by means of large-bore peripheral catheters placed percutaneously in the median cubital veins at the elbow or saphenous veins at the ankle or by cutdown in the saphenous veins at the ankle or groin. Intraosseous access may be necessary if intravenous access is not rapidly obtained. Simple hypovolemia usually responds to 20 to 40 mL/kg of warmed lactated Ringer's solution. However, frank hypotension (clinically defined by a systolic blood pressure less than 70 mm Hg plus twice the age in years) typically requires 40 to 60 mL/kg of warmed

lactated Ringer's solution followed by 10 to 20 mL/kg warmed packed red blood cells. Insertion of central venous catheters, except in rare cases in which venous access cannot otherwise be obtained, is not indicated. Urinary output should be measured in all seriously injured children as an indication of tissue perfusion.

Because of the ability of a child's blood vessels to compensate vigorously for hypovolemia by intense vasoconstriction, frank hypotension is a late sign of shock and may not develop until 30% to 35% of circulating blood volume is lost.<sup>85</sup> Thus, any child who cannot be stabilized after infusion of 40 to 60 mL/kg of lactated Ringer's solution and 10 to 20 mL/kg of packed red blood cells likely has internal bleeding and needs an emergency operation. If a child initially is in shock, has no signs of intrathoracic, intra-abdominal, or intrapelvic bleeding, but fails to improve despite seemingly adequate volume resuscitation, other forms of shock (obstructive, cardiogenic, neurogenic) should be considered: (1) tension pneumothorax or cardiac tamponade, (2) myocardial contusion, or (3) spinal cord injury. Yet, it must be emphasized that most children in hypotensive shock are victims of unrecognized hemorrhage that can be reversed only if promptly recognized and appropriately treated by means of rapid blood transfusion and immediate surgical intervention, particularly if major intrathoracic or intra-abdominal vessels are injured.<sup>86-89</sup>

Assessment of disability (neurologic status) relies on use of the GCS score (for level of consciousness) and evaluation of bilateral pupillary responses (to exclude mass lesions), and serves as a critical indicator of core organ function (Table 14-10). Traumatic coma (GCS score, 8) and pupillary asymmetry mandate immediate involvement of neurosurgical consultants. Further resuscitation is guided by findings on complete exposure of the patient (Table 14-11). The resuscitation phase concludes with use of adjuncts selected expressly to warn of conditions likely to affect the integrity of the airway, breathing, and circulation (Table 14-12).

## Secondary Survey

Once the primary survey has been performed, a secondary survey is undertaken for definitive evaluation of the injured child. This consists of a “SAMPLE” history (Symptoms, Allergies, Medications, Past illnesses, Last meal, Events, and Environment) and a complete head-to-toe examination, addressing all body regions and organ systems. The examination should be targeted particularly to the head and neck (for any history of blunt injury above the clavicles, alteration in level of consciousness, or neck pain or swelling) and to the chest (for any history of chest pain, noisy or rapid breathing, respiratory insufficiency, or hemoptysis, or if associated with severe deceleration injuries, such as high-speed motor vehicle accidents, which may suggest thoracic aortic injury). Finally, attention is turned to the abdomen (for any history of abdominal pain, tenderness, distention, or vomiting, especially if the emesis is stained with blood or bile, and, most important, abdominal bruising from seat belts, especially when associated with severe deceleration injuries, such as high-speed motor vehicle accidents, which may suggest abdominal aortic injury).<sup>25,89</sup> In examining the child, the physician’s first responsibility is to identify life-threatening injuries that may have been overlooked during the primary survey, such as tension pneumothorax and gastric dilatation.

Drainage from the nose or ears, or any evidence of midface instability, suggests the presence of a basilar skull fracture (which precludes passage of a nasogastric tube) or an oromaxillofacial fracture (which may threaten the airway). Evidence of neck tenderness, swelling, torticollis, or spasm suggests the presence of a cervical spine fracture (which may not be detected on lateral cervical spine films in patients with SCIWORA). On chest examination, point tenderness, palpable bony deformity, crepitus or subcutaneous emphysema on inspection or palpation, or inadequate chest rise or air entry on auscultation or percussion suggests the presence of a rib fracture. Air or blood in the hemithorax indicates the need to search for an associated or subclinical pneumothorax or hemothorax. An abdomen that remains distended after gastric decompression suggests the presence of intra-abdominal bleeding (most often from the spleen or liver) or a disrupted hollow viscus (especially if fever, tenderness, or guarding are found together with abdominal distention or nasogastric aspirate stained with blood or bile).

All skeletal components should be palpated for evidence of instability or discontinuity, especially bony prominences such as the anterior superior iliac spines, which commonly are injured in major blunt trauma. In the absence of obvious deformities, fractures should be suspected if bony point tenderness, hematoma, spasm of overlying muscles, an unstable pelvic girdle, or perineal swelling or discoloration is found. The integrity of the pelvic ring may be tested in two ways: (1) by auscultating over one anterior superior iliac spine, while gently tapping over the other, to see if bone conduction is preserved, which will be the case only if the ring is intact; and (2) by compressing simultaneously,

posteriorly, on the anterior superior iliac spines to see if the pelvic wings “spring” apart because of separation of the pubic symphysis, after first compressing simultaneously, medially, on the iliac crests to preclude further rift in a potential “open book” fracture. This is the compression-distraction test. Most long-bone fractures will be self-evident, but such injuries are occasionally missed during the secondary survey, which emphasizes the (1) assumption that a fracture is present on the basis of history alone (even if no obvious deformity is seen) until proven otherwise and (2) performance of ongoing evaluation of all injured extremities for evidence of pain, pallor, pulselessness, paresthesias, and paralysis (the classic signs of associated neurovascular trauma).

Laboratory evaluation is an integral part of the secondary survey. Arterial blood gases are of paramount importance in determining the adequacy of ventilation ( $\text{PaCO}_2$ ), oxygenation ( $\text{PaO}_2$ ), and perfusion (base deficit).<sup>90,91</sup> However, the critically important determinant of blood oxygen content, hence tissue oxygen delivery (assuming the  $\text{PaO}_2$  exceeds 60 mm Hg), is the blood hemoglobin concentration. Serial hemoglobin values better reflect the extent of blood loss than does the initial value. Elevations in serum levels of transaminases or amylase and lipase suggest injury to the liver or pancreas, but the infrequency of pancreatic injury makes the latter cost ineffective versus the former.<sup>92,93</sup> Urine that is grossly bloody or is positive for blood by dipstick or microscopy (> 50 red blood cells per high-power field) suggests kidney trauma. Damage to adjacent organs due to the high incidence of associated injuries should be suspected.<sup>94</sup>

Radiologic evaluation is another important part of the secondary survey. Arrangements should be made, before additional plain films are ordered beyond those already obtained during the primary survey, to obtain computed tomography (CT) of the head (without contrast) and abdomen (double contrast), as indicated. Other imaging studies may also be needed.

CT of the head should be performed whenever loss of consciousness has occurred, or in accordance with evidence-based decision rules that demonstrate abnormal mental status, clinical signs of skull fracture, history of vomiting, scalp hematoma, and headache to be associated with less-than-minimal risk of traumatic brain injury.<sup>95</sup> CT of the chest adds little to what is already known from the chest radiograph obtained during the primary survey, since the incidental pulmonary contusions identified by CT of the chest do not correlate with increased fatality. CT of the abdomen should be obtained (1) in intubated patients; (2) with signs of internal bleeding (abdominal tenderness, distention, bruising, or gross hematuria), a history of hypotensive shock (which has responded to volume resuscitation), or a hematocrit less than 30%; (3) if a femur fracture is evident; (4) if serum transaminase levels are elevated; (5) if significant microscopic hematuria is present, or (6) if the mechanism of injury is deemed significant.<sup>96-99</sup> Focused assessment with sonography for trauma (FAST) may be useful in detecting intra-abdominal blood. However, it is not sufficiently reliable to exclude blunt abdominal injury in hemodynamically stable children, although it does have the advantage that such

injuries can be detected by repeated examination.<sup>100-107</sup> Therefore, like diagnostic peritoneal lavage, which it has largely supplanted, FAST adds comparatively little to the management of pediatric abdominal trauma. Unstable patients with suspected intra-abdominal injuries are candidates for immediate operation, whereas stable patients are managed nonoperatively without regard to the presence of intra-abdominal blood.<sup>108-112</sup> However, FAST has been successfully used in screening for intra-abdominal injuries.<sup>113</sup>

## Critical Care

Definitive management of childhood trauma begins once the primary survey and resuscitation phases have concluded. This care is the responsibility not of a single individual or specialty but of a multidisciplinary team of professionals specializing in pediatric health care led by a surgeon with experience in the care of both trauma and children. It begins with the secondary survey and re-evaluation of vital functions and progresses through the tertiary survey (a scrupulous repetition of the primary and secondary surveys conducted by the admitting team once the patient is transferred to definitive care) to ensure no injuries were missed. It persists throughout the duration of hospitalization and concludes with rehabilitation, fully encompassing the operative, critical, acute, and convalescent phases of care. Avoidance of secondary injury (injury due to persistent or recurrent hypoxia or hypoperfusion) is a major goal of definitive management and mandates reliance on continuous monitoring of vital signs, GCS score, oxygen saturation, urinary output, and, when necessary, arterial and central venous pressure.

Definitive management of childhood trauma also depends on the type, extent, and severity of the injuries sustained. Any child requiring resuscitation should be admitted to the hospital under the care of a surgeon experienced in the management of childhood injuries. Such a child should initially not receive oral intake (because of the temporary paralytic ileus that often accompanies major blunt abdominal trauma and because general anesthesia may later be required) but intravenous fluid at a maintenance rate (assuming both normal hydration at the time of the injury and normalization of both vital signs and perfusion status after resuscitation). Soft tissue injuries also should receive proper attention, including wound closure and tetanus prophylaxis. Intravenous lines inserted under substerile circumstances should be replaced to prevent the development of thrombophlebitis.

## Brain

The overall mortality and morbidity of major pediatric trauma are closely linked with the functional outcome of the brain injury that typically occurs after significant blunt impact. The results of treatment of severe closed-head trauma are somewhat better in children age 3 to 12 years than in adults, an advantage that is ablated in the presence of hypotension. Conversely, outcomes are worse in children younger than 3 years.

Although the general principles of definitive management of traumatic brain injury are similar in children and adults, nonoperative management predominates because diffuse brain injuries are more common than focal injuries in pediatric patients. Surgically remediable causes of intracranial hypertension must be treated if found, but medically remediable causes are addressed aggressively. The goal of treatment is to optimize cerebral blood flow through the maintenance of cerebral perfusion pressure and avoidance of prolonged hyperventilation, which causes cerebral ischemia.

Current management of traumatic brain injury in children should adhere to evidence-based consensus guidelines (see Chapter 17).<sup>114</sup> Conservative treatment, including discharge to home care under the supervision of responsible adult caretakers who have been instructed to return if signs of increased intracranial pressure (nausea, vomiting, increasing lethargy) develop, suffices for management of mild head injury (GCS score, 13 to 15). At the same time, noncontrast CT is indicated for all patients who have a documented loss of consciousness or are amnesic, in accordance with evidence-based decision rules.<sup>95</sup> Expectant management, consisting of hospital admission, CT, and continuous neurologic observation, is used for all patients with moderate head injury (GCS score, 9 to 12).

Controlled ventilation is initiated after endotracheal intubation via rapid-sequence technique for all patients with severe head injury (GCS score, 3 to 8, or a rapid deterioration in GCS score of  $\geq 2$  points). Hyperventilation ( $P_{aCO_2}$ , 25 to 30 mm Hg) and mannitol (0.5 mg/kg) are reserved for patients with evidence of transtentorial (pupillary asymmetry, neurologic posturing) or cerebellar (ataxic breathing) herniation.

Immediate operation is necessary for all acute collections of intracranial (epidural, subdural, intracerebral) blood of sufficient size to cause a mass effect, for all open skull fractures, and for all depressed skull fractures that invade the intracranial vault by more than the thickness of the adjacent skull. Intravenous antibiotics are used only for patients with open skull fractures. Anticonvulsants (phenytoin preceded by diazepam, as needed) are indicated for all patients with active seizures, impact seizures, or moderate or severe brain injury but should be discontinued after 2 weeks of therapy because no benefit accrues after this treatment interval.<sup>115</sup> Therapy with corticosteroids is not advantageous in traumatic brain injury.<sup>116</sup> Moreover, nitrogen losses may be accelerated.<sup>117</sup>

Acute complications of severe traumatic brain injury include hyperglycemia, diabetes insipidus, the syndrome of inappropriate antidiuretic hormone secretion, and brain death. The first three are managed, respectively, through the use of insulin, desmopressin, and water restriction. Brain death results from uncontrolled intracranial hypertension and is manifested in a normothermic patient by the total absence of brain stem function on neurologic examination, a positive apnea test, isoelectric activity on the electroencephalogram on two successive occasions (preferably 24 hours apart), or complete absence of cerebral perfusion on nuclear scan or cerebral arteriography.

Due consideration should be given to organ preservation and donation under such circumstances.

## Spine

The cervical region is often injured. High-dose methylprednisolone was previously thought efficacious in mitigating the effects of spinal cord injury. Currently, it is now believed to add little, if any, benefit to the management of patients with spinal cord injury.<sup>118,119</sup> Early care with volume resuscitation followed by vaso-pressor agents as needed should focus on management of neurogenic shock and immobilization of associated fractures (extrication collar and backboard followed by skeletal traction with Gardner-Wells tongs), realizing that SCIWORA is more common in children than in adults. Later care addresses repair of associated vertebral fractures through the use of halo traction with or without surgical fusion.

The critical care of patients with spinal cord injury is chiefly supportive. Alternating-pressure or air-fluidizing mattresses should be used whenever available to prevent the development of decubitus ulcers. Indwelling urinary catheterization, followed by intermittent clean catheterization, should be used to prevent the development of urinary stasis and subsequent infection. Aggressive pulmonary toilet, including bronchoscopy, should be used to prevent the development of pulmonary infections, especially in patients with intercostal or diaphragmatic muscle paralysis.

## Chest

Most life-threatening chest injuries can be managed expectantly, or by tube thoracostomy inserted via the fifth intercostal space in the midaxillary line (Table 14-13). Indications for resuscitative thoracotomy are limited to patients with physical or electrocardiographic signs

**Table 14-13** Early Assessment and Management of Chest Injuries in Childhood

	Clinical Signs	Emergency Treatment
<b>Immediate Threats</b>		
Upper airway obstruction	Incomplete: noisy breathing Snoring (soft tissue collapse) Gurgling (secretions, blood) Stridor (edema, foreign body) Hoarseness (laryngeal fracture) Complete: rocking chest-wall motions unrelieved by simple measures	Incomplete: clear obstruction Jaw thrust, oral airway Oropharyngeal suction Foreign body retrieval Tracheostomy and repair Complete: needle or surgical cricothyroidotomy
Tension pneumothorax	Ipsilaterally decreased breath sounds, contralaterally shifted trachea, hyper-resonance to percussion	Needle decompression without waiting for chest radiograph followed by urgent tube thoracostomy
Open pneumothorax	Chest-wall defect, sucking chest wound	Occlusive dressing followed by urgent tube thoracostomy
Massive hemothorax	Ipsilaterally decreased breath sounds, midline trachea, dullness to percussion	Volume resuscitation together with urgent tube thoracostomy
Cardiac tamponade	Muffled heart tones, distended neck veins, narrowed pulse pressure, Focused Assessment by Sonography in Trauma (FAST)	Pericardiocentesis followed by urgent operative repair
Flail chest	Paradoxical chest-wall motions, bony crepitus	Endotracheal intubation for respiratory failure
<b>Potential Threats</b>		
Pulmonary contusion	Rales, rhonchi	Supplemental oxygen
Myocardial contusion	Cardiac arrhythmias	Monitoring, antiarrhythmics
Diaphragmatic rupture	Elevated hemidiaphragm, nasogastric tube in hemithorax	Urgent operative repair
Aortic rupture	Murmur radiating to back, widened mediastinum	Urgent operative repair
Bronchial disruption	Persistent large air leak, persistent pneumothorax despite thoracostomy	Urgent operative repair
Esophageal disruption	Food or saliva draining from thoracostomy, pneumomediastinum	Urgent operative repair
<b>Possible Threats</b>		
Simple pneumothorax	Ipsilaterally decreased breath sounds, midline trachea, hyper-resonance to percussion	Urgent tube thoracostomy
Simple hemothorax	Ipsilaterally decreased breath sounds, midline trachea, dullness to percussion	Urgent tube thoracostomy
Rib fractures	Bony crepitus	Analgesics
Traumatic asphyxia	Multiple petechiae of head and neck	Supportive and expectant

of life in the field or emergency department after penetrating chest trauma. The universally dismal results preclude its use in blunt chest or abdominal trauma,<sup>120</sup> even though cardiopulmonary resuscitation by itself is associated with a 23.5% survival rate.<sup>121</sup> Emergency thoracotomy is reserved for injured patients with massive hemothorax (20 mL/kg) and ongoing hemorrhage (2 to 4 mL/kg/hr), massive air leak, and food or salivary drainage from the chest tube. Severe pulmonary contusions, if complicated by aspiration, overhydration, or infection, can predispose the patient to development of acute respiratory distress syndrome (ARDS) or post-traumatic pulmonary insufficiency. These complications require aggressive ventilatory support and, occasionally, extracorporeal membrane oxygenation. Traumatic asphyxia, characterized by facial and conjunctival petechiae, requires no specific treatment but serves to indicate the considerable severity of the impacting force.

Critical care of the respiratory insufficiency that accompanies severe chest injury also is expectant. To avoid both oxygen toxicity and resorption atelectasis, it is best to use the least amount of artificial respiratory support necessary to maintain the PaO<sub>2</sub> at 70 to 80 mm Hg (hence the SpO<sub>2</sub> at 90% to 100%) and the PaCO<sub>2</sub> (or the PETCO<sub>2</sub>) at 35 to 45 mm Hg. Continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP) should be used for maintenance of functional residual capacity whenever the FIO<sub>2</sub> exceeds 40%, but adverse effects on the circulation should be avoided. Peak inspiratory pressure should be kept below 20 to 25 cm H<sub>2</sub>O whenever positive-pressure ventilation is required, especially if pneumothoraces, or fresh bronchial or pulmonary suture lines, are present. Pulmonary contusions uncomplicated by aspiration, overhydration, or infection can be expected to resolve in 7 to 10 days. Thus, the judicious use of pulmonary toilet, crystalloid fluid, loop diuretics, and therapeutic (not prophylactic) antibiotics to preclude the development of ARDS or post-traumatic pulmonary insufficiency is required.

## Abdomen

Immediate management of intra-abdominal and genitourinary injuries in children is chiefly nonoperative, although not necessarily nonsurgical, as mature surgical judgment is needed to determine whether, or when, operation is needed. Bleeding from renal, splenic, and hepatic injuries is mostly self-limited and resolves spontaneously in most cases, unless the patient is in hypotensive shock or the transfusion requirement exceeds 40 mL/kg of body weight (half the circulating blood volume) within 24 hours of injury.<sup>65-67</sup> Laparotomy for management of renal, pancreatic, gastrointestinal, and genitourinary injuries is performed as indicated, including damage-control methods for patients in extremis and staged closure for patients with abdominal compartment syndrome (Table 14-14).<sup>122</sup> A pancreatic pseudocyst is heralded by the development of a tender epigastric mass 3 to 5 days after upper abdominal trauma and is likely to

**Table 14-14** Indications for Early Operation in Abdominal Trauma in Childhood

### Blunt

Hemodynamic instability despite adequate volume resuscitation  
 Transfusion requirement >50% of estimated blood volume  
 Physical signs of peritonitis  
 Endoscopic evidence of rectal tear  
 Radiologic evidence of intraperitoneal or retroperitoneal gas  
 Radiologic evidence of gastrointestinal perforation  
 Radiologic evidence of renovascular pedicle injury  
 Radiologic evidence of pancreatic transection  
 Bile, bacteria, stool, or >500 WBC/mm<sup>3</sup> on peritoneal lavage

### Penetrating

All gunshot wounds  
 All stab wounds associated with evisceration; blood in stomach, urine, or rectum; physical signs of shock or peritonitis; radiologic evidence of intraperitoneal or retroperitoneal gas  
 All suspected thoracoabdominal injuries (unless excluded by thoracoscopy or laparoscopy)  
 Bile, bacteria, stool, or >500 WBC/mm<sup>3</sup> on peritoneal lavage

WBCs, white blood cells.

respond to nonoperative management composed of 4 to 6 weeks of bowel rest and total parenteral nutrition. However, the presence of a high-grade pancreatic injury on CT of the abdomen suggests that nonoperative management may fail and that either an internal drainage procedure or, in selected cases, endoscopic retrograde cholangiopancreatography with pancreatic ductal stenting, may ultimately be required.<sup>123-125</sup>

## Skeleton

Because fractures of the long bones are rarely life threatening unless associated with major bleeding (bilateral femur fractures, unstable pelvic fractures), the general care of the injured patient takes precedence over orthopedic care. At the same time, early stabilization will serve both to decrease patient discomfort and to limit the amount of hemorrhage. Closed treatment predominates for fractures of the clavicle, upper extremity, tibia, and femur (infants and preschoolers), although fractures of the femur increasingly involve the use of external fixation and intramedullary rods (school-age children and adolescents). Operative treatment is required for open fractures, displaced supracondylar fractures (because of their association with ischemic vascular injury), and major or displaced physeal fractures (which must be reduced anatomically). Owing to the ability of most long-bone fractures to remodel, reductions need not be perfectly anatomic. However, remodeling is limited in torus and greenstick fractures as the hyperemia typical of complete fractures is unlikely to occur.

Critical care of skeletal injuries consists of careful immobilization, with emphasis on the avoidance of immobilization-related complications (e.g., friction

burns and bed sores) through the use of supportive and assistive devices (e.g., egg-crate or similar mattresses and a trapeze to permit limited freedom of movement). Fracture-associated arterial insufficiency is recognized by the presence of a pulse deficit on serial observation. Detection of compartment syndrome may require measurement of compartment pressure, which mandates fasciotomy when greater than 40 cm H<sub>2</sub>O. Traumatic fat embolism, after long-bone fracture, and rhabdomyolysis, after severe crush injury, are rare but require aggressive respiratory support and crystalloid diuresis. Early rehabilitation is vital to optimal recovery and mandates routine psychiatric consultation on admission.

## Physical Support

The care of children with major traumatic injury also involves assessment and treatment of somatic pain, for quantification of which two scales have now been validated, although neither correlates with injury severity.<sup>126</sup> In patients who are not eating, nutritional support and anti-acid therapies with both topical and systemic agents to avoid gastric stress ulcer bleeding are recommended.<sup>127</sup> In children with hematomas of the liver, spleen, or pelvis, low-grade fever may develop as these are resorbed, but high spiking fevers should prompt investigation for a source such as infected hematomas, effusions, or pelvic osteomyelitis. In children with large retroperitoneal hematomas, hypertension may develop on rare occasions, presumably owing to pressure on the renal vessels. The temporary use of antihypertensive agents may be required, but the hematomas usually resolve without the need for surgical decompression. Children with chest tubes or long-term indwelling urinary catheters are at risk for systemic infection and should receive prophylactic or suppressive antibiotics as long as the tube is required.

## Emotional Support

Efforts must be made to attend to the emotional needs of the child and family, especially for those families facing the death of a child or a sibling.<sup>128</sup> In addition to the loss of control over their child's destiny, parents of seriously injured children also may feel enormous guilt, whether or not these feelings are warranted. The responsible surgeon should attempt to create as normal an environment as possible for the child and allow the parents to participate meaningfully in postinjury care. In so doing, treatment interventions will be facilitated as the child perceives that parents and staff are working together to ensure an optimal recovery.

## SPECIAL CONSIDERATIONS

### Child Abuse

Child abuse is the underlying cause of 3% of major traumatic injuries in childhood.<sup>10</sup> A detailed review of the mechanisms, patterns, presentations, and findings

of physical abuse is beyond the scope of this chapter, but child abuse may be suspected when (1) an unexplained delay occurs in obtaining treatment, although this occasionally occurs with unintentional injury as well, (2) the history is vague or otherwise incompatible with the observed physical findings, (3) the caretaker blames siblings or playmates or other third parties, or (4) the caretaker protects other adults rather than the child.<sup>129,130</sup> Although the recognition and sociomedico-legal management of suspected cases of child abuse require a special approach, assessment and medical treatment of physical injuries is no different from that for any other mechanism of injury. Most important, confrontation and accusation hinder treatment and rehabilitation and have no place in the surgical management of any pediatric patient, regardless of the nature of the injury (although reports of suspected child abuse must be filed with local child protective services in every state and territory).

## Penetrating Injuries

Early involvement of social services, psychiatric support, pastoral care, and responsible law enforcement and child protective agencies is mandatory, especially in cases of nonaccidental injury for which the initial history is rarely accurate and the potential for recidivism is significant. All penetrating wounds are contaminated and must be treated as infected. Accessible missile fragments should be removed (once swelling has subsided) to prevent the development of lead poisoning (especially those in contact with bone or joint fluid).<sup>131</sup> Thoracotomy is usually not required except for massive hemothorax (20 mL/kg) or ongoing hemorrhage (2 to 4 mL/kg/hr) from the chest tube, persistent massive air leak, or food or salivary drainage from the chest tube. Laparotomy is always required for gunshot wounds as well as stab wounds associated with hemorrhagic shock, peritonitis, or evisceration. Thoracoabdominal injury should be suspected whenever the torso is penetrated between the nipple line and the costal margin, if peritoneal irritation develops after thoracic penetration, if food or chyle is recovered from the chest tube, or if injury-trajectory or imaging studies suggest the possibility of diaphragmatic penetration. Tube thoracostomy, followed by laparotomy or laparoscopy for repair of the diaphragm and/or damaged organs, is mandated with such signs.<sup>132</sup>

## Systems Issues

Pediatric patients, at high risk of death from multiple and severe injuries, are best served by a fully inclusive trauma system (each component of which experienced in pediatric care) that incorporates all appropriate health care facilities and personnel to the level of their resources and capabilities.<sup>133,134</sup> Moreover, collaboration with local public health agencies (in programs for injury prevention and control), as well as local public health, public safety, and emergency-management agencies (in regional disaster-planning efforts) is necessary.<sup>133,134</sup> Although the regional trauma center is at

the hub of the system (and ideally also is the regional pediatric trauma center), area trauma centers may be needed in localities distant from the regional trauma center. All trauma centers, whether adult or pediatric, must be capable of the initial surgical management of pediatric trauma. This requires the immediate availability of a resuscitation team trained and credentialed for the management of pediatric trauma. All other hospitals in the region should participate as they are able but must be fully capable of initial resuscitation, stabilization, and transfer of pediatric trauma patients. Finally, a regional trauma advisory committee should include pediatric representation that has the authority to develop and implement guidelines for triage of pediatric trauma within the system to verified pediatric-capable trauma centers, since participation in the trauma center verification process has been shown to result in better survival outcomes.<sup>135,136</sup> Mature systems should expect that seriously injured pediatric patients will be preferentially transported to pediatric trauma centers.<sup>137</sup>

### Transport Issues

Pediatric victims of multisystem trauma should undergo direct primary transport from the injury scene to a pediatric-capable trauma center.<sup>27-44</sup> If this is not possible, additional secondary transport from the initial trauma receiving hospital to the pediatric trauma center is needed. Transport providers must be capable of critical pediatric assessment and monitoring and skilled in the techniques of endotracheal intubation and vascular access, as well as drug and fluid administration in children.<sup>138,139</sup> Specialized pediatric-transport teams, staffed by physicians and nurses with advanced training in pediatric trauma and critical care treatment and transport, should be used whenever possible because complications related to endotracheal intubation and vascular access are the leading causes of adverse events during transport. These adverse events occur at twice the rate of those in the pediatric intensive care unit and 10 times more frequently when specialized teams are not used.<sup>140,141</sup>

### Hospital Preparedness

Regional pediatric trauma centers should be located in trauma hospitals with comprehensive pediatric

services (e.g., a full-service general, university, or children's hospital) that demonstrates an institutional commitment to pediatric trauma care, including child abuse.<sup>27-36,133</sup> Adult trauma centers can achieve results comparable to those of pediatric trauma centers if pediatric subspecialty support (pediatric emergency and critical care medicine) is available.<sup>37-44,133</sup> Finally, an organized pediatric trauma service must be available within the regional pediatric trauma center that, in addition to exemplary patient care, supports education and research in pediatric trauma and provides leadership in pediatric trauma system coordination.

### Emergency Preparedness

Recent literature describing pediatric disaster management has focused on multiple casualty incidents involving children that resulted from motorized transport crashes, natural disasters, and terrorist incidents, underscoring the need for meaningful involvement of pediatric trauma surgeons and pediatric trauma hospitals in regional disaster-planning efforts for pediatric patients. Airplane crashes predominantly cause severe traumatic brain injuries, severe intrathoracic hemorrhage, and femur fractures, whereas bus crashes predominantly cause closed-head injuries, soft tissue damage, and superficial lacerations.<sup>142,143</sup> Injuries sustained during major hurricanes appear to result chiefly in open wounds, gastroenteritis, skin infections, and, to a lesser extent, hydrocarbon and bleach ingestions, whereas those from earthquakes appear to result chiefly in orthopedic and soft tissue injuries as well as burns.<sup>144-146</sup> Building collapses after massive bomb explosions are associated with high fatality rates (due chiefly to lethal head and torso injuries, as well as traumatic amputations).<sup>147</sup> In the aftermath of the April 19, 1995, bombing of the Murrah Federal Building in Oklahoma City, Oklahoma, and the September 11, 2001, suicide airliner attacks on the World Trade Center in New York and the Pentagon near Washington, DC, thoughtful approaches to pediatric disaster planning as well as dissemination of policy guidelines from key professional organizations and experts in pediatric emergency and disaster medicine have evolved.<sup>148-156</sup>

# THORACIC TRAUMA

Devin P. Puapong, MD • David W. Tuggle, MD

**T**horacic trauma is an important cause of morbidity and mortality in children. Although it accounts for a small minority of pediatric trauma injuries (4%-25%), it is associated with a 20-fold increase in mortality when compared with pediatric trauma patients without thoracic trauma.<sup>1-10</sup> Moreover, the mortality rate of head and abdominal trauma in association with thoracic trauma in children increases to 25%. Children with neurosurgical trauma, thoracic trauma, and abdominal trauma may have a mortality rate that approaches 40%. Isolated thoracic trauma in a child is associated with a mortality rate of approximately 5%, which is largely due to penetrating trauma.<sup>1</sup>

Epidemiologic studies have reported a twofold to threefold higher incidence of thoracic trauma in boys as compared with girls.<sup>9-15</sup> Most injuries (80%-95%) are the result of blunt trauma, typically resulting from a traffic accident in which the child involved is a passenger or pedestrian.<sup>2,10</sup> Not surprisingly, many children will have involvement of other organ systems with a high Injury Severity Score (ISS). When penetrating trauma does occur, older children and adolescents are more likely to be the victims. This is associated with a higher mortality rate.<sup>5</sup>

Contusion or laceration of the pulmonary parenchyma is the most common injury and may be associated with rib fractures and pneumothorax or hemothorax. Injuries to other organs such as the tracheobronchial tree (<1%), esophagus (<1%), aorta (<1%), diaphragm (4%), and heart (6%) are uncommon but not insignificant.<sup>12</sup>

## ANATOMY AND PHYSIOLOGY

Children have unique anatomic and physiologic properties that are salient to the diagnosis and management of thoracic trauma. As in any trauma patient, sequential management of the airway, breathing, and circulation is of primary importance. The pediatric airway may be complicated by numerous factors. The head of an infant is proportionally much larger than that of an adult, thus predisposing to neck flexion and occlusion of the airway in the supine position. The larger tongue

and soft palate, as well as the more anterior glottis, can make the airway difficult to visualize. The child's trachea is shorter relative to body size, narrower, and more easily compressed compared with the adult. The subglottic region is the narrowest part of the airway in children. Because of its small cross-sectional diameter, the pediatric airway is more susceptible to plugging with mucus and to small amounts of airway edema.

With regard to breathing, the chest wall is more compliant in children, with less muscle mass for soft tissue protection. This allows a greater transmission of energy to underlying organs when injury occurs. The thinner chest wall also allows for easier transmission of breath sounds, which may obscure the diagnosis of a hemothorax or pneumothorax. Children are also at an increased risk for hypoxia owing to their higher oxygen consumption per unit body mass and their lower functional residual capacity to total lung volume ratio.

When assessing circulation, it is important to note that the mediastinum is more mobile than in older patients, and this is particularly true in young children. Unilateral changes in thoracic pressure, such as with a pneumothorax, can lead to a tension pneumothorax. This can shift the mediastinum to the extent that venous return is markedly reduced. The pathophysiologic effect is similar to hypovolemic shock. This response is more pronounced than is typically seen in an adult.

Children compensate for a decrease in cardiac output by increasing their heart rate. In the infant, improvement in stroke volume provides little in the way of compensation in the hypotensive child. Pediatric patients also have a higher body surface area to weight ratio than the adult, which predisposes them to hypothermia. This, in turn, may complicate the assessment of perfusion.

## SPECIFIC INJURIES AND MANAGEMENT

Thoracic injuries in children can be categorized by location:

- I. Chest Wall
  - a. Flail chest
  - b. Open pneumothorax

- c. Rib fracture
- d. Traumatic asphyxia
- II. Pleural Cavity/Pulmonary Parenchyma
  - a. Tension pneumothorax
  - b. Hemothorax
  - c. Simple pneumothorax
  - d. Pulmonary contusion/laceration
  - e. Diaphragmatic injury
- III. Mediastinum
  - a. Pericardial tamponade
  - b. Aortic/great vessel injury
  - c. Tracheobronchial injury
  - d. Cardiac contusion
  - e. Esophageal injury

## Chest Wall

### Rib Fractures

Young children have a compliant thorax and begin to resemble adults around 8 to 10 years of age. As a consequence, rib fractures are relatively uncommon in young children and occur more frequently in adolescents. Rib fractures are often suspected with physical examination and are identified on a chest radiograph (CXR) during the initial assessment. By themselves, rib fractures are infrequently a cause of major morbidity or mortality, but they are indicators of significant energy transfer.<sup>16</sup> If a rib fracture is found in a child younger than 3 years of age, child abuse should be considered.<sup>17,18</sup> Bone scans and bone surveys are useful in diagnosing remote fractures of the bony thorax in abused children, and follow-up studies improve identification of these injuries.<sup>19</sup> In older children, rib fractures should draw attention to the risk of an associated underlying injury. Fractures and dislocations of the bony thorax and joints may cause significant long-term pain. In addition to pneumothorax and hemothorax, children with first rib fractures may have fractures of the clavicle, central nervous system injury, facial fractures, pelvic fractures, extremity injuries, and major vascular trauma.<sup>20,21</sup> When children present with multiple rib fractures, mortality has been reported to be as high as 42%.<sup>21</sup> A careful survey of the child must be performed to look for significant injuries in other regions of the body.

The management of rib fractures is typically supportive. Good pain relief will prevent atelectasis and pneumonia. Because rib fractures can be associated with a hemothorax or pneumothorax, immediate drainage of fluid and blood collections or air with a tube thoracostomy is appropriate.

### Flail Chest

Because of the increased pliability of the chest wall, multiple rib fractures in series (flail chest) are not commonly seen in younger children.<sup>22</sup> However, when flail chest does occur, respiratory effort can be depressed with a paradoxical motion of the flail segment. The large force required to produce this injury invariably results in injury to the underlying lung, which

contributes to the respiratory compromise. Treatment of the pediatric flail chest includes good pain relief, adjusted to avoid respiratory depression. Nonsteroidal anti-inflammatory medications are useful to treat the pain from rib fractures after the acute phase. Occasionally, positive-pressure ventilation may be required in children with a flail chest and respiratory insufficiency. In the case of a severe flail chest there is some evidence to suggest that operative fracture stabilization of a flail chest will decrease morbidity and improve outcome in selected cases.<sup>23</sup>

### Open Pneumothorax

Open pneumothorax (sucking chest wound) occurs when there is a gaping defect in the chest wall typically caused by blast injury, severe avulsion injuries, or impalement (Fig. 15-1). This is not commonly seen in children but may be acutely life threatening when present. The negative pressure in the pleural cavity sucks air into the thorax. Air trapping results in collapse of the ipsilateral lung and mediastinal shift as with a tension pneumothorax. Treatment requires placement of an occlusive dressing to prevent further air from entering the chest cavity as well as chest tube insertion to drain any hemo/pneumothorax that may have accumulated.

### Traumatic Asphyxia

Traumatic asphyxia is typically caused by a large compressive force on the chest combined with deep inspiration against a closed glottis (Valsalva maneuver). The increased thoracic pressure compresses the right atrium, precluding blood return from the superior vena cava, and resulting in rupture of venules and capillaries of the face and head.<sup>24</sup> Patients will exhibit conjunctival hemorrhages, facial swelling, and petechial hemorrhages on the face and upper chest. Although severe cases may result in loss of vision or

**Figure 15-1.** Open pneumothorax (sucking chest wound) in a child who was impaled by a door handle along his right lateral chest wall.

other permanent neurologic sequelae, the morbidity and mortality associated with traumatic asphyxia is generally related to associated injuries. The majority of children who survive exhibit good outcomes.<sup>25,26</sup>

## Pleural Cavity and Pulmonary Parenchyma

### *Pneumothorax—Pulmonary Lacerations*

Pneumothorax may occur with penetrating injury to the chest wall or air leak into the pleural space from a pulmonary laceration or disruption of the airway more proximally. It is a relatively common finding in children with blunt and penetrating thoracic trauma. An air leak from the injury may dissect under the pleura to cause pneumomediastinum and subcutaneous emphysema. A simple pneumothorax is often asymptomatic because the lack of increased intrathoracic pressure limits the recognition of symptoms. For this reason, a screening CXR is an important component of the evaluation of pediatric thoracic injury. Air within the pleural cavity can layer anteriorly, posteriorly, or in the subpulmonic space, and a simple pneumothorax can be easily missed on chest film but can be identified on a subsequent computed tomographic (CT) scan.<sup>27</sup> However, a recent study analyzing the utility of CT scan as a screening modality to replace initial CXR concluded that although a CT scan is highly sensitive, it should not be used as a primary imaging tool given its cost and the acceptable sensitivity of routine CXR.<sup>28</sup> Ultrasonography is another diagnostic modality that has been shown to be nearly as sensitive as CT in determining the presence of an occult pneumothorax and has gained wide acceptance as a screening tool for traumatic pneumothorax.<sup>29,30</sup>

The need for intervention in the presence of a simple pneumothorax will depend on the degree of pneumothorax and the patient's clinical condition (Fig. 15-2). Some authors have suggested that if the volume of

the pneumothorax is greater than 20% of the pleural space, then drainage is indicated.<sup>31</sup> Although insertion of a chest tube can be considered appropriate in almost every circumstance of traumatic pneumothorax, there are alternatives to conventional chest tubes, such as pigtail catheters.<sup>32</sup> Additionally, there may be a benefit in treating with supplemental oxygen alone. The rationale for this therapy is that atmospheric gas (78% nitrogen) comprises the majority of the entrapped air collection. If the nitrogen level in the blood is "washed out" by increased inspired oxygen, a nitrogen gradient will be created that will cause accelerated absorption of the air collection. Oxygen can be delivered by way of nasal cannula, a hood, or a mask. Treatment with supplemental oxygen is usually only required for 24 to 48 hours.

In contrast, tension pneumothorax is a life-threatening condition that requires expeditious decompression of the involved hemithorax. A tension pneumothorax likely causes symptoms due initially to hypoxemia<sup>33</sup> and later to increased intrapleural pressure with subsequent decreased venous return and cardiovascular collapse. If the clinician suspects a tension pneumothorax in a patient with appropriate signs and symptoms, it is reasonable to proceed with needle decompression of the pneumothorax without waiting for a CXR to confirm the clinical suspicion. If rapid drainage of intrapleural air cannot be accomplished with a needle, insertion of a pigtail catheter or a chest tube should be performed. A tension pneumothorax treated initially with needle decompression will usually require placement of a chest tube due to the continuing collection of air under pressure in the involved hemithorax. If one or both lungs have been under compression due to a prolonged tension pneumothorax, re-expansion pulmonary edema can occur.<sup>34</sup>

Systemic air embolism can occur with any pulmonary parenchymal injury and increased intrabronchial pressure, creating a bronchopulmonary venous fistula.<sup>35</sup> This is most often seen when positive-pressure

**Figure 15-2.** This 7-year-old was involved in a motor vehicle accident. The patient was not wearing restraints at the time of injury and had multiple other injuries. **A**, Multiple rib fractures and pneumothorax with collapsed right lung (arrows) are seen. **B**, A chest tube has been placed for initial management. **C**, Several days later there has been complete re-expansion of the lung and resolution of the right lower lobe pulmonary contusion.

ventilation is required to support the injured patient. Sudden neurologic findings or cardiovascular decompensation may be the initial sign that air has embolized to the coronary or cerebral vessels. If this complication is recognized, steps should be taken to prevent further air embolism. If possible, the removal of the intravascular air should be considered. Treatment options include tube thoracostomy, but more often an emergency thoracotomy will provide immediate reversal of the physiology promoting air embolism. The hilum of the lung should be occluded to prevent further escape of air into the venous system, and operative control of the bronchial-venous interface should be obtained. The mortality associated with this complication is high.

### **Hemothorax**

Hemothorax can result from blunt or penetrating injury to any of the intrathoracic vessels, the chest wall vessels, the pleura, or the pulmonary parenchyma. Occasionally, a rib fracture may lacerate intercostal blood vessels or the lung. Rarely, the aorta or vena cava may be injured by pressure or shearing. Blood in the thorax may be asymptomatic unless the volume of blood is large. Smaller volumes may be more easily detected on CT scan, which also allows for measurement of Hounsfield density to aid in the diagnosis.<sup>36</sup> Each hemithorax can hold approximately 40% of a child's blood volume.<sup>37</sup> It is difficult to estimate the amount of blood loss on a CXR. Prompt chest tube placement allows for evacuation of blood from the pleural space and re-expansion of the lung. It also allows the surgeon to assess the volume of blood lost and whether the blood loss is ongoing.

There are instances in which an operation may be needed to stop ongoing intrathoracic blood loss. The immediate blood loss after tube thoracostomy of 15 mL/kg or ongoing losses of 2 to 3 mL/kg/hr for 3 or more hours are indicators for thoracic exploration in children to control bleeding.<sup>38,39</sup> If undrained, the hemothorax can become organized with the clot eventually replaced by a fibrothorax that can cause a restrictive lung defect. This predisposes to atelectasis, ventilation-perfusion mismatching, and pneumonia.

Residual blood is an excellent culture medium. Empyema and sepsis can result from infection of an undrained hemothorax. Tube thoracostomy may not adequately evacuate an organizing post-traumatic hemothorax in up to 12% of patients.<sup>40</sup> In this situation, thoracoscopy is indicated to evacuate the residual clot. Patients who undergo earlier thoracoscopy may experience less morbidity according to some authors.<sup>41,42</sup> However, there are also data to suggest that thrombolytic therapy with streptokinase or urokinase is equally effective at treating a retained hemothorax.<sup>40</sup>

### **Chylothorax**

Chylothorax caused by injury to thoracic lymphatic channels is an uncommon complication of thoracic trauma. Chylothorax usually becomes evident 3 to

7 days after injury. The diagnosis is made by obtaining a sample of the pleural fluid and identifying the lymphatic and lipid content. Treatment includes tube thoracostomy and either enteral feedings with medium-chain triglycerides or parenteral nutrition.

### **Pulmonary Contusion**

One of the most common thoracic injuries in children is a pulmonary contusion, which can occur with blunt or penetrating trauma.<sup>1</sup> The flexible chest wall of the child allows contusion of the lung without rib fracture, resulting in areas of lung consolidation and chest wall contusion. Microscopically, pulmonary contusions show alveolar hemorrhage, consolidation, and edema. The presence of a pulmonary contusion contributes to decreased pulmonary compliance, hypoxia, hypoventilation, and a ventilation-perfusion mismatch. A CXR taken during the initial assessment may demonstrate a pulmonary contusion. However, because this is invariably a supine film, it is sometimes difficult to differentiate fluid/blood in the pleural space from a lung contusion. To this end, a chest CT scan can show areas of pulmonary contusion not appreciated on the radiograph and can differentiate a parenchymal process (contusion) from free fluid.<sup>43</sup> When a contusion is seen on CXR, however, these children typically have a larger volume of lung that has been injured with a higher degree of impaired oxygenation.<sup>44</sup> Also, a significant percentage will require ventilatory support.<sup>45</sup> When a pulmonary contusion is seen only on CT, the morbidity of the injured child does not appear to be affected when compared with children with normal CT findings.<sup>45</sup> The overall injury severity, associated injuries, and outcomes in these patients are similar to those seen in adults.<sup>43</sup> Treatment includes appropriate fluid resuscitation, supplemental oxygen, pain management, and strategies to prevent atelectasis and pneumonia.

A significant percentage of patients may develop pneumonia or the acute respiratory distress syndrome (ARDS) after pulmonary contusion.<sup>13</sup> In an occasional patient, the pulmonary contusion may cause life-threatening hypoxia that cannot be supported with conventional ventilation, including high-frequency oscillation. Extracorporeal life support has been used in extreme circumstances to support patients with severe pulmonary contusions or ARDS.<sup>46</sup> Children with pulmonary contusions may have prolonged changes in respiratory function and radiographic abnormalities. These changes may persist for an extended period of time after resolution of the symptoms.<sup>47</sup> However, these children do not appear to suffer from any significant long-term sequelae.<sup>15</sup>

### **Diaphragmatic Injuries**

Blunt diaphragmatic rupture is an uncommon occurrence. The left diaphragm is involved more often because of the protective effect of the right lobe of the liver. There have been occasional reports of bilateral injury (Fig. 15-3).<sup>48,49</sup> The frequency of associated

**Figure 15-3.** Bilateral diaphragmatic rupture after blunt abdominal trauma. The hemostats have been placed on the lower rim of the diaphragmatic rupture.

injuries, especially liver and spleen injuries, is very high.<sup>49</sup> Blunt injury to the diaphragm may have several manifestations. Children may have chest pain that radiates to the shoulder, shortness of breath, or abdominal pain. On physical examination, breath sounds may be diminished on the ipsilateral side and bowel sounds may be heard.<sup>50</sup>

On radiographic imaging, an abnormal diaphragm contour, a high-riding diaphragm, or a questionable overlap of abdominal visceral shadows may indicate injury. Visceral herniation or the abnormal placement of a nasogastric tube into the hemithorax should be considered diagnostic. Many diaphragmatic ruptures are not identified in the first few days after injury and may not be detected for a considerable period of time.<sup>51</sup> CXR findings may be obscured by associated contusion or atelectasis in the lung bases. In patients requiring intubation, herniation of abdominal viscera through the injury may not occur until after the patient is off positive-pressure ventilation.<sup>52</sup> CT has been used to establish this diagnosis, but the CT may appear normal in some patients. A heightened awareness of this injury should be present to avoid the late complications of visceral herniation or bowel complications. Repair of an acute diaphragmatic rupture is often best accomplished using an abdominal approach (see Fig. 15-3). If a late diagnosis of a diaphragmatic injury is made, a thoracic approach for repair is often considered to avoid the scarring and adhesions that might have formed.

When penetrating trauma is sustained below the nipple line, consideration should be given to the presence of a diaphragmatic injury. Imaging evaluation is unreliable in this setting. Therefore after determining whether other life-threatening injuries to the heart, lung, liver, spleen, or gastrointestinal tract exists, consideration should be given for operative exploration and repair.<sup>50</sup> If exploration is undertaken, laparoscopy, thoracoscopy, thoracotomy, or laparotomy have all been used with success.

## Mediastinum

### Airway Injury

Injuries to the tracheobronchial tree are infrequent in children. Airway disruption may occur with penetrating injury or with blunt injury such as high-energy acceleration or deceleration. Up to three fourths of these injuries are noted within 2 cm of the carina and almost half occur within the first 2 cm of the right main-stem bronchus.<sup>53</sup> Most patients with tracheal injuries have mediastinal air on CXR, although more distal injuries may rupture into the pleural space and present as a tension pneumothorax. Other findings associated with a major airway injury include a persistent large air leak from a chest tube, mediastinal air, cervical subcutaneous emphysema without pneumothorax, or florid respiratory compromise. Rarely, complete transection of a distal main-stem bronchus will appear on CXR with total lung collapse and mediastinal displacement.<sup>54</sup> Persistent pneumomediastinum and pneumothoraces on CXR after adequate tube thoracostomy should alert the clinician to consider an injury to the tracheobronchial tree (Fig. 15-4).

Once recognized, these injuries require prompt diagnosis and treatment. Pleural air or fluid collections should be drained until an accurate diagnosis of the airway injury is made. Mechanical ventilation may be necessary because of respiratory failure in this setting. Fiberoptic bronchoscopy allows for evaluation of the

**Figure 15-4.** Chest radiograph of a 2-year-old patient who was run over by an automobile. Note the persistent large right pneumothorax despite the adequate placement of a chest tube. This patient was found to have a complete disruption of the right main-stem bronchus at the orifice of the right upper lobe bronchus

airway and may improve the probability of successful intubation. Many airway injuries are diagnosed by rigid or flexible bronchoscopy. Chest CT with a multiple-array scanner may have a role in visualizing tracheal or bronchial injuries especially if three-dimensional reconstructions of the airway are used (virtual bronchoscopy) (Fig. 15-5).<sup>55,56</sup>

A delay in diagnosis, however, is not uncommon in children. A retrospective review found that 75% of cases with a delayed diagnosis of tracheobronchial injury occurred in children younger than the age of 15.<sup>57</sup> This was thought to be related to the probability that incomplete tears in children cause minimal symptoms and the possibility that children involved in a severe accident with the loss of a family member may be reluctant to express physical complaints.

In general, when a tracheobronchial injury is identified, surgical repair is indicated. Repair may be delayed if the symptoms can be managed without morbidity. Repair of some bronchial injuries can be successful even a year after injury.<sup>53</sup> Occasionally, more distal bronchial injuries may heal with nonoperative management.<sup>58</sup> Distal bronchial injuries, both acute and chronic, are generally well managed by pulmonary resection, whereas more proximal airway trauma is best treated by surgical repair. Nonoperative management of a tracheobronchial injury may result in a high incidence of airway stenosis. When the diagnosis of a tracheobronchial injury is substantially delayed, scarring may obliterate the airway lumen and cause chronic collapse of the lung segment or lobe. The degree of injury may also play a role in determining whether a repair, as opposed to a resection, is needed. Complete transections are commonly associated with an obliterated distal bronchus, which may spare the pulmonary parenchyma from infection, thus making repair possible. Incomplete tears, on the other hand,

**Figure 15-5.** CT scan of the chest in a child who sustained penetrating trauma. This image was taken from the upper thoracic region. Note the air in the subcutaneous tissue and mediastinum. This child was found to have a tracheal and an esophageal injury.

form granulation tissue and scar that result in a patent, but narrowed lumen, predisposing the supplied lung to recurrent infection and retained secretions. This usually necessitates future resection. Three-dimensional reconstructions of the trachea and bronchi, taken from spiral CT images, have been found to be useful in planning surgical treatment. If the esophagus and the airway are injured near one another, a traumatic tracheoesophageal fistula can occur.<sup>59</sup>

### Heart and Great Vessel Injuries

Injuries to the heart and great vessels of the thorax are rare in young children. The National Trauma Data Bank reports the incidence of blunt aortic injury to be 0.1% with a mortality rate of over 40%.<sup>60</sup> Traumatic thoracic aortic disruptions can occur in children as young as 4 years of age.<sup>61,62</sup> However, these injuries are more likely in the older child. Eighty percent of children who sustain a thoracic aortic tear will have significant associated injuries to the lung, heart, skeletal system, abdominal organs, or central nervous system.<sup>63</sup> Only one half of these patients will have external evidence of thoracic injury. Most aortic injuries in children are related to falls or motor vehicle collisions, especially when children are unrestrained.

The diagnosis of an aortic injury in a child can be difficult. Findings on a chest film may include a left apical cap, pulmonary contusion, mediastinal widening, a shift of the trachea to the right, downward depression of the left main-stem bronchus, and an indistinct aorta (Fig. 15-6A).<sup>62</sup> However, none of these findings is specific enough to make the diagnosis of aortic injury. A normal CXR, however, is highly predictive for the absence of an aortic injury.<sup>64</sup> A CT scan may reveal a mediastinal hematoma or an actual aortic injury. Transesophageal echocardiography has also been useful for diagnosing an aortic injury.<sup>65</sup> Whereas thoracic CT and transesophageal echocardiography can diagnose aortic injuries, aortic angiography gives excellent anatomic detail (see Fig. 15-6B). The most common finding with a traumatic aortic injury is a pseudoaneurysm located at the proximal descending aorta. This is thought to occur secondary to tethering of the aorta by the ligamentum arteriosum at the time of injury, resulting in a tear in the aortic intima and media.<sup>66</sup>

There is no large collective study of children with aortic injuries. However, of those who survive until diagnosis, more than 70% will live to discharge.<sup>62,63</sup> Spinal cord ischemia is a complication with thoracic aortic injury and may be associated with preoperative cardiovascular instability.<sup>67</sup> Although urgent operative repair is thought to be the best treatment in most patients, recent experience has demonstrated the ability to delay operative intervention by using  $\beta$ -adrenergic blockers while other injuries are managed.<sup>61,67,68</sup> Several pediatric patients have received aortic endostents to repair an aortic injury.<sup>68-70</sup> Although this experience is limited, in the future its risk-benefit ratio may be better than that of open operative intervention.<sup>69</sup>

**Figure 15-6.** An 8-year-old patient presented with injuries from being an unrestrained passenger in a motor vehicle accident. **A,** On the chest radiograph, note the widened mediastinum and loss of definition of the aortic knob (*arrow*). There is also a right pneumothorax that was treated with tube thoracostomy. **B,** An aortogram shows a pseudoaneurysm (*arrow*) at the location of the ligamentum arteriosum just distal to the left subclavian artery, representing the partial transection of the descending aorta at this point.

Blunt cardiac injury such as myocardial contusion, cardiac laceration, or cardiac rupture is rare, occurring in less than 5% of children with blunt thoracic trauma.<sup>71,72</sup> Penetrating trauma is more often a cause of cardiac and aortic injury in this age group. Cardiac contusion accounts for 95% of blunt cardiac injuries in the child, followed by valvular dysfunction and ventricular septal defect.<sup>72</sup> Clinical manifestations of cardiac injury after blunt thoracic trauma include arrhythmia, new-onset murmur, and heart failure. These findings, however, may be absent in children, and CXR and electrocardiographic findings are generally nonspecific.<sup>72</sup>

The management of a cardiac contusion is supportive. Children with a cardiac contusion who are hemodynamically stable on presentation rarely have deterioration of their cardiac rhythm. Patients should be monitored with continuous electrocardiography and frequent blood pressure determinations. Echocardiography should be performed early in the evaluation of children with a suspected cardiac contusion. In patients with a suspected cardiac contusion, serum cardiac troponin I levels may be useful to confirm the diagnosis.<sup>73</sup>

Inotropic agents are occasionally needed to provide cardiac support in the presence of a cardiac contusion. Whereas blunt cardiac injury with heart rupture and cardiac tamponade is very rare, only immediate diagnosis and treatment will be lifesaving, as is also true for penetrating cardiac trauma. A delayed diagnosis of cardiac rupture in children has been described.<sup>74,75</sup> Immediate ultrasonography in the emergency department may provide the clinical information necessary to identify this injury quickly.<sup>76</sup> Pericardiocentesis in this setting may provide a temporary solution while operative intervention is organized. If urgent pericardiocentesis is required in a child, it should be kept in mind that the distance from the skin to the pericardium is significantly reduced in younger patients relative to adults. Undercompensating or overcompensating

for chest wall thickness may lead to inadequate decompression or iatrogenic cardiac injury. Once stabilized, children with a blunt cardiac injury should be followed closely and monitored for sequelae such as valvular insufficiency or ventricular septal defect.<sup>72</sup> Very rarely, extracorporeal life support may be needed to manage a child with a severe blunt cardiac injury.

Comotio cordis has become a widely recognized problem in pediatric thoracic trauma.<sup>77</sup> Typically, a young baseball player is struck in the chest with a hit or thrown ball and collapses suddenly. Comotio cordis is characterized by the absence of cardiac contusion, coronary artery abnormalities, structural abnormalities, or conduction system pathology. It is thought that a sudden blow to the chest will result in a disorganized cardiac rhythm followed by rapid cardiovascular collapse. Although chest protective devices seem useful, they do not provide total protection against asystole.<sup>78</sup> Automatic electrical defibrillators may have a place in treating this rare sports-related injury.

### Esophagus

Pediatric esophageal injuries are uncommon, occurring in less than 1% of children sustaining either blunt or penetrating thoracic trauma.<sup>79-81</sup> The esophagus is a relatively elastic, mediastinal structure that is largely protected by the bony thorax. This elasticity allows the esophagus mobility so that when blunt force is applied it can move or decompress, which limits the likelihood of rupture. Penetrating injuries are more likely to cause esophageal trauma (see Fig. 15-5). Esophageal disruption may manifest as dyspnea, dysphagia, cyanosis, mediastinal air, subcutaneous emphysema, pleural effusion, chest or epigastric pain, fever, or sepsis.<sup>82</sup> Initial symptoms, however, may be vague and nonspecific. Esophagography with a water-soluble contrast agent and esophagoscopy are typically the studies that will identify an esophageal injury.

If the esophagus is ruptured or perforated, conventional treatment is operative repair. This is performed for the purpose of drainage and/or repair of the injured esophagus. Treatment is initiated with fluid resuscitation and parenteral antibiotics.<sup>83</sup> Operative repair consists of direct suture closure of the injury. If possible, pleural flap coverage and tube thoracostomy are performed. If an operation is undertaken early after the injury, this treatment, along with bowel rest and total parenteral nutrition has good success. If the perforation is not identified early, treatment becomes more difficult. If the perforation is more than 24 hours old, operative closure becomes technically much more difficult owing to the degree of inflammation and the amount of contamination. Techniques used in this

circumstance include attempted repair, esophageal isolation, multiple drain placement, gastrostomy, and total parenteral nutrition.

In selected cases of esophageal perforation, nonoperative management may be successful.<sup>82</sup> This might be the case with certain types of blunt trauma and with iatrogenic injury such as a perforation at the time of endoscopy. Nonoperative management is based on the clinical status of the patient and the injury seen on imaging studies. For example, a patient might have a small leak identified, manifested by mediastinal air or pneumothorax. If there is no fever, no effusion, and the patient looks well, nonoperative treatment with total parenteral nutrition and intravenous antibiotics, along with serial examinations, may be reasonable.

# ABDOMINAL AND RENAL TRAUMA

Steven Stylianos, MD • Barry A. Hicks, MD

The management of children with major abdominal injuries has changed significantly in the past 2 decades. An increased awareness of the anatomic patterns and physiologic responses characteristic of trauma in children has resulted in the successful non-operative treatment of most abdominal solid organ injuries.<sup>1</sup> Our colleagues in adult trauma care have acknowledged this success and have applied many of the principles learned in pediatric trauma to their patients.<sup>2,3</sup> A recent review of the National Pediatric Trauma Registry (NPTR) indicates that 8% to 12% of children with blunt trauma have an abdominal injury.<sup>4</sup> Fortunately, more than 90% survive. Only 22% of the deaths in the NPTR were related to the abdominal injury. Although abdominal injuries are 30% more common than thoracic injuries, they are 40% less likely to be fatal.

Historically, adult trauma surgeons unfamiliar with the nonoperative management of solid organ injuries raised doubts about the wisdom of this approach. Their concerns included the potential for increased transfusion requirements, increased length of hospitalization, and missed associated injuries. Some even questioned the need for involvement of pediatric surgeons in pediatric trauma care. The clinical experience accumulated over the past 20 to 30 years, which has settled these concerns, is reviewed.

Few surgeons have extensive experience with massive abdominal solid organ injury requiring immediate surgery. It is imperative that surgeons familiarize themselves with current treatment algorithms for life-threatening abdominal trauma. Important contributions have been made in the diagnosis and treatment of children with abdominal injury by radiologists and endoscopists. The resolution and speed of computed tomography (CT), screening capabilities of focused assessment with sonography for trauma (FAST), and the percutaneous, angiographic, and endoscopic interventions of nonsurgeon members of the pediatric trauma team have all enhanced patient care and improved outcomes. Each section of this chapter focuses on the more common blunt injuries and unique aspects of their care in children.

## DIAGNOSTIC MODALITIES

The initial evaluation of the acutely injured child is similar to that of the adult. Plain radiographs of the cervical spine, chest, and pelvis are obtained after the primary survey and evaluation of the airway, breathing, and circulation.<sup>5</sup> Plain abdominal radiographs offer little in the urgent evaluation of the pediatric trauma patient. The rapid availability and quality of imaging modalities has improved dramatically in recent years, both in the urban and in the rural settings. Prompt identification of potentially life-threatening intra-abdominal injuries with rapid resuscitation and therapeutic intervention is now possible in the overwhelming majority of children.

## Computed Tomography

CT has become the standard of care in the evaluation of the pediatric trauma patient. Newer-generation CT scanners are now readily accessible in most health care facilities. CT is noninvasive, rapid, and highly accurate in identifying and qualifying the extent of abdominal injury. This has significantly reduced the incidence of nontherapeutic exploratory laparotomy.<sup>6</sup> A head CT, when indicated, should be performed without use of a contrast agent before abdominal CT to avoid having the contrast conceal a hemorrhagic brain injury. Intravenous contrast is then administered, and the vascular and parenchymal resolution is enhanced utilizing a “dynamic” scanning mode. The finding of a contrast “blush” on CT in children with blunt liver injury has been associated with larger transfusion requirements and a higher mortality rate.<sup>7</sup> A CT blush after significant hepatic or splenic injury should prompt the surgeon caring for the child to consider surgical or interventional radiologic control of the bleeding based on the hemodynamic status and stability of the child. Enteral contrast for enhancement of the gastrointestinal tract is generally not required in the acute trauma setting and can actually be detrimental secondary to aspiration of the contrast agent.<sup>8</sup>

Not all children with potential abdominal injuries are candidates for acute CT evaluation. Obvious

**Figure 16-1.** CT scans are highly accurate in demonstrating solid organ injuries. **A**, Hemoperitoneum with a liver laceration (arrow) and a shattered spleen is seen. **B**, Hemoperitoneum and a left renal laceration (arrow) is shown.

penetrating injury necessitates immediate operative intervention. Diagnostic laparoscopy may be very beneficial in determining if peritoneal penetration has occurred in the setting of an abdominal or flank stab wound.<sup>9</sup> The hemodynamically unstable child should never be taken from an appropriate resuscitation arena for a CT scan. These children may benefit from an alternative diagnostic study, such as diagnostic peritoneal lavage (DPL), FAST, or urgent operative intervention. Hemodynamically unstable patients with clinical evidence of abdominal trauma who are hypotensive and not responsive to resuscitative efforts should go immediately to the operating room without imaging.

Modern generation CT scanners are highly sensitive in the evaluation of possible solid organ (Fig. 16-1A) and retroperitoneal injuries (see Fig. 16-1B). The greatest limitation of abdominal CT in trauma is the lack of ability to reliably identify acute intestinal rupture.<sup>10,11</sup> Findings suggestive but not diagnostic of intestinal perforation are pneumoperitoneum, bowel wall thickening, free intraperitoneal fluid, bowel wall enhancement, and dilated bowel.<sup>12</sup> There must be a high index of suspicion for a hollow viscus injury in the child with free intraperitoneal fluid and no identifiable solid organ injury on CT (Fig. 16-2).<sup>13</sup>

Recent concerns about the risk of the radiation involved in CT have arisen, particularly in the pediatric population. Epidemiologic studies of populations exposed to radiation have shown that children are considerably more sensitive to radiation than adults. Because children have more rapidly dividing cells and

have a longer life expectancy, the odds that children may develop cancers from x-ray radiation may be significantly higher than adults.<sup>14</sup> The actual lifetime risk from CT is not clearly known. Efforts to reduce the numbers of CT scans, unnecessary scans, and efforts to reduce the CT-related radiation dose in individual patients are important measures that should be kept in mind when caring for and evaluating the injured child.

### Focused Abdominal Sonography for Trauma

Clinician-performed sonography for the early evaluation of the injured child has been shown to be useful in many situations but does have limitations. Examination of Morrison's pouch, the pouch of Douglas, the left flank to include the perisplenic region, and a subxiphoid view to visualize the pericardium is the standard four-view FAST examination. This bedside study may be useful as a rapid screening study, particularly in the patient too unstable to undergo an abdominal CT scan. Free intraperitoneal fluid seen on FAST examination in the unstable child not responding to resuscitative measures may support a decision to operate immediately. This modality is the study of choice for the evaluation of possible hemopericardium with tamponade.

A negative FAST exam (absence of hemoperitoneum) does not exclude a significant solid organ or hollow viscus injury.<sup>15</sup> There is at least a 15% false-negative rate for detecting hemoperitoneum with sonography. FAST may miss up to 25% of liver

**Figure 16-2.** **A**, Bowel wall thickening and enhancement is seen on a CT scan of a patient with documented traumatic small bowel perforation. **B**, Free intra-loop fluid and bowel wall thickening are found on this CT scan in a patient with a small bowel perforation from a lap belt injury.

and spleen injuries, most acute renal injuries, retroperitoneal bleeding, and virtually all pancreatic, mesenteric, and bowel and bladder injuries.<sup>16</sup> Compared with CT, FAST is only about 63% sensitive for detecting moderate amounts of free intraperitoneal fluid in the trauma setting. Also, the documentation of free fluid in the abdomen does not necessarily indicate the need for surgical intervention. FAST may be very useful in decreasing the number of CT scans performed for “low-likelihood” injuries. The study may be repeated on a serial basis and results correlated with the clinical scenario.

## Diagnostic Peritoneal Lavage

Since its description in 1965, the use of DPL has diminished significantly, especially in the pediatric population. The ready availability of high-resolution CT scanners and the nonoperative management of many pediatric injury patterns have increased, thus minimizing the utility of DPL. Although very accurate for identifying hemoperitoneum, retroperitoneal injuries may be missed with DPL. Incisional pain after a negative DPL may interfere with serial examinations in a child being managed nonoperatively. Also, a positive DPL may lead to a nontherapeutic laparotomy if based on hemoperitoneum alone. Because the majority of solid organ injuries do not require surgical intervention, intraperitoneal blood documented by DPL has little clinical significance. The need for operative management is determined by clinical instability, associated injuries, and the requirement for ongoing blood replacement.

There are clinical situations in which a DPL may prove to be very beneficial. The hemodynamically unstable child may have a rapid DPL to exclude the abdomen as a source of significant hemorrhage. Children with a lap belt injury pose a particular diagnostic challenge, particularly if concomitant neurologic injury is present. The initial abdominal CT is frequently normal in those with lap belt injuries, including acute hollow viscus perforations, but a DPL may document the presence of an occult visceral injury with the return of bile, bacteria, feculent matter, or an increased leukocyte count. Infusion of 10 mL/kg of normal saline into the peritoneal cavity is followed by allowing the infusate to drain. The criteria for a positive lavage are listed in [Table 16-1](#).

## Diagnostic and Therapeutic Laparoscopy

The use of laparoscopy for the injured child may have its place in the evaluation armamentarium of

**Table 16-1** Positive Peritoneal Lavage Criteria

10 mL gross blood return with lavage catheter insertion
>100,000 red blood cells/mm <sup>3</sup>
>500 white blood cells/mm <sup>3</sup>
Bile, bacteria, or vegetable matter on microscopic examination
Amylase >175 IU/dL

**Figure 16-3.** Diagnostic laparoscopy in a stable patient after a stab wound to the upper abdomen revealed this diaphragmatic injury. Repair was performed by using minimal access techniques.

the hemodynamically stable patient. The sensitivity is comparable to that of DPL, but the specificity is higher, as would be expected by actually visualizing the injury.<sup>17</sup> A decrease in the number of nontherapeutic laparotomies has been demonstrated in adult series.<sup>18</sup> Studies also have shown that not only may the traumatic injury be identified with laparoscopy but the definitive repair also can be frequently performed ([Fig. 16-3](#)).<sup>19,20</sup>

## Interventional Radiology in Pediatric Trauma

The role of the interventional radiologist in the evaluation and treatment of the injured child continues to expand as technology and indications prove to be safe and efficacious. Initially utilized solely for the assessment and identification of vascular injuries, the use of image-guided therapy is now an important part of the trauma team approach that leads to optimal care of the injured patient.<sup>21</sup> Endovascular transcatheter therapies, including placement of stents, embolotherapy, and thrombolysis, offer both primary and adjunctive modes of therapy for vascular injuries. Drainage of fluid collections, bile leaks, pancreatic pseudocysts, or loculated thoracic fluid or air collections can be very useful in the treatment of the injured child.

## SOLID ORGAN INJURY

### Spleen and Liver

The spleen and liver are the organs most commonly injured in blunt abdominal trauma, with each accounting for one third of the injuries. Nonoperative treatment of isolated splenic and hepatic injuries in stable children is now standard practice. Although nonoperative treatment of children with isolated, blunt spleen or liver injury has been universally successful,

**Table 16-2** Resource Utilization and Activity Restriction in 832 Children with Isolated Spleen or Liver Injury

CT Grade	I	II	III	IV
Admitted to intensive care unit	55.0%	54.3%	72.3%	85.4%
No. hosp days (mean)	4.3 days	5.3 days	7.1 days	7.6 days

Activity restriction (mean)	5.1 wk	6.2 wk	7.5 wk	9.2 wk
Activity restriction (range)	2-6 wk	2-8 wk	4-12 wk	6-12 wk

\*Grade III vs. grade IV,  $P < .014$ .†Grade III vs. grade IV,  $P < .0001$ .From Stylianos S and APSA Trauma Committee: Evidence-based guidelines for resource utilization in children with isolated spleen or liver injury. *J Pediatr Surg* 35:164-169, 2000.

great variation is seen in the management algorithms used by individual pediatric surgeons. Review of the NPTR and recent surveys of the American Pediatric Surgical Association (APSA) membership confirm the wide disparity in practice.<sup>22,23</sup> Controversy also exists regarding the utility of CT grading as a prediction of outcome in liver and spleen injury.<sup>24-27</sup> In 1999, the APSA Trauma Committee defined consensus guidelines for resource utilization in hemodynamically stable children with isolated liver or spleen injury. These guidelines are based on CT grading and were developed by analyzing a contemporary, multi-institution database of 832 children treated nonoperatively at 32 centers in North America from 1995 to 1997 (Table 16-2).<sup>28</sup> Consensus guidelines on the length of intensive care unit (ICU) stay, length of total hospitalization, use of follow-up imaging, and physical activity restriction for clinically stable children with isolated spleen or liver injuries (grades I to IV) were defined by analysis of this database (Table 16-3).

The guidelines were then applied prospectively to 312 children with liver or spleen injuries treated nonoperatively at 16 centers from 1998 to 2000.<sup>29</sup> (It is imperative to emphasize that these proposed guidelines assume hemodynamic stability.) Patients with other minor injuries such as nondisplaced, noncomminuted fractures or soft tissue injuries were included as long as the associated injuries did not influence the variables in this study. The patients were grouped by

severity of injury and defined by CT grade. Compliance with the proposed guidelines was analyzed for age, organ injured, and injury grade. All patients were followed for 4 months after injury. The extremely low rates of transfusion and need for operation document the stability of the study patients.

Specific guideline compliance was 81% for criteria for ICU hospitalization, 82% for length of hospitalization, 87% for follow-up imaging, and 78% for activity restriction. A significant improvement in compliance was noted from year 1 to year 2 for ICU stay (77% vs. 88%;  $P < .02$ ) and activity restriction (73% vs. 87%;  $P < .01$ ). No differences in compliance were found by age, gender, or organ injured. Deviation from guidelines was the surgeon's choice in 90% and patient related in 10%. Six (1.9%) patients were readmitted, although none required operation. Compared with the previously studied 832 patients, the latter 312 patients managed prospectively under the proposed guidelines had a significant reduction in ICU stay ( $P < .0001$ ), total hospitalization ( $P < .0006$ ), follow-up imaging ( $P < .0001$ ), and interval of physical activity restriction ( $P < .04$ ) within each grade of injury.

From these data, it was concluded that prospective application of specific treatment guidelines based on injury severity resulted in conformity in patient management, improved utilization of resources, and validation of guideline safety. Significant reduction of ICU care, hospital stay, follow-up imaging, and

**Table 16-3** Proposed Guidelines for Resource Utilization in Children with Isolated Spleen or Liver Injury

CT Grade	I	II	III	IV
Days in intensive care unit	None	None	None	1 day

activity restriction was achieved without adverse sequelae when compared with the retrospective database. Recent single-institution studies have suggested that further reduction in resource utilization may be safe.<sup>30,31</sup> A large retrospective series showed that once hemodynamic stability was achieved and there was no evidence of ongoing bleeding, patients are unlikely to begin bleeding again.<sup>30</sup> This evidence challenges the assumption that bed rest is the key variable in treatment. In reality, bed rest is simply a period of observation, for which the current recommendations may be longer than necessary. Another institution has employed a management strategy based on the patient's hemodynamic status instead of injury grade and recorded a dramatic decrease in hospital stay compared with the current guidelines without an adverse event.<sup>31</sup> A prospective, multicenter trial is underway to delineate the safety of an abbreviated protocol.

The surgeon's decision to operate for spleen or liver injury is best based on evidence of continued blood loss such as hypotension, tachycardia, decreased urine output, and decreasing hematocrit unresponsive to crystalloid and blood transfusion. The rates of successful nonoperative treatment of isolated blunt splenic and hepatic injury now exceed 90% in most pediatric trauma centers or adult trauma centers with a strong pediatric commitment.<sup>28-31</sup> A recent study of more than 100 patients from the NPTR indicated that nonoperative treatment of spleen or liver injury is indicated even in the presence of associated head injury, if the patient is hemodynamically stable.<sup>32</sup> In this study, the rates of operative intervention for blunt spleen or liver injury were similar with or without an associated closed-head injury.

Surgeons unfamiliar with current treatment algorithms for blunt splenic injuries in children occasionally question the nonoperative approach. This is important because the majority of seriously injured children are treated outside dedicated pediatric trauma centers. Although several adult trauma services have reported excellent survival rates for pediatric trauma patients, analysis of treatment for spleen and liver injuries reveals an alarmingly high rate of operative treatment.<sup>33-36</sup> It is possible that adult trauma surgeons, influenced by their past experience with adult patients, are more likely to favor operative treatment than are

their pediatric surgical colleagues. Adult trauma surgeons caring for injured children must consider the anatomic, immunologic, and physiologic differences between pediatric and adult trauma patients and incorporate these differences into their treatment protocols. The major concerns regarding nonoperative management are related to the potential risks of increased transfusion requirements, missed associated injuries, and increased length of hospital stay. Each of these concerns has been shown to be without merit.<sup>23,37-42</sup>

## Outcomes in the Treatment of Blunt Spleen Injury

Many early attempts at comparing care in pediatric trauma focused on the treatment of blunt spleen injury. Hospital and physician expertise were used as the basis for comparison in the treatment of children with blunt splenic injury in seven studies between 1985 and 1998 (Table 16-4).<sup>33,34,36,43-45</sup>

In one study there was a marked difference in the incidence of operative treatment of a splenic injury within a single trauma center, depending on physician expertise (pediatric surgeon vs. nonpediatric surgeon).<sup>36</sup> The overall splenectomy rate was nearly twofold higher in children treated by adult surgeons (24% vs. 13%,  $P < .05$ ). Transfusion requirements and hospital costs were lower for patients managed nonoperatively. A significant increase in the use of nonoperative treatment for pediatric spleen injury in Vermont between 1985 to 1995 was found after the institution of statewide educational programs.<sup>34</sup> The rate of nonoperative treatment of pediatric splenic injury at the state trauma center remained significantly higher (77% vs. 57%,  $P < .001$ ) than at rural hospitals. In a report on the treatment of 126 children with splenic injury using the New Hampshire Uniform Hospital Discharge Data Sets, a large majority of patients (84%) were treated by adult surgeons at general hospitals.<sup>33</sup> Risk-adjusted operative rates were 10% at the children's hospital compared with 41% at general hospitals ( $P < .005$ ). The authors concluded that the overwhelming majority of splenectomies and splenorrhaphies could have been avoided if general hospitals treated children with splenic injury in a manner similar to the treatment at the children's hospital. In a report from

the Pennsylvania Trauma Outcome Study, more than 13,000 injured children were treated from 1993 to 1997 at two regional pediatric trauma centers (PTCs) and 24 adult trauma centers (ATCs).<sup>43</sup> Significantly more children had successful nonoperative treatment for spleen (91.5% vs. 62.1%,  $P < .001$ ) and liver injury (96.6% vs. 84.1%,  $P < .05$ ) at a PTC compared with an ATC despite similar injury severity.

In contrast, two reports on children treated at single institutions during the mid to late 1990s found rates of nonoperative treatment for pediatric splenic injury by adult trauma surgeons similar to those of the just-referenced pediatric centers.<sup>44,45</sup> These two studies highlight the fact that dedicated trauma surgeons, familiar with contemporary processes of care advanced in pediatric centers, can achieve excellent results. They also implicate the potential importance of information dissemination and education efforts based on the benchmarks derived from examination of large public data sources. A statewide quality improvement initiative in Washington state was associated with a reduction in the rate of splenectomy in children in both pediatric and adult hospitals.<sup>46</sup>

Despite the two studies mentioned previously, several recent studies provide a basis for ongoing concern regarding the disparity of appropriate treatment in children with blunt spleen injury.<sup>47-51</sup> Using large non-selected databases and adjusting for risk, these studies indicate that the disparity in care between adult and children's hospitals is substantial and continuing on a regional and national basis (Table 16-5).

In an analysis from the Healthcare Cost and Utilization Project's National Inpatient Sample (HCUP-NIS), which contains a sample of discharges from 1300 hospitals in 28 states (representing 20% of all hospital discharges in the United States), children with splenic injury treated at rural hospitals had a risk-adjusted odds ratio for laparotomy of 1.64 (95% confidence interval [CI], 1.39-1.94) when compared with those treated at an urban teaching hospital.<sup>47</sup> The APSA Center on Outcomes compared the treatment of pediatric splenic injury using discharge datasets from four states.<sup>48</sup> The authors found a risk-adjusted odds ratio for laparotomy of 2.1 (95% CI, 1.4-3.1) when

comparing treatment at nontrauma centers versus centers with trauma expertise. In a review of more than 2600 children with spleen injury from the New England Pediatric Trauma Database, the authors found that similarly injured patients treated by nonpediatric surgeons had a risk-adjusted odds ratio for laparotomy of 3.1 (95% CI, 2.3-4.4) when compared with those treated by pediatric surgeons.<sup>49</sup> The last two studies found even greater disparity when comparing the treatment of children with isolated spleen injury as contrasted to those with multiple injuries. Data from the Kids' Inpatient Database (KID2000) of the Healthcare Cost and Utilization Project, sponsored by the Agency for Healthcare Research and Quality, were recently reviewed.<sup>50</sup> This administrative database represents an 80% sample of non-newborn discharges from 2784 hospitals in 27 states (2.5 million pediatric discharges). The authors found a risk-adjusted odds ratio for laparotomy of 5.0 (95% CI, 2.2-11.4) when comparing treatment at general hospitals versus children's hospitals in pediatric patients with spleen injury. In a review of discharge data from 175 hospitals in Pennsylvania, the risk-adjusted odds ratio for laparotomy was 6.2 (95% CI, 4.4-8.6) when comparing treatment at adult trauma centers versus pediatric trauma centers.<sup>51</sup> Although all these studies suggest marked differences in the processes of care, administrative datasets do not readily allow risk adjustment for differences in physiologic status at presentation, a potential major limitation.

A recent report surveyed 281 surgeons (114 pediatric, 167 adult) regarding their treatment of children with solid organ injury.<sup>52</sup> For all clinical scenarios, adult surgeons were more likely to operate or pursue interventional radiologic procedures than their pediatric colleagues (relative risk [RR]: 8.6 with isolated solid organ injury,  $P < .05$ ; 14.8 with multiple solid organ injuries,  $P < .001$ ; 17.9 solid organ injury with intracranial hemorrhage,  $P < .0001$ ). Adult surgeons were also more likely to consider any transfusion a failure (13.3% vs. 1.2%,  $P < .01$ ) and had a much lower transfusion threshold.

The importance of these data is further amplified by the fact that the overwhelming majority

From Stylianos S, Egorova N, Guice KS, et al: Variation in treatment of pediatric spleen injury at trauma centers versus non-trauma centers: A call for dissemination of APSA benchmarks and guidelines. *J Am Coll Surg* 202:247-251, 2006.

(68%-87%) of pediatric patients are treated at hospitals or by physicians with the higher likelihood of operation.<sup>49-51</sup> However, in contrast, hospitals with trauma expertise had a significantly lower rate of operation for both multiply injured patients (15.3% vs. 19.3%,  $P < .001$ ) and those with isolated injury (9.2% vs. 18.5%,  $P < .0001$ ) when compared with nontrauma centers (Table 16-6).<sup>48</sup>

The operative rates at both trauma centers and nontrauma centers exceeded published APSA benchmarks (Table 16-7) for all children with spleen injury (3%-11%) and those with isolated spleen injury (0%-3%).<sup>28,29,33,50,51,53</sup> Thus, trauma centers and their corresponding state or regional trauma systems may represent rational targets for dissemination of current pediatric trauma guidelines and benchmarks. Broad application of existing APSA guidelines for spleen injury should encourage conformity of care and result in reduced rates of operative intervention and diminished resource utilization.<sup>29</sup>

Failure of nonoperative management can have serious consequences. Therefore, patient selection is important. Two recent multi-institutional reviews sought to evaluate the timeline and the characteristics of patients who fail nonoperative management.<sup>54,55</sup> One hundred twenty of 1813 (6.6%) children with solid organ injury underwent laparotomy in a median time of 2.4 hours, with 90% of the patients having surgery within 24 hours. Pediatric patients who sustained pancreatic injuries were more likely to fail nonoperative management (odds ratio [OR] 7.49; 95% CI, 3.74-15.01) compared with those who suffered other injuries. The patients who failed nonoperative management

had a higher Injury Severity Score ( $28 \pm 17$ ) than those who were managed successfully nonoperatively ( $14 \pm 10$ ,  $P < .001$ ). Severely head-injured patients (Glasgow Coma Scale score [GCS] = 8) had a higher failure rate for nonoperative management (OR 5.09; 95% CI, 3.04-8.52). Factors associated with an increased failure rate include a bicycle-related injury mechanism, isolated pancreatic injury, more than one solid organ injury, and an isolated grade 5 solid organ injury. The time to failure of nonoperative management peaked at 4 hours and then declined over 36 hours from admission. Thus, continued surgical evaluation and assessment during the entire hospitalization is required to limit morbidity and mortality.

### Missed Associated Abdominal Injuries

Advocates of surgical intervention for splenic trauma cite their concern about missing associated abdominal injuries if an operation is not performed. One study reported successful nonoperative treatment in 110 (91%) of 120 children with blunt splenic trauma. In that report, 22 (18%) had associated abdominal injuries.<sup>39</sup> Only 3 (2.5%) of these 120 patients had gastrointestinal injuries, and each was found at early celiotomy performed for a specific indication. No morbidity occurred from missed injuries or delayed surgical intervention. Similarly, a review of the NPTR from 1988 through 1998 revealed 2977 patients with solid abdominal visceral injury. Only 96 (3.2%) had an associated hollow viscus injury.<sup>40</sup> Higher rates of hollow viscus injury were observed in assaulted patients and those with multiple solid visceral injury or pancreatic

The microcatheter used to deploy the coils is marked by the arrowheads and the embolic coils are marked by the arrows.

injury. Differences in mechanism of injury may account for the much lower incidence of associated abdominal injuries in children with splenic trauma. No justification exists for an exploratory celiotomy solely to avoid missing potential associated injuries in children.

### Complications of Nonoperative Treatment

Nonoperative treatment protocols have been the standard for most children with blunt liver and spleen injury during the past 2 decades. The cumulative experience allows an evaluation of both the benefits and risks of the nonoperative approach. Fundamental to the success of the nonoperative strategy is the early, spontaneous cessation of hemorrhage. Transfusion rates for children with isolated spleen or liver injury have decreased to less than 10%, confirming the lack of continued blood loss in the majority of patients.<sup>26-29,56</sup> Despite these many favorable observations, obvious ongoing hemorrhage and hemodynamic instability require the presence of skilled surgeons, operating room staff, and blood bank capabilities. The role of angioembolization in adult trauma patients with splenic injury is expanding with variable success.<sup>57,58</sup> To date, most pediatric trauma centers have not utilized angioembolization in acutely bleeding patients with splenic injury.<sup>59,60</sup>

Isolated reports of significant delayed hemorrhage with adverse outcome continue to appear.<sup>61-64</sup> Two children with delayed hemorrhage 10 days after blunt liver injury have been reported.<sup>63</sup> Both children had persistent right upper quadrant (RUQ) and right shoulder pain despite having normal vital signs and stable hematocrits. The authors recommended continued in-house observation for injured patients until symptoms resolve. Recent reports described patients with significant bleeding 38 days after a grade II spleen injury and 24 days after a grade IV liver injury.<sup>62,64</sup> These rare occurrences create anxiety in identifying the minimal safe interval before resuming unrestricted activities.

Routine follow-up imaging studies have identified pseudocysts and pseudoaneurysms after splenic injury.<sup>65-67</sup> Splenic pseudoaneurysms are often asymptomatic and appear to resolve with time. The true incidence of self-limited, post-traumatic splenic pseudoaneurysms is unknown as routine follow-up

imaging after successful nonoperative management has been largely abandoned. Once it is identified, the actual risk of splenic pseudoaneurysm rupture also is unclear. Angiographic embolization techniques can be used to treat these lesions successfully, obviating the need for operation and loss of splenic parenchyma (Fig. 16-4).<sup>65</sup>

Splenic pseudocysts may reach enormous size, leading to pain and gastrointestinal disturbance (Fig. 16-5). Simple percutaneous aspiration leads to a high recurrence rate. Laparoscopic excision and marsupialization is highly effective.

The immunocompetence of a shattered spleen that heals without surgery is debated, and vaccination practices in these children vary widely. Recent evidence using differential interference contrast microscopy in adult trauma patients indicates immunocompetence in patients with healed grade IV injuries.<sup>68</sup>

### Sequelae of Damage Control Strategies

Even the most severe solid organ injuries can be treated nonoperatively if a prompt response to resuscitation occurs.<sup>69</sup> In patients who are hemodynamically unstable, despite fluid and packed red blood cell transfusion, emergency laparotomy is indicated. Most spleen and liver injuries requiring operation are amenable to simple methods of hemostasis,

**Figure 16-5.** CT scan showing a post-traumatic splenic pseudocyst (arrow).

using a combination of manual compression, direct suture, and an increasing array of topical hemostatic agents.<sup>70,71</sup> In young children with significant hepatic injury, the sternum can be divided rapidly to expose the suprahepatic or intrapericardial inferior vena cava. Children will tolerate clamping of the inferior vena cava above the liver as long as their blood volume is replenished. With this exposure, the liver and major perihepatic veins can be isolated and the bleeding controlled to permit direct suture repair or ligation of the injured vessel.

The early morbidity and mortality of severe hepatic injuries are related to the effects of massive blood loss and replacement with large volumes of cold blood products. The consequences of prolonged operations with massive blood-product replacement include hypothermia, coagulopathy, and acidosis. Although the surgical team may keep pace with blood loss, serious physiologic and metabolic consequences are inevitable, and many of these critically ill patients are unlikely to survive. A multi-institutional review identified exsanguination as the cause of death in 82% of 537 intraoperative deaths at eight academic trauma centers.<sup>72</sup> The mean serum pH was 7.18, and the mean core temperature was 32°C before death. Survival in only 5 (40%) of 12 consecutive operative cases of retrohepatic vascular or severe parenchymal liver injury in children has been reported.<sup>73</sup>

Maintenance of physiologic stability during the struggle for surgical control of severe bleeding is a formidable challenge even for the most experienced operative team, particularly when hypothermia, coagulopathy, and acidosis occur. This triad creates a vicious cycle in which each derangement exacerbates the others. The physiologic and metabolic consequences of this triad often preclude completion of the procedure. Lethal coagulopathy from dilution, hypothermia, and acidosis can rapidly occur.<sup>74</sup>

Increased emphasis on physiologic and metabolic stability in emergency abdominal operations has led to the development of staged, multidisciplinary treatment plans, including abbreviated laparotomy, perihepatic packing, temporary abdominal closure, angiographic embolization, and endoscopic biliary stenting.<sup>75-77</sup> In a series of 22 patients with grade IV or V hepatic injuries treated between 1992 and 1997, mean blood loss was estimated at 4.6 L and mean packed red cell transfusion was 15 units.<sup>78</sup> Ten patients underwent packing of the hepatic injuries at the first operation. Fifteen patients had postoperative angiographic embolization in an attempt to control hemorrhage (Fig. 16-6). Survival was 92% in 13 grade IV patients and 78% in 9 grade V patients.

Abbreviated laparotomy with packing for hemostasis allowing resuscitation before planned reoperation is an alternative in unstable patients in whom further blood loss would be untenable. This “damage control” philosophy is a systematic, phased approach to the management of the exsanguinating trauma patient.<sup>79-81</sup> Packing of the retroperitoneum while avoiding entry into the abdomen in unstable patients with severe pelvic fractures has also gained popularity.<sup>82</sup> The three

**Figure 16-6.** This hepatic artery angiogram was performed in a patient with persistent hemorrhage after initial damage-control laparotomy. The site of hemorrhage is identified (arrow), and embolization was successfully performed.

phases of damage control are detailed in Table 16-8. Although controversial, several resuscitative endpoints have been proposed beyond the conventional vital signs and urine output, including serum lactate, base deficit, mixed venous oxygen saturation, and gastric mucosal pH. Studies from recent military experience indicate that the optimal ratio of transfused packed red blood cells and fresh frozen plasma should approach 1:1 in massive transfusion scenarios.<sup>83</sup>

There has been increasing experimental and clinical evidence that recombinant activated factor VII (rFVIIa) may be a useful adjunctive therapy in injured patients with ongoing hemorrhage. In the laboratory, reduced clot formation due to hypothermia was reversed with rFVIIa.<sup>84</sup> Military experience indicates a survival advantage in injured soldiers requiring massive transfusion with early use of rFVIIa.<sup>85</sup> The use of rFVIIa has been described in eight children with blunt injuries to the spleen, liver, or kidney and signs of ongoing hemorrhage.<sup>86</sup> Bleeding was successfully controlled after a single dose of rFVIIa. Only three patients required transfusion, and there were

**Table 16-8** “Damage Control” Strategy in the Exsanguinating Trauma Patient

Phase 1	Abbreviated laparotomy for exploration Control of hemorrhage and contamination Packing and temporary abdominal wall closure
Phase 2	Aggressive resuscitation in intensive care unit Core rewarming Optimize volume and oxygen delivery Correction of coagulopathy
Phase 3	Planned reoperation for packing change, evacuation, and definitive repair of injuries Abdominal wall closure

no thromboembolic events. The indications, optimal dosages and intervals, and risk profile still need to be developed before rFVIIa can be a mainstay in pediatric trauma care.

Once patients become normothermic, coagulation factors replaced, and oxygen delivery optimized, a second procedure is performed for pack removal and definitive repair of the injuries. A review of nearly 700 adult patients from several institutions who were treated with abdominal packing demonstrated hemostasis in 80%, survival of 32% to 73%, and abdominal abscess rates of 10% to 40%.<sup>87,88</sup>

Although abdominal packing with planned reoperation has been used with increasing frequency in adults during the past 2 decades, little published experience has been reported in children.<sup>89-96</sup> Nevertheless, this technique has a place in the management of children with massive intra-abdominal bleeding, especially after blunt trauma. A 3-year-old child required abdominal packing for a severe liver injury, making closure of the abdomen impossible.<sup>90</sup> A polymeric silicone "silo" was constructed to accommodate the bowel until the packing could be removed. The patient made a complete recovery.

The combined technique of abdominal packing and a "silo" allows time for correction of the hypothermia, acidosis, and coagulopathy without compromise of respiratory mechanics. A recent review reported 22 infants and children with refractory hemorrhage (ages 6 days to 20 years) who were treated with abdominal packing.<sup>91</sup> The anatomic site of hemorrhage was the liver and/or hepatic veins in 14, retroperitoneum and/or pelvis in 7, and the pancreatic bed in 1. Primary fascial closure was accomplished in 12 (55%) patients, and temporary skin closure or prosthetic material was used in the other 10. Abdominal packing controlled hemorrhage in 21 (95%) of the 22 patients. Removal of the packing was possible within 72 hours in 18 (82%) patients. No patient re-bled after removal of abdominal packing. However, 2 patients died with the packing still in place. In 7 (32%) patients, an abdominal or pelvic abscess developed. All were successfully drained by laparotomy (6 patients) or percutaneously (1 patient). Six of the 7 patients with abdominal sepsis survived. Overall, 18 (82%) patients survived. Two deaths were due to multisystem organ failure, 1 patient succumbed to cardiac failure from complex cardiac anomalies, and another died of exsanguination after blunt traumatic liver injury. No differences were noted in the volume of intraoperative blood transfusion, time to initiate abdominal packing, physiologic status, or type of abdominal closure between survivors and nonsurvivors.

Although the success of abdominal packing is encouraging, it may contribute to significant morbidity such as intra-abdominal sepsis, organ failure, and increased intra-abdominal pressure. Fluid samples taken from 28 patients with abdominal packing found peritoneal endotoxin and mediator accumulation even when cultures were sterile.<sup>97</sup> The assumption was that fluid accumulating after damage-control laparotomy can contribute to neutrophil dysfunction by enhancing

neutrophil respiratory burst and inhibiting neutrophil responses to specific chemotactic mediators needed to fight infection. Thus, the known propensity of such patients for both intra-abdominal and systemic infection may be related to changes in neutrophil receptor status and effector function related to an accumulation of inflammatory mediators in the abdomen. Early washout, repetitive packing, and other efforts to minimize mediator accumulation deserve consideration.

It is essential to emphasize that the success of the abbreviated laparotomy and planned reoperation depends on a decision to use this strategy before irreversible shock. Abdominal packing, when used as a desperate, "last-ditch" effort after prolonged, failed attempts at hemostasis, has been uniformly unsuccessful. Indications for abdominal packing based on physiologic and anatomic criteria have been identified. Most have focused on intraoperative parameters including pH (~7.2), core temperature (<35°C), and coagulation values (prothrombin time >16 seconds) in the patient with profuse hemorrhage requiring large volumes of blood-product transfusion.

The optimal time for re-exploration is controversial because neither the physiologic endpoints of resuscitation nor the increased risk of infection with prolonged packing is well defined. The obvious benefits of hemostasis provided by packing also are balanced against the potential deleterious effects of increased intra-abdominal pressure on ventilation, cardiac output, renal function, mesenteric circulation, and intracranial pressure. Timely alleviation of the secondary "abdominal compartment syndrome" may be a critical salvage maneuver for patients. We recommend temporary abdominal wall expansion in all patients requiring packing until the hemostasis is obtained and visceral edema subsides.

A staged operative strategy for unstable trauma patients represents advanced surgical care and requires sound judgment. Intra-abdominal packing for control of exsanguinating hemorrhage is a lifesaving maneuver in highly selected patients in whom coagulopathy, hypothermia, and acidosis render further surgical procedures unduly hazardous. Early identification of patients likely to benefit from abbreviated laparotomy techniques is crucial for its success.

## Abdominal Compartment Syndrome

*Abdominal compartment syndrome* is a term used to describe the deleterious effects of increased intra-abdominal pressure.<sup>98</sup> The "syndrome" includes respiratory insufficiency from worsening ventilation/perfusion mismatch, hemodynamic compromise from preload reduction due to inferior vena cava compression, impaired renal function from renal vein compression as well as decreased cardiac output, intracranial hypertension from increased ventilator pressures, splanchnic hypoperfusion, and abdominal wall overdistention. The causes of intra-abdominal hypertension in trauma patients include hemoperitoneum, retroperitoneal and/or bowel edema, use of abdominal/pelvic packing, and secondary to massive resuscitation of

**Figure 16-7.** **A**, Abdominal wall expansion was performed in this patient with a bowel bag. **B**, Abdominal wall expansion in this patient was accomplished with a polytetrafluoroethylene patch.

non-abdominal trauma.<sup>99</sup> The combination of tissue injury and hemodynamic shock creates a cascade of events including capillary leak, ischemia-reperfusion, and release of vasoactive mediators and free radicals that combine to increase extracellular volume and tissue edema. Experimental evidence indicates significant alterations in cytokine levels in the presence of sustained intra-abdominal pressure elevation.<sup>100,101</sup> Once the combined effects of tissue edema and intra-abdominal fluid exceed a certain level, abdominal decompression must be considered.

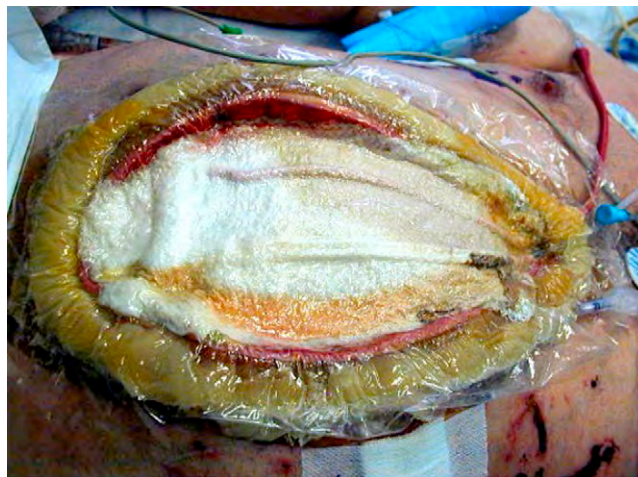

The adverse effects of abdominal compartment syndrome have been acknowledged for decades. However, abdominal compartment syndrome has only recently been recognized as a life-threatening, yet potentially treatable entity.<sup>76,102</sup> The measurement of intra-abdominal pressure can be useful in determining the contribution of abdominal compartment syndrome to altered physiologic and metabolic parameters.<sup>103-105</sup> Intra-abdominal pressure can be determined by measuring bladder pressure. This involves instilling 1 mL/kg of saline into the urinary catheter and connecting it to a pressure transducer or manometer via a three-way stopcock. The symphysis pubis is used as the zero reference point, and the pressure is measured in centimeters of H<sub>2</sub>O or millimeters of mercury. Intra-abdominal pressures in the range of 20 to 35 cm H<sub>2</sub>O or 15 to 25 mm Hg have been identified as an indication to decompress the abdomen. Many surgeons prefer to intervene according to alterations in other physiologic and metabolic parameters rather than a specific pressure measurement. One series reported 11 adult trauma patients with abdominal compartment syndrome, measured by pulmonary artery catheters and gastric tonometry, had improved preload, pulmonary function, and visceral perfusion after abdominal decompression.<sup>104</sup>

Experience with abdominal decompression for abdominal compartment syndrome in children is limited.<sup>91,102,105-107</sup> Nonspecific abdominal CT findings in children with abdominal compartment syndrome include narrowing of the inferior vena cava, direct renal compression or displacement, bowel wall thickening with enhancement, and a rounded appearance of the abdomen.<sup>106</sup> One study reported the use of patch abdominoplasty in 23 infants and children, of whom only 3 were trauma patients.<sup>107</sup> These authors found that patch abdominoplasty for abdominal

compartment syndrome effectively decreased airway pressures and oxygen requirements. Failure to respond with a decrease in airway pressures or FIO<sub>2</sub> was an ominous sign in their series. Several authors found that abdominal decompression resulted in decreased airway pressures, increased PO<sub>2</sub>, and increased urine output in children with abdominal compartment syndrome.<sup>102,105,107</sup> Many materials have been suggested for use in temporary patch abdominoplasty, including Silastic sheeting, polytetrafluoroethylene (PTFE) sheeting, intravenous bags, cystoscopy bags, ostomy appliances, and various mesh materials (Fig. 16-7). The vacuum pack technique, used increasingly in adults, is applicable in pediatric patients and seems promising (Fig. 16-8).<sup>80,96</sup>

## Bile Duct Injury

Nonoperative management of pediatric blunt liver injury is highly successful but is complicated by a 4% risk of persistent bile leakage.<sup>108,109</sup> The majority of patients with bile leaks sustained high grade (III-V) injuries.<sup>110</sup> Radionuclide scanning is recommended when biliary injury is suspected.<sup>111</sup> Delayed views may show a bile leak even if early views are normal. Endoscopic retrograde cholangiopancreatography (ERCP) can be performed with placement of

**Figure 16-8.** This photograph shows an open abdomen in a child treated with vacuum packing for hemostasis.

**Figure 16-9.** Endoscopic retrograde cholangiopancreatography demonstrates several areas of bile leaks after blunt liver injury.

transampullary biliary stents for biliary duct injury after blunt hepatic trauma. Although ERCP is invasive and requires conscious sedation, it can pinpoint the site of injury and allow treatment of the injured ducts without laparotomy (Fig. 16-9). Endoscopic transampullary biliary decompression is a recent addition to treatment for patients with persistent bile leakage. The addition of sphincterotomy during ERCP for persistent bile leakage after blunt liver injury has been advocated to decrease intrabiliary pressure and promote internal decompression.<sup>112-115</sup> Also, it is important to note that endoscopic biliary stents may migrate or clog.

### Injury to the Pancreas

Blunt traumatic injury to the pancreas occurs infrequently in children and can be very difficult to diagnose. It is estimated that injuries to the pancreas compose 3% to 12% of intra-abdominal injuries in children sustaining blunt trauma.<sup>116</sup> The lack of surrounding fat planes and the small size of the retroperitoneal gland make it challenging to document even a major ductal injury by routine CT.<sup>117</sup> A dynamic CT pancreatogram, with multiple thin slices while infusing a contrast medium, gives much more detail than routine abdominal CT. Magnetic resonance cholangiopancreatography also is a useful diagnostic modality but is not appropriate in the acute resuscitative phase of the child with multiple injuries.<sup>118</sup> Elevations in serum amylase and lipase levels are very common in abdominal trauma but are not indicative of the extent of injury or need for surgical intervention. Hyperamylasemia also may occur with salivary gland injury, bowel perforation or obstruction, intracranial

hemorrhage, or other nonspecific mesenteric injuries.<sup>119</sup> In contrast, ERCP is a very accurate technique in evaluating potential injury to the pancreatic ductal system.<sup>120</sup> It is not widely used in the early evaluation of the acutely injured child because of the highly specialized skills required, the need for general anesthesia, and the likelihood of significant need for treatment of associated head and thoracic injuries.

Nonoperative management of blunt injuries to the liver, spleen, and kidney in children is accepted as the standard of care in the majority of cases. Controversy exists when discussing management of the child with a significant pancreatic injury. Those with a pancreatic contusion without major ductal disruption will heal spontaneously. Successful nonoperative treatment of 28 children with pancreatic injuries ranging from contusions to complete transections by CT scan has been described.<sup>121</sup> Pseudocysts developed in 36% of patients and were treated with observation or percutaneous aspiration.

Direct visualization of the pancreas is very important when exploring a child's abdomen for a traumatic injury. The lesser sac is entered above the transverse colon, and the body and tail of the gland are carefully inspected. A Kocher maneuver is then used to inspect the duodenum and head of the pancreas. The posterior surface of the gland may be accessed by mobilization of the spleen along with the tail of the pancreas from a lateral to medial direction.

In the child with a major pancreatic ductal injury (Fig. 16-10), early operative intervention has been reported to shorten hospitalization and lessen dependence on total parenteral nutrition compared with those children who were initially managed nonoperatively.<sup>122-125</sup> Pseudocyst formation occurs in 45% to 100% of ductal injuries managed nonoperatively.<sup>121,126</sup> Of these, a significant number, up to 60%, may resolve with time. Percutaneous or cyst-enteric drainage procedures may be needed if resolution does not occur spontaneously. These children have an increased length of hospitalization as well as an increased dependence on total parenteral nutrition compared with those undergoing early distal pancreatectomy.

**Figure 16-10.** This abdominal CT scan demonstrates blunt transection of the pancreas (arrow).

**Figure 16-11.** In some patients it is not always clear whether a significant intestinal injury has occurred from either blunt or penetrating trauma. Diagnostic laparoscopy is a useful technique in these patients. **A**, Perforation of the bowel from penetrating trauma is seen at laparoscopy. This was closed primarily. **B**, Full-thickness injury to the colon (arrow) in a patient with blunt trauma is shown. The laparoscopic approach was converted to an open operation for treatment of this injury.

ERCP as a diagnostic and therapeutic option has recently gained some favor in selected centers with pediatric ERCP expertise. Documentation of a ductal injury, sphincterotomy, and possible stenting of the injury are all maneuvers useful for healing.<sup>120,127,128</sup>

## HOLLOW VISCUS INJURY

Gastrointestinal tract injuries in children may occur by either blunt or penetrating mechanisms. Penetrating injuries to the abdomen account for less than 10% of cases of abdominal trauma in most series. They require minimal diagnostic evaluation before operative management if penetration of the peritoneal cavity is evident, if the child has a clinical examination consistent with peritoneal irritation, or in the unstable child. Blunt intestinal injury may be seen with obvious indications for surgical intervention or may have a more subtle, insidious presentation. The mechanism may be from a compressive force (crush injury or child abuse), a deceleration shearing force (fall from a height), or a combination of the two (lap belt injury).

CT diagnosis of a bowel injury is often quite difficult. CT findings have been described in an effort to improve its diagnostic accuracy in victims of blunt abdominal trauma. Bowel wall thickening and enhancement, mesenteric stranding, and free intraperitoneal fluid in the absence of solid organ injury should alert the caregiver to a possible hollow viscus injury. Pneumoperitoneum often is not present, even with a full-thickness bowel wall disruption. Virtually all neurologically intact patients have findings or symptoms suggestive of peritoneal contamination from a perforated viscus, such as pain, tachycardia, rebound tenderness, or guarding.<sup>129</sup> Laparoscopy can be useful for diagnostic purposes in some patients (Fig. 16-11). The unconscious patient with multiple injuries presents a significant diagnostic challenge, and a high index of suspicion is needed.<sup>130</sup> These neurologically injured patients may benefit from DPL if the abdominal CT shows suspicious findings but laparoscopy poses substantial risks due to associated injuries.

Children who have a visible contusion of the anterior abdominal wall from a seat-belt lap restraint have been documented to have an increased incidence of abdominal injuries (Fig. 16-12). These include both solid and hollow abdominal organs as well as associated fractures of the lower thoracic and lumbar spine. These children must have frequent in-hospital assessments, serial physical examination by the same surgeon, and diagnostic imaging to assess for abdominal and spinal injuries. Several series have documented 80% to 100% of children with major blunt intestinal injuries who had evidence of abdominal wall ecchymosis.<sup>10,129</sup> The presence of a visible contusion does not, in itself, mandate exploration but should prompt careful observation.

## Injury to the Stomach

Injuries to the stomach due to penetrating mechanisms are variable in the amount of tissue destruction and are dependent primarily on the velocity of the offending missile or penetrating object. Blunt injury to the stomach, which is relatively infrequent, occurs when a compressive force causes a burst injury in a patient with a full stomach following a meal.

**Figure 16-12.** A lap belt sign is seen across this child's lower abdomen. This child had an underlying intestinal injury.

The diagnosis of a gastric injury from blunt force is often problematic. Free air may not be seen on the initial radiograph or CT scan. A nasogastric tube lying outside the stomach contour on a radiograph or CT scan is diagnostic. The child with abdominal wall ecchymosis, tenderness, and/or free fluid in the peritoneal cavity should prompt the suspicion of hollow viscus injury.

Surgical exploration for a suspected gastric injury is initiated with an upper midline laparotomy incision. The stomach and duodenum should be adequately mobilized, and hemorrhage should be controlled. Particular attention should be paid to the lesser curve and to the posterior stomach near the gastroesophageal junction, which are sites of possible missed injuries.<sup>131</sup> The lesser sac should always be opened to explore the posterior wall of the stomach adequately. Owing to the excellent blood supply of the stomach, repairs usually heal well.

### Injury to the Duodenum

Duodenal injuries may be extremely difficult to manage because of the intimate association with the pancreas, extrahepatic biliary system, and intra-abdominal vascular systems. Thorough mobilization is key to identifying injuries, both blunt and penetrating. The technique used to repair a duodenal injury is dependent on the overall status of the patient, the location of the injury, and the amount of tissue destruction encountered. Extravasation of air or enteral CT contrast material into the paraduodenal, pararenal, or retroperitoneal space is the key finding in those patients with a duodenal perforation. This is not seen in patients sustaining a duodenal hematoma.<sup>132</sup>

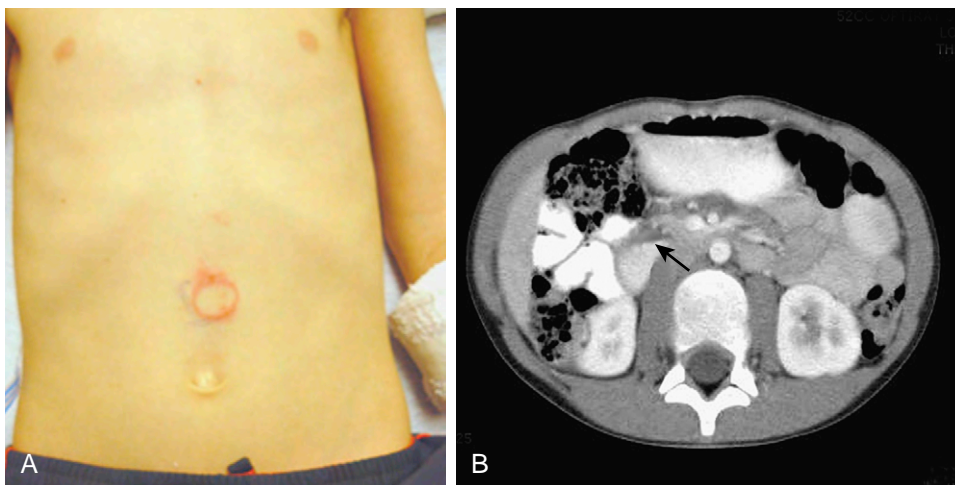

An intramural duodenal hematoma due to blunt force applied to the epigastrium (kick, punch, handlebar) may be managed nonoperatively if the child has no evidence of full-thickness injury or peritonitis (Fig. 16-13).<sup>133</sup> The CT scans or upper gastrointestinal contrast studies typically reveal duodenal narrowing, spiraling, or partial obstruction of the duodenum. No contrast or air is seen outside the bowel lumen. When

managed nonoperatively, nasogastric decompression and total parenteral nutrition may be required for an average of 1 to 3 weeks. If a duodenal hematoma is encountered during exploration for additional abdominal trauma, the serosa may be incised and the clot carefully evacuated, taking care not to enter the duodenal lumen.

Full-thickness duodenal injuries may be closed primarily if the amount of tissue destruction is not excessive and if the closure will not compromise the duodenal lumen or drainage of the biliary and pancreatic ductal system. Adequate surgical drainage of the paraduodenal area is important if a pancreatic injury or major duodenal tissue devitalization has occurred. Duodenal closure may be obtained with the aid of a Roux limb of jejunum sewn to the viable debrided duodenum. A duodenal drainage tube for decompression is left in place. Temporary pyloric exclusion with an absorbable suture via a gastrotomy also may be valuable in the management of a complex duodenal repair. This allows healing of the duodenum before spontaneous recanalization of the pyloric channel once the pyloric sutures resorb. A gastrotomy tube for decompression may also be utilized instead of a nasogastric tube. Placement of a feeding jejunostomy will be helpful for enteral nutritional support. Surgical drains placed near the injured tissue at the time of initial repair will control a fistula resulting from any enteric leak. Somatostatin analogs may be helpful in decreasing pancreatic and intestinal secretions and are useful in management of a fistula should one occur. Rarely is a pancreaticoduodenectomy required for blunt trauma in children.<sup>134</sup>

### Small Bowel Injury

Penetrating injury to the abdomen frequently injures the small intestine. The small bowel must be carefully and systematically visualized for mesenteric and bowel wall injuries. Extensive injuries should be managed by resection and anastomosis. Isolated perforations and lacerations may be repaired with debridement and closure, with care to avoid luminal narrowing.

**Figure 16-13.** This child sustained a duodenal hematoma (**B**, arrow) from a handlebar injury to the epigastrium (**A**).

**Figure 16-14.** The small bowel mesentery has been avulsed, resulting in ischemic bowel.

Hematomas in the mesentery should be explored, and control of bleeding vessels should be meticulously performed. If a segment of bowel is in jeopardy because of a mesenteric injury, bowel resection and primary anastomosis should be performed to avoid stricture formation. Injuries to the superior mesenteric artery or vein should be repaired with a vein patch as needed to avoid stenosis of the affected vessel. Delayed diagnosis of injuries may also be seen with a delayed bowel infarction due to rapid deceleration injury with avulsion of the bowel from its mesentery (Fig. 16-14). A late sequela of blunt intestinal injury is intestinal stricture.<sup>135</sup> Crush injury to the bowel wall results in ischemic injury and resulting scarring and fibrosis. Intolerance of feeding, bilious emesis, and evidence of a bowel obstruction 1 to 6 weeks after blunt abdominal trauma is the most common presenting scenario.

### Injury to the Colon

Injuries to the colon in children may occur by the same mechanisms as small bowel injuries, but the consequences may be more significant. Delayed diagnosis with peritoneal contamination may result in severe and life-threatening septic complications. If isolated colonic injuries are identified and repaired early in a hemodynamically stable child, a primary bowel anastomosis with appropriate perioperative antibiotic coverage is safe. This approach also avoids the potential complications of stomas and the need for reoperation for stoma closure. Once a colonic injury has been identified and controlled, multiple factors influence surgical management. In the absence of shock or delayed diagnosis with severe fecal contamination, many colon injuries may be safely repaired primarily. A diverting stoma may be necessary if extensive abdominal wall or perineal tissue devitalization is present, if the child is in shock, or if severe peritoneal soilage has occurred. Care must be taken in selecting the site for placement of the proximal diverting stoma to avoid ongoing wound contamination.

### Rectal Injuries

The etiology of the majority of perineal and rectal injuries in children is either accidental falls in a straddle fashion onto sharp or blunt objects or sexual abuse. Typically, rectal perforations require proximal diversion with an end colostomy and drainage of the distal injured perirectal space. Identification of these injuries may be difficult. The ability to ascertain the extent of the injury will frequently require a formal examination under general anesthesia (Fig. 16-15). In the female, care is taken to carefully inspect the vaginal vault for evidence of a penetrating injury either through or into the vagina.<sup>136</sup> Proctosigmoidoscopy in a nonprepared colon may not clearly localize an obvious perforation, but the presence of endoluminal blood must be assumed to be evidence of injury. After proximal colostomy and presacral drainage has been performed, the distal rectum should be cleared of any remaining feces. Meticulous repair of the injured anal sphincter musculature must be performed. Any nonviable tissue should be debrided at this setting. Closure of the rectal injury or perforation may be accomplished transanally if the injury is low enough to permit this approach.

### Urinary Bladder

The bladder can rupture either in an intraperitoneal or an extraperitoneal location. The young child's bladder is predominantly an intra-abdominal organ. Blunt trauma to a child with a full bladder is the mechanism in the vast majority of bladder injuries. Careful examination for possible pelvic fractures and associated intra-abdominal injuries must be performed. Gross hematuria is frequently, but not always, present as a presenting symptom. Plain cystography or CT cystography is the study of choice to evaluate a suspected bladder injury based on hematuria or an abnormal abdominal CT scan. Contrast extravasation from the bladder or a large amount of free intraperitoneal

**Figure 16-15.** This teenager developed this full-thickness straddle rectal injury after falling off a trampoline. It was possible to close the injury over drains placed in the perirectal tissues. He has recovered uneventfully with full continence.

fluid not explained by solid organ injury in a child with hematuria should prompt a study to exclude bladder perforation. Extraperitoneal bladder rupture may be treated with bladder catheter drainage, which allows complete healing in most cases. Intraperitoneal rupture will require surgical repair after adequate debridement of devitalized tissue. One or two layered closure with absorbable suture material and adequate bladder decompression with transurethral or suprapubic drains are utilized. Careful inspection for associated concomitant injuries is essential to avoid preventable sequelae.

## INJURY TO THE DIAPHRAGM

Traumatic injury to the diaphragm is infrequently observed, even at the largest pediatric trauma centers. The etiology may be either blunt or penetrating mechanisms. In most series, blunt traumatic rupture of the diaphragm after motor vehicle crashes accounts for 80% to 90% of cases. These injuries are caused by massive compressive forces to the abdomen, which create acceleration of abdominal contents cephalad, followed by rupture of the diaphragmatic muscle. The pressure gradient between the pleural and peritoneal cavities enables abdominal viscera to herniate into the thoracic cavity.

The diagnosis is frequently suggested by a plain chest radiograph as part of the secondary survey of the injured child. Other studies are occasionally helpful but may not aid in the diagnosis.<sup>137</sup> The plain radiographic findings include the following:

- Obscured hemidiaphragm
- Elevated hemidiaphragm
- Gas in herniated viscus above the diaphragm
- Tip of nasogastric tube in thorax
- Atypical pneumothorax
- Plate-like atelectasis adjacent to the diaphragm

Historically, it was believed that left-sided traumatic diaphragmatic hernias were much more common, accounting for 80% to 90% of reported cases. More recent series and autopsy studies have shown that actually the right- and left-sided ruptures occur with equal frequency.<sup>138</sup> It is likely that these traumatic hernias do occur equally, but the more severe injuries causing a right-sided rupture result in fewer survivors, resulting in fewer documented cases in trauma series.

Multiple-system and multiple-organ injury in this population is the rule rather than the exception. In the Toronto series of 16 pediatric patients with traumatic diaphragmatic rupture, 81% had multiple injuries, which included liver lacerations (47%), pelvic fractures (47%), major vascular injuries (40%), bowel perforations (33%), fractures of the long bones (20%), renal lacerations (20%), splenic lacerations (13%), and closed-head injuries (13%).<sup>137</sup> As would be expected, many complications in this group of severely injured patients were noted, with a significant risk of fatal injury.

Emergent operative exploration with minimal diagnostic testing is often necessary in patients with multiple abdominal injuries. Observation and careful

palpation of both diaphragms must be a routine part of the abdominal exploration in this setting. Direct suture repair of the injury is usually possible after debridement of any devitalized tissue. Pledged sutures may aid in buttressing the repair made with mild tension without tearing the muscle. If the defect to be closed is too large to repair primarily without undue tension, a prosthetic patch of PTFE or an acellular collagen patch implant can be used in the manner of repairing congenital diaphragmatic hernias in the newborn. Successful laparoscopic or thoracoscopic repair of diaphragmatic injuries in hemodynamically stable children and in delayed repairs is technically feasible, with care being taken to search for additional associated injuries.<sup>139,140</sup> Renal avulsion into the chest through a traumatically ruptured diaphragm has been reported.<sup>141,142</sup> Because of the rarity of this injury, a high index of suspicion must be maintained when the mechanism and associated injuries suggests the possibility of this injury.<sup>143</sup> As always, a thorough and systematic exploration of the entire abdomen and palpation of the retroperitoneal structures is emphasized.

## RENAL TRAUMA

The kidney is the most commonly injured organ in the urogenital system. Children appear to be more susceptible to major renal trauma than adults.<sup>144</sup> Several unique anatomic aspects contribute to this observation, including less cushioning from perirenal fat, weaker abdominal musculature, and a less well-ossified thoracic cage. The child's kidney also occupies a proportionately larger space in the retroperitoneum than does an adult's kidney. In addition, the pediatric kidney may retain fetal lobulations, permitting easier parenchymal disruption.

Renal trauma is broadly classified as being blunt or penetrating. Blunt trauma is more common, accounting for more than 90% of injuries in some series.<sup>145</sup> The kidney, which is relatively mobile within Gerota's fascia, can be crushed against the ribs or vertebral column, resulting in parenchymal lacerations or contusions. The kidney also can be lacerated by fractured ribs. Penetrating trauma accounts for only 10% to 20% of renal injuries, yet it is responsible for the majority of renal injuries that require operation.<sup>146</sup> Penetrating injuries to the chest, abdomen, flank, and lumbar regions should be assumed to have caused renal injury until proven otherwise.

Preexisting or congenital renal abnormalities, such as hydronephrosis, tumors, or abnormal position, make the kidney vulnerable to relatively mild traumatic forces. Historically, congenital abnormalities in injured kidneys have been reported to vary from 1% to 21%, although recent reviews have shown that the incidence rates are closer to 1% to 5%.<sup>147,148</sup> Renal abnormalities, particularly hydronephrosis, may be discovered as a result of minor blunt abdominal trauma. Rarely, the child may be seen with an acute abdomen secondary to intraperitoneal rupture of a hydronephrotic kidney.<sup>149</sup>

Major deceleration/flexion injuries may produce renal arterial or venous injuries due to stretching of a normally fixed vascular pedicle. This type of injury may be more common in children because of their increased flexibility and relatively increased renal mobility.<sup>150-152</sup> Post-traumatic thrombosis of the renal artery follows an intimal tear that occurs because the media and adventitia of the renal artery are more elastic than the intima. The intimal tear produces thrombosis that results in renal ischemia. A high index of suspicion must be maintained to identify these injuries in a timely fashion.

## Diagnosis

Once the patient has been resuscitated and life-threatening injuries have been addressed, evaluation of the genitourinary system can be undertaken. After any blunt injury, the presence of hematuria (microscopic or gross), a palpable flank mass, or flank hematomas are indications for urologic evaluations. Most major blunt renal injuries occur in association with other major injuries of the head, chest, and abdomen. Urologic investigations should be undertaken when trauma to the lower chest is associated with rib, thoracic, or lumbar spine fractures. It also should be performed in all crush injuries to the abdomen or pelvis when the patient has sustained a severe deceleration injury. Because a renal pedicle injury or ureteropelvic junction disruption may not be associated with one of the classic signs of renal injury such as hematuria, radiologic evaluation to demonstrate bilateral renal function should always be considered in patients with a mechanism of injury that could potentially injure the upper urinary tract.

Gross hematuria is the most reliable indicator for serious urologic injury.<sup>153</sup> The need for imaging in the patient with blunt trauma and microscopic hematuria is not so clear. Moreover, the degree of hematuria does not always correlate with the degree of injury.<sup>154</sup> Renal vascular pedicle avulsion or acute thrombosis of segmental arteries can occur in the absence of hematuria, whereas mild renal contusions can appear with gross hematuria.<sup>155</sup> In adults, the vast majority of patients with blunt trauma with microscopic hematuria and no evidence of shock (systolic blood pressure < 90 mm Hg) have minor renal injuries and thus do not need to be studied radiographically.<sup>155,156</sup> Guidelines for evaluating the pediatric population are not so clearly defined. All children with any degree of microscopic hematuria after blunt trauma have traditionally undergone renal imaging. Recently, a meta-analysis of all reported series of children with hematuria and suspected renal injury revealed that only 11 (2%) of 548 patients with insignificant microscopic hematuria (<50 red blood cells/high-power field [RBCs/HPF]) had a significant renal injury.<sup>157</sup> However, all 11 of these patients were found to have multiple organ trauma and renal imaging would have been performed in the course of evaluation despite the relatively minor amount of microscopic hematuria. Detection of significant renal injury was found to increase to 8% with significant

microhematuria (>50 RBCs/HPF) and to 32% in those with gross hematuria after blunt trauma. Thus, it seems reasonable to consider observation without renal imaging in children with microscopic hematuria of less than 50 RBCs/HPF who are stable, unless they have multiple organ system injuries.

Historically, excretory urography (intravenous pyelography [IVP]) has been the radiographic imaging study of choice in suspected renal trauma. The sensitivity has been reported as high as 90% in diagnosing renal injury. Unfortunately, IVP misses other intra-abdominal injuries and may miss or understage renal injury in children by 50% compared with CT.<sup>158,159</sup> CT is now used almost exclusively as the imaging study of choice for suspected renal trauma in hemodynamically stable adults and children.<sup>160</sup> CT is both sensitive and specific for demonstrating a parenchymal laceration or urinary extravasation, for delineating segmental parenchymal infarcts, for determining the size and location of the surrounding retroperitoneal hematoma, and/or for diagnosing associated intra-abdominal injury (Fig. 16-16). CT also allows accurate staging of the renal injury.

The most commonly used staging system for renal trauma is from the American Association for the Surgery of Trauma. This classification categorizes renal trauma into five grades that have predictive value in the subsequent management strategy of these injuries.<sup>161</sup> The ultimate goal of staging is to provide sufficient information for management that results in the preservation of renal parenchyma and the salvage of injured kidneys.

Ultrasonography also has been used to assess renal trauma. However, in comparison to CT, its sensitivity in demonstrating renal injury is only 25% to 70%. Also, it may miss associated intra-abdominal injuries. Unfortunately, FAST has been shown to have a low sensitivity for solid organ injury in children. It also provides little information concerning renal function or pedicle injuries. At present, renal ultrasonography is not currently recommended as a useful screening

**FIGURE 16-16.** Severe right kidney disruption, resulting in a large perirenal hematoma, is seen on this CT scan after intravenous administration of a contrast agent.

tool for urologic evaluation in the setting of blunt renal trauma.<sup>162</sup>

It is imperative to acknowledge that major renal injuries such as ureteropelvic junction disruption or segmental arterial thrombosis may occur without the presence of hematuria or hypotension. Therefore, a high index of suspicion is necessary to diagnose these injuries. Nonvisualization of the injured kidney on IVP and failure of contrast uptake with a large associated perirenal hematoma on CT are hallmark findings for renal artery thrombosis. Ureteropelvic junction disruption is classically seen as perihilar extravasation of contrast agent with nonvisualization of the distal ureter.<sup>163</sup>

## Treatment

In most patients, attempts should be made to manage all renal injuries nonoperatively.<sup>164-166</sup> Minor renal injuries constitute the majority of blunt renal injuries and usually resolve without incident.<sup>167,168</sup> The management of major renal parenchymal lacerations, although accounting for only 10% to 15% of all renal trauma patients, is currently controversial. Operative intervention is not always mandatory, and many major renal injuries due to blunt trauma can be managed without operation.<sup>169-171</sup> When necessary, the goals of surgical renal exploration are either to treat major renal injuries definitively with preservation of renal parenchyma when possible or to evaluate thoroughly a suspected renal injury. The need for surgical exploration is much higher in patients with penetrating trauma as opposed to blunt trauma.

The indications for renal exploration vary greatly between individual trauma centers. Most centers expectantly manage grade I to III injuries with bed rest and observation. Controversies arise in the management of grade IV to V injuries. The majority of blunt renal injuries sustained are minor contusions and lacerations. Even in the presence of gross hematuria, most blunt renal injuries will not require exploration and have excellent long-term outcomes.<sup>171</sup> Absolute indications for renal exploration include persistent life-threatening bleeding; an expanding, pulsatile, or uncontained retroperitoneal hematoma; or suspected renal pedicle avulsion. Relative indications for exploration include substantial devitalized renal parenchyma or urinary extravasation. Injuries with significant (>25%) nonviable renal tissue associated with parenchymal laceration that are managed nonoperatively have a complication rate of more than 75%.<sup>172</sup> When such renal injuries are associated with an intraperitoneal organ injury, the postinjury complication rate is much higher unless the kidney is surgically repaired. By surgically repairing such injuries, surgeons reduced the overall morbidity from 85% to 23%.

Urinary extravasation alone does not demand surgical exploration. In patients with major renal injury and urinary extravasation who are managed nonoperatively, urinary extravasation resolved spontaneously in 87%.<sup>165</sup> Extravasation persisted in 13% and was successfully managed endoscopically. Incomplete

staging of the renal injury demands either further imaging or renal exploration and reconstruction. Most commonly, these patients undergo renal exploration because they are bleeding persistently or because they have an associated injury that requires laparotomy.

When the nonoperative approach is chosen, supportive care with bed rest, hydration, antibiotics, and serial hemoglobin and blood pressure monitoring is required. After the gross hematuria resolves, limited activity is advised for 2 to 4 weeks until microscopic hematuria ceases. Complications can occur during the period of observation within the first 4 weeks of injury and include delayed bleeding, abscess, sepsis, urinary fistula, urinary extravasation, urinoma, and hypertension. The greatest risk is life-threatening hemorrhage occurring within the first 2 weeks of injury. Immediate surgical exploration or angiographic embolization is indicated. Angiographic embolization is an alternative to exploration in a hemodynamically stable patient in whom persistent gross hematuria signifies persistent low-grade hemorrhage from the injured kidney. Persistent urinary extravasation has successfully been managed by percutaneous drainage. Hypertension in the early post-trauma period is uncommon. Hypertension may develop in the ensuing months and, in most instances, is treated medically.

## Renal Exploration and Reconstruction

If operation is required, early control of the vessels increases the rate of renal salvage.<sup>173</sup> When proximal vascular control is initially achieved before any renal exploration, nephrectomy is required in fewer than 12% of cases.<sup>174</sup> When primary vascular control is not achieved and massive bleeding is encountered, in the rush to control bleeding, a kidney that could have been salvaged may need to be removed. The surgeon must carefully identify the kidney's relations with the posterior abdomen and the posterior parietal peritoneum. The colon is lifted from the abdomen and placed on the anterior chest to allow mobilization of the small bowel. The inferior mesenteric vein and the aorta are identified at this point, and the posterior peritoneum is incised medial to the inferior mesenteric vein. The aorta is dissected superiorly to the ligament of Treitz, where the left renal vein is found crossing anterior to the aorta. Retraction of the left renal vein exposes both renal arteries beneath it. These arteries may now be isolated and controlled with vessel loops. Once vessel isolation is complete, an incision is made in the peritoneum just lateral to the colon. The colon is reflected medially to expose the retroperitoneal hematoma in its entirety, and the kidney may be exposed. If significant bleeding is encountered, the ipsilateral renal vessels may be occluded. Warm ischemia time should not surpass 30 minutes.<sup>174</sup>

Renal vascular injuries must be addressed promptly. Major lacerations to the renal vein are repaired directly with venorrhaphy. Repair of renal arterial injuries may require a variety of techniques, including resection with end-to-end anastomosis, bypass graft with autogenous vein or a synthetic graft, and arteriorrhaphy.

Traumatic renal artery occlusion requires many of the same techniques for repair. However, this must be performed in the first 12 hours from the time of injury. Otherwise, the kidney is usually nonviable after this length of ischemia.

### **Single Kidney and Sports Participation**

Physician opinions and practice patterns regarding the participation of children and adolescents with single,

normal kidneys in contact/collision sports vary widely. A recent survey of the American Society of Pediatric Nephrology indicated that the majority (62%) of nephrologists do not permit contact/collision sports participation in patients with a solitary kidney.<sup>175</sup> Interestingly, only 5% barred cycling. These opinions are not supported by the literature because a sports-related kidney injury was found in 0.4 per million children per year from all sports, and cycling caused three times more kidney injuries than football.

# PEDIATRIC HEAD TRAUMA

Kelly Tieves, DO

**T**raumatic brain injury (TBI) is an important cause of death and disability in children.<sup>1</sup> Among children from birth to 14 years, there are an estimated 2685 deaths, 37,000 hospitalizations, and 435,000 emergency department visits each year in the United States for TBI. An estimated 30,000 children and youth suffer permanent disability. The two highest-risk age groups are birth to 4-year-olds and 15- to 19-year-olds. Falls and abuse account for the majority of injury in the infants and small children, whereas motor vehicle crashes are the predominant mechanism of injury in teens and young adults.<sup>2,3</sup> In the entire American population, more than 1.4 million people sustain TBI each year, with over 50,000 deaths, 235,000 hospitalizations, and 1.1 million treated and released from an emergency department.<sup>2</sup> The economic burden of TBI totaled an estimated \$60 billion in the United States in 2000.<sup>4</sup>

Although TBI is often referred to as the leading cause of death and disability in children, there are currently no population-based studies to estimate the actual personal and public health burden of TBI in children and youth. The number of mild injuries in children, including concussions, is estimated to be three to four times that of the more severe cases. Current studies, including longitudinal outcome studies in adults, often omit this population from study, producing underestimates of the burden of disease.<sup>5</sup>

Head trauma as a result of child abuse remains a significant concern.<sup>6</sup> In children younger than age 1 year, nonaccidental trauma secondary to abuse is the most common cause of fatal TBI.<sup>7,8</sup> Head trauma associated with abuse has a higher rate of subdural hematoma, subarachnoid hemorrhage, and retinal hemorrhages when compared with nonabusive head trauma. Public health campaigns have brought attention to the dangers of shaking a young child and provided resources to parents and caretakers who may be at risk of harming a child.<sup>9</sup>

Although the reasons are not entirely clear, there has been a general trend in improved outcome after severe TBI in children.<sup>10</sup> Declines in morbidity and mortality have been due to improved prehospital care, regionalization of pediatric trauma care, adherence to

evidence-based practice guidelines, more aggressive care, such as intracranial pressure (ICP) monitoring and early surgical evacuation of mass lesions, improved diagnostic imaging (computed tomography [CT], magnetic resonance imaging [MRI]), and advances in intensive care. In July 2003, evidence-based practice guidelines were published for the acute medical management of severe TBI in infants, children, and adolescents.<sup>11</sup> These guidelines have provided a format to decrease variability in care across centers, but there is a striking lack of data from well-designed, randomized controlled trials.

## BRAIN INJURY MECHANISMS

### Nonpenetrating Cranial Trauma

Head injuries can be classified by their pathologic or morphologic descriptions. Blunt or nonpenetrating trauma occurs as the result of a direct impact on the brain and calvaria. These injuries often occur after a motor vehicle collision or fall and account for the vast majority of TBI in the United States. This type of injury typically results in focal damage to the underlying brain (*coup*). In some instances, *contrecoup* damage occurs from the rebound movement of the viscoelastic brain within its rigid encasement. The predominant contrecoup damage occurs on the side opposite the impact. This is commonly seen with subdural hemorrhages with associated cortical contusion when the brain rebounds off the skull, causing disruption of delicate surface vessels. The inner surface of the skull at its base is irregular, ridged, and restrictive at its anterior margins. As a result, the anterior and inferior portions of the temporal and frontal lobes are often injured by abrupt brain acceleration or deceleration in a sagittal plane.

### Penetrating Trauma

Penetrating injury, caused by bladed weapons and projectiles, such as handguns and rifles, cause cerebral lacerations with deleterious effects on the underlying

neurons, their functional interconnections, and the cerebral vasculature at the surface of the brain. Penetrating injuries also carry a risk of increased infection, especially if foreign material is introduced into the brain.

## Axonal Shearing

Axonal injury or shearing occurs as the result of changes in the angular momentum of the head. Axonal injury or shear injury is often coupled with vascular injury. Axonal shearing may occur between white matter bundles and deeper subcortical neuronal structures such as the basal ganglia and thalamus and within the upper brain stem where the cerebrum rotates on its axis. This shearing injury coupled with vascular injury is classically observed as petechial hemorrhages in white matter and commonly referred to as diffuse axonal injury (DAI). Impact depolarization occurs at the time of severe impact injury, resulting in the release of the excitatory amino acid glutamate and with massive increases in extracellular potassium, which initiates excitotoxicity. This cascade plays a crucial role in secondary injury and is discussed later. The neurologic impact due to axonal shearing can present as a transient loss of consciousness or as profound and persistent neurologic deficits, even leading to death.

## Concussion

The term *concussion* is often used to describe the constellation of symptoms that occur after mild to moderate TBI when no hematoma nor other intracranial pathologic process is identified. Classic symptoms include headache, nausea, vomiting, difficulty concentrating, retrograde and/or anterograde amnesia, and personality changes. These findings are the result of neuronal dysfunction and axonal injury that can occur even after a mild TBI. Complete recovery after concussion injury is common. However, long-term consequences have been described and include impaired attention and working memory and slowed processing speed.

## PATHOPHYSIOLOGY

The intracranial contents include brain parenchymal tissue, cerebrospinal fluid (CSF), and blood. The brain parenchyma accounts for approximately 80% of the intracranial contents, with the remainder being evenly distributed between CSF and blood. The majority of the CSF is in the subarachnoid spaces, and the remainder is in the ventricles, with the postcapillary circulation containing most of the intracranial blood.

The Monro-Kellie doctrine is a simple, yet vitally important concept relating to the understanding of ICP dynamics (Fig. 17-1). Given that the cranium is a rigid, nonexpansile container, it states that the total volume of the intracranial contents must remain constant and any increase in the volume of one component must be at the expense of the others, assuming the intracranial volume remains constant. Thus, very

**Figure 17-1.** Monro-Kellie doctrine. The Monro-Kellie doctrine states that the cranial compartment is incompressible and that the volume inside the cranium is a fixed volume. The cranium and its constituents (blood, cerebrospinal fluid [CSF], and brain tissue) create a state of volume equilibrium such that any increase in volume of one of the cranial constituents must be compensated by a decrease in volume of another.

early after injury, a mass such as an expanding hematoma may be enlarging while the ICP remains normal. Once the limit of displacement of CSF and intravascular blood has been reached, ICP rapidly increases (Fig. 17-2). In children with distensible skulls, there is controversy about the application of this principle. Some argue that the open fontanelle allows for expansion of the intracranial contents and therefore affords increased protection from elevation of ICP. However, studies have indicated that the smaller neural axis of infants and young children results in a less compliant pressure-volume relationship with an increased risk of intracranial hypertension.<sup>12,13</sup> Although this doctrine is important to understanding the dynamics of ICP, it uses a hydraulic approach to the cerebral circulation.

**Figure 17-2.** Intracranial pressure (ICP)-volume relationship. Small increases in brain volume do not lead to immediate increase in ICP because of the ability of the cerebrospinal fluid to be displaced into the spinal canal as well as the slight ability to stretch the falx cerebri between the hemispheres and the tentorium between the hemispheres and the cerebellum. However, once the ICP has reached around 25 mm Hg, small increases in brain volume can lead to marked elevations in ICP.

Subsequent work has shown that the relationship between ICP and cerebral blood flow (CBF) is much more complex and variable. Whereas simultaneous measurement of ICP and CBF would be most helpful in optimizing therapeutic strategies, the Monro-Kellie doctrine provides a reasonable basic explanation of intracranial dynamics.

CBF is defined as the velocity of blood through the cerebral circulation. In normal adults, CBF is 50 to 55 mL/100 g of brain tissue/min. In children, CBF may be much higher depending on their age. At 1 year of age it approximates adult levels, but at 5 years of age, normal CBF is approximately 90 mL/100 g/min and then gradually declines to adult levels by the mid to late teens. Flow is inversely related to vascular resistance, with resistance increasing as vessel diameter becomes smaller. CBF is proportional to the pressure gradient and, in accordance to Poiseuille's law, inversely proportional to blood viscosity. Brain injury severe enough to cause coma can cause a 50% reduction in CBF during the first 6 to 12 hours after injury.<sup>14,15</sup> It usually increases over the next 2 to 3 days, but for those patients who remain comatose, CBF remains below normal for days or weeks after injury. There is increasing evidence that such low levels of CBF are inadequate to meet the metabolic demands of the brain early after injury and that regional, if not global, cerebral ischemia is common.<sup>16,17</sup>

Cerebral perfusion pressure (CPP) is the differential pressure of arterial inflow and venous outflow to the brain. CPP is considered the transmural pressure gradient that is ultimately the driving force required for supplying cerebral metabolic needs. Intracranial venous pressure is usually slightly less than ICP and CSF pressure. As ICP increases from head injury, the difference between CPP and ICP narrows. At a CPP of 10 mm Hg, blood vessels collapse and blood flow ceases.

Current techniques available to measure CBF are still considered experimental in the management of severe TBI. Such techniques include transcranial Doppler and xenon-enhanced CT imaging. Because CPP is easily determined in the clinical situation in which ICP monitoring is done, it has become a critical parameter for defining treatment options. Studies have shown a good correlation between CPP and CBF in patients with intact cerebral autoregulation.<sup>18</sup> However, cerebral autoregulation is often disrupted after severe TBI and measures of cerebral vascular resistance may be more useful in guiding therapy.<sup>19,20</sup>

Historically, treatment protocols were principally directed toward reducing ICP. Hyperventilation and fluid restriction were important components in these older protocols. Current treatment strategies seek to optimize CPP while reducing ICP, with little reliance on hyperventilation or fluid restriction. Maintenance of a CPP of greater than 70 mm Hg was initially recommended in the adult TBI guidelines developed by the Brain Trauma Foundation. However, more recent studies have shown conflicting data regarding the optimal CPP and how best to achieve it. Current adult evidence-based guidelines recommend maintenance

of a 50 to 70 mm Hg CPP. CPP is likely an age-related continuum, thus making problematic treatment protocols based on a single number for all age groups. To date, no study has demonstrated that active maintenance of CPP above any target threshold in pediatric TBI improves mortality or morbidity. However, there seems to be a threshold of less than 40 mm Hg that is associated with increased mortality. Guidelines for pediatric TBI suggest maintenance of CPP greater than 40 mm Hg and a CPP between 40 and 65 mm Hg may be optimal for an individual patient.<sup>11</sup>

Cerebral autoregulation refers to a homeostatic process that allows CBF to remain constant given a wide range of mean arterial pressures (MAP). Arterial vessels can dilate or constrict in response to various physiologic changes, including ICP and systemic arterial pressure to maintain normal flow and normal brain metabolism. In healthy adult patients, CBF remains constant with a MAP between 60 and 160 mm Hg or a CPP between 50 and 150 mm Hg.<sup>21</sup> Normally, reflexive vasoconstriction will occur in the presence of elevated systemic blood pressure to impede intracranial hypertension. In contrast, a moderate decrease in systemic blood pressure will paradoxically result in increased ICP because reflex vasodilatation will occur in compensation. When perfusion pressure falls below 50 mm Hg, cerebral ischemia occurs and compensatory cerebral arteriole vasodilatation is exhausted. When perfusion pressure exceeds 150 mm Hg, cerebral arteriolar impedance is overcome, the affected vessels passively dilate, and fluid is forced through a damaged endothelium into the brain, causing diffuse vasogenic edema. Impaired cerebral autoregulation after TBI and age-related changes in CBF make the immature brain susceptible to secondary injury both from diminished as well as excess CBF. Not only is diminished blood flow and cerebral ischemia associated with poor neurologic outcome, excess CBF, or hyperemia, it is also associated with impaired cerebral autoregulation and poor neurologic outcome.<sup>22</sup>

In addition to changes in CBF, the brain has some structural differences from its adult counterpart that may explain the different responses to injury often seen in children after TBI. The brain doubles in size in the first 6 months of life and reaches approximately 80% of adult size by age 2. The developing brain has a higher water content and incomplete neuronal synapse formation and arborization. In addition, incomplete myelination and neurochemical changes result in neuronal plasticity after birth. The subarachnoid space is generally smaller and offers less protection than the mature brain, owing to less buoyancy, and thereby provides less protection to the brain parenchyma during changes in head momentum. This contributes to the higher incidence of diffuse cerebral edema and parenchymal injuries in children.

## Primary Brain Injury

Primary injury occurs as a result of direct injury to the brain parenchyma due to shear forces at the time of impact. Both cortical disruption and axonal injury can

occur, resulting in a cascade of events contributing to secondary brain injury (see later). Cortical disruption, if occurring within minutes to hours, is not likely to be amenable to resuscitative therapy.

Skull fractures occur commonly with head injury and are readily diagnosed with CT. In children, a skull fracture should prompt an evaluation of the underlying brain parenchyma given the significant impact it takes to injure the skull. Fractures of the skull vault can occur in either a linear or a stellate fashion. Fractures involving the skull base are typically associated with a greater force than simple cranial vault fractures. The classic signs of basilar skull fractures include Battle's sign (ecchymoses over the mastoid process associated with an ipsilateral skull fracture), raccoon eyes and CSF rhinorrhea (associated with a cribriform plate fracture), and otorrhea (associated with fracture of the mastoid air cells or temporal bone fracture). Meningitis associated with a basilar skull fracture occurs in 2% to 9%.<sup>23</sup> Despite the risk of infection, the routine use of prophylactic antibiotics is not recommended because this does not prevent meningitis from occurring and tends to select out for resistant organisms.<sup>24,25</sup> Vaccination against *Streptococcus pneumoniae* should be considered for all patients with a basilar skull fracture and CSF leak because of the increased risk of pneumococcal-associated meningitis.<sup>26</sup>

Post-traumatic intracranial hemorrhage includes epidural hematomas, subdural hematomas, and subarachnoid hemorrhages. Epidural hematomas usually occur in the middle fossa and are often associated with an injury to the middle meningeal artery, although they can occur in the anterior or posterior fossa. The classic CT description is a lenticular hematoma, bound by suture lines, because of the tightly bound dura (Fig. 17-3). Clot formation under the calvaria compresses the dura and can cause rapid neurologic deterioration as the brain becomes further displaced. Skull fractures overlying the epidural hematoma are common. The classic presentation of a patient with a lucid interval followed by clinical deterioration is rare in children. Only after the hematoma enlarges is clinical evidence of elevated ICP noted. Typical symptoms include headache, lethargy, emesis, irritability, confusion, and decreased level of consciousness. Progressive deterioration results in seizures, changes in vital signs with hypertension and respiratory instability, pupillary changes, posturing, and cardiovascular compromise. Prompt neurosurgical evacuation is imperative for patient survival and good outcome. Evacuation of extremely large clots (>40 mL) in children often results in very good long-term results, provided that surgical intervention is timely.

Subdural hemorrhages are classified as acute (<3 days old), subacute (3 to 10 days old), and chronic (>10 days old). Acute and subacute subdural hemorrhages are not infrequent in infants, often the result of birth injury or abuse (Fig. 17-4). They usually result from torn or bridging veins or from associated contusions hemorrhaging into the subdural space. The superficial cortical veins in small children lack any reinforcement from arachnoidal trabeculae and

**Figure 17-3.** CT scan demonstrates a very large epidural hematoma that compresses the right hemisphere and causes midline shift. This 7-month-old patient reportedly fell and became obtunded. On examination, she had a fixed and dilated right pupil. She had a good recovery after immediate surgical evacuation of her epidural hemorrhage, with persistent partial third nerve and facial palsies on the side ipsilateral to the hemorrhage. (Courtesy of Dr. Lisa Lowe.)

are susceptible to inertial loading. Infants are particularly susceptible to the development of a subdural hemorrhage. Subdural hematomas tend to follow the convexities of the brain and cover the entire hemisphere. CT demonstrates hyperdense crescent-shaped

**Figure 17-4.** Hyperacute subdural bleeding is seen on the right side on this cranial CT scan. Compression of right-sided cerebral structures is found with no intraparenchymal bleeding. Despite immediate craniotomy and evacuation of the subdural blood, the patient had a prolonged convalescence. He is hemiparetic on the left side and has significant developmental and cognitive delay. (Courtesy of Dr. Lisa Lowe.)

blood collections at the surface of the brain, often associated with mass effect and cortical edema. On CT, particularly when anemia is present, acute subdural hematomas may have an isodense appearance that belies their actual hemorrhagic character later found at the time of operation. Surgical intervention is indicated when neurologic deterioration occurs as a result of the combined effect of subdural hemorrhage and parenchymal injury, either from the compressive effect of the subdural blood or from the combined effect of impact forces on the entire cerebrum and diffuse bleeding. In infants, it is possible to tap the subdural space at the level of the fontanelle and produce rapid decompression. Large subdural hematomas with significant mass effect require more extensive craniotomies. Acute subdural hemorrhages are usually associated with a worse prognosis than patients with an epidural hematoma, primarily related to the underlying brain damage.

Subacute subdural hematomas in the context of trauma are much less frequent in the pediatric population. However, they will be seen in emergency settings when they are a cause of neurologic problems and when they are considered a manifestation of previous or recurrent nonaccidental head trauma. As with acute hematomas, subacute subdural hematomas will have a nonspecific presentation. Affected children have both the symptoms of increased ICP (coma, irritability, lethargy, emesis, seizures) and the signs of elevated ICP (frontal bossing, enlarged heads, dilated scalp veins, sun-setting eyes, papilledema, and bulging fontanelles). The CT scan often shows isodense or hypodense fluid collections at the cerebral convexities. MRI studies are often valuable in making the diagnosis of these bleeding events. As with acute subdural hematomas, surgical intervention is often necessary.

Chronic subdural hematomas can cause pathologic elevation of the ICP and may require surgical intervention to control cranial growth and CSF pressure. Patients present with symptoms similar to those of a subacute subdural hematoma. Interventions include serial percutaneous drainage, limited craniotomies to drain and irrigate the subdural space, and subdural/peritoneal shunts.

Subarachnoid bleeding in acutely traumatized children is common and rarely the result of aneurysmal bleeding (Fig. 17-5). Bleeding occurs from disruption of the fragile pia-arachnoidal vasculature. Often this occurs over the convexities of the brain affected by coup type of injuries or the frontotemporal poles affected by contrecoup injuries. Subarachnoid hemorrhage from trauma can also occur in the interhemispheric fissure and in the basilar cisterns. If subarachnoid bleeding is an isolated finding resulting from minor trauma, no specific therapies are indicated except symptomatic amelioration of chemical meningitis, meningismus, and photophobia. Subarachnoid hemorrhage may result in hydrocephalus and may require ventricular shunting to relieve the increased ICP. In patients with severe TBI, subarachnoid hemorrhage is associated with a poor outcome and may be further associated with cerebral vasospasm. Techniques such as

**Figure 17-5.** Subarachnoid hemorrhage secondary to trauma is present on this cranial CT scan without contrast. Blood is seen in the perimesencephalic, prepontine, and suprasellar cisterns. The patient was involved in a motor vehicle accident and complained of headache. He was neurologically normal. (Courtesy of Dr. Lisa Lowe.)

transcranial Doppler imaging can be utilized to identify vasospasm. Nimodipine, a calcium channel blocking agent, has been used in vasospasm occurring in the setting of postaneurysmal subarachnoid bleeding. Nimodipine is not often used in the context of TBI, in part because of its hypotensive effects. Moreover, in children, there are little data looking at its efficacy in the setting of post-TBI subarachnoidal bleeding.<sup>27,28</sup>

## Secondary Brain Injury

The cornerstone of management of TBI is the prevention of secondary injuries. Secondary brain injury includes both the evolution of damage within the brain related to a cascade of macroscopic and microscopic events as described here and the effects of secondary insults, including hypoxia and hypotension. Endogenous secondary brain injury involves the macroscopic cascade of edema, ischemia, necrosis, elevated ICP, and inadequate CPP. The cellular changes after TBI have been the focus of much research, and several cellular mechanisms have been elucidated and are described later.

Brain swelling or edema traditionally has been described as either vasogenic or cytotoxic. Vasogenic edema results from the disruption of the blood-brain barrier. The blood-brain barrier is maintained by tight junctions between endothelial cells that line the vessels of the brain. Injury to these cells allows extravasation of fluid and proteins into the interstitial space of the brain parenchyma. Disruption of these cells may occur from the primary impact injury or result from free radical formation, cytokines, and other secondary mechanisms of brain injury. Cytotoxic edema is edema of the cells themselves, resulting from a failure of cellular ion homeostasis and membrane

function. The time course of brain edema is variable. It is thought, however, that vasogenic edema occurs early after injury and cytotoxic edema occurs in a more delayed fashion.

Edema of the brain is an important marker for injury and is also a cause of secondary injury. In children, rapid formation of edema is commonly seen on serial CT scans after trauma. In early (<24 hours after injury), fatal closed-head injuries in children, CT scans often demonstrate little or no significant parenchymal bleeding. However, diffuse brain swelling is seen with obliteration of the ventricles and loss of the basilar cisterns and subarachnoid space. As edema progresses and the compensatory mechanisms of the brain are exhausted, ICP increases markedly with small changes in intracranial volume (see Fig. 17-2). Cerebral edema typically develops early after injury, typically peaking at 72 to 96 hours and then gradually resorbs over the course of a week in survivors.<sup>29</sup>

Sustained elevations in ICP above 20 mm Hg are poorly tolerated by the injured brain and have been associated with poor neurologic outcome and increased mortality in pediatric patients.<sup>30</sup> Sustained elevation in ICP may result in cerebral ischemia if cerebral perfusion is impaired and ultimately may result in cerebral herniation.

Studies in adults utilizing xenon CT have shown a reduction in CBF that occurs early after severe TBI.<sup>14,31</sup> This hypoperfusion may be further exacerbated by hypotension and hypoxia. It is clear that this early hypoperfusion or ischemia occurring after severe TBI is associated with poor outcome.<sup>32,33</sup> Proposed mediators involved in early post-traumatic ischemia include direct vascular disruption, production of endothelin-1 (a potent vasoconstrictor), loss of endogenous vasodilators (endogenous nitric oxide synthase), and likely many other complex, interrelated cellular and metabolic events.

The release of excitatory amino acids, such as glutamate, results in neuronal injury after TBI. Glutamate is the most studied and most abundant neurotransmitter in the brain. However, toxic levels cause neuronal cell death.<sup>34,35</sup> After TBI, glutamate and other excitatory amino acids are released, resulting in neuronal swelling. Glutamate works on a variety of receptors; the best demonstrated is the *N*-methyl-D-aspartate (NMDA) receptor, which results in large fluxes of calcium into the neuron. The resultant stimulation of enzymes leads to cell death with the breakdown of the cytoskeleton, free radical formation, alterations in gene expression and protein synthesis, and membrane dysfunction. Studies have failed to demonstrate efficacy of anti-excitotoxic therapies, perhaps owing to their application in all patients with TBI rather than those with excitotoxicity and because treatment may have been initiated too late.<sup>36</sup>

Oxidative stress with free radical formation is an important mechanism leading to secondary injury. Free radicals are molecules or atoms possessing an unpaired electron in the outer orbit, making them highly reactive. Free radicals damage endothelial cells and injure the brain parenchyma. This results

in disruption of the blood-brain barrier and resultant vasogenic and cytotoxic edema. Free radical scavengers, such as vitamin E, ascorbic acid, and superoxide dismutase attempt to minimize injury by binding with the free radicals. However, these mechanisms often become overwhelmed and the process becomes self-perpetuating. Clinical studies are ongoing to identify pharmacologic free radical scavenging agents.

Apoptosis requires a cascade of intracellular events for completion of cell death and is thus termed *programmed cell death*. The signals for cell death have now been elucidated in vitro and are becoming more clearly understood in vivo. Calcium influx into the cell, oxidative stress, and energy depletion all appear to be important intracellular triggers of apoptosis. Knowledge of the mechanisms involved in cellular signaling of apoptosis is important in the development of new therapeutic approaches to the management of TBI. As our understanding of the complex biochemical, cellular, and molecular responses to TBI progresses, application of therapeutic strategies and agents may help halt the secondary injury processes.

## INITIAL EVALUATION AND MANAGEMENT OF HEAD INJURY

The key principles of management after TBI rest on the foundation of the Monro-Kellie doctrine and the avoidance of secondary brain injury. Interventions that decrease CSF and hyperemia, while ensuring adequate oxygenation and blood flow, form the basis for all management strategies discussed here.

The initial management and resuscitation, as with any trauma management, begins with the assessment of airway, breathing, and circulation. Ensuring adequate oxygenation and ventilation and promptly addressing sources of ongoing blood loss serve as the basic principles in the management of persons suspected or confirmed to have head injury. Hypotension and hypoxia in the field are proven secondary injury insults that are associated with poor outcomes, with hypotension being considerably more detrimental than hypoxia.<sup>32,37</sup> There has been no documented advantage to endotracheal intubation over effective bag-valve-mask ventilation in the field.<sup>38,39</sup> Providers inexperienced in pediatric airway management should defer endotracheal intubation. Efforts should be made to control bleeding, including scalp lacerations, which may be a source of shock in the pediatric patient. The administration of isotonic crystalloid solution should be utilized to promptly restore the intravascular volume. The withholding of fluid because of concerns of concomitant head injury is unjustified and may contribute to secondary brain injury with ineffective CBF. Young children are prone to hypoglycemia; however, hypoglycemia occurring early after trauma is rare. Hyperglycemia may be detrimental during periods of cellular hypoxia owing to a shift to anaerobic metabolism and lactate production. Therefore, unless there is documented hypoglycemia,

dextrose-containing fluids should be avoided in the early phases of resuscitation.

Current recommendations do not support ICP-directed measures in the field, even if the patient has focal or lateralizing signs, such as a decreased level of consciousness and an enlarging pupil, with the possible exception of hyperventilation and hyperosmolar therapy for signs of herniation.<sup>11,40</sup> Every effort should be made to transport the patient to a pediatric trauma center or to an adult center equipped to manage pediatric trauma patients. Careful attention should be paid to cervical spine immobilization because there is an increased risk of spinal cord injury with TBI.

On arrival in the emergency department, the Advanced Trauma Life Support (ATLS) protocol of the American College of Surgeons should be followed.<sup>41</sup> This provides a systematic approach to the traumatized patient and emphasizes evaluation and management of airway, breathing, and circulation first. Early hospital evaluation and management is the same as that described for the prehospital setting. Placement of a secure airway utilizing endotracheal intubation should be performed in the initial hospital management if not already performed in the prehospital setting. After initial stabilization and fluid resuscitation, a brief neurologic examination should be performed, preferably before the administration of sedation and neuromuscular blockade. Adjunctive diagnostic studies should be performed only after the initial resuscitation phase.

The severity of brain injury is often classified using the modified Glasgow Coma Scale (GCS) score.<sup>42</sup> Even with modifications, the GCS score has limitations in its use for infants and very young children (Table 17-1). In addition, the use of sedation and pharmacologic paralysis, orbital swelling making eye opening impossible, endotracheal intubation making verbal responses impossible, and preexisting conditions such as alterations in motor function further limit the use of the GCS score. Nonetheless, it is the best tool currently available to classify TBI and to share information between treating physicians.

### Mild TBI: GCS 14-15

Approximately 80% of patients presenting to the emergency department with brain injury are categorized as having a mild brain injury. These patients may have a brief loss of consciousness and be amnesic to the events surrounding the injury. Most patients with mild TBI recover fully. However, a small percentage of patients will experience deterioration, resulting in severe neurologic dysfunction unless prompt recognition and resuscitation is performed. All patients should have a general examination to exclude other injuries and a limited neurologic examination. Adjunctive studies such as cervical spine evaluation and other imaging studies should also be performed as needed. Although less common in younger children, alcohol or other intoxicants can confuse the findings and make examination results unreliable. Neuroimaging is essential in

<b>Table 17-1</b>		
<b>Modified Glasgow Coma Scale for Infants and Children</b>		
<b>Child</b>	<b>Infant</b>	<b>Score</b>
<b>Eye Opening</b>		
Spontaneous	Spontaneous	4
To verbal stimuli	To verbal stimuli	3
To pain only	To pain only	2
No response	No response	1
<b>Verbal Response</b>		
Oriented, appropriate	Coos and babbles	5
Confused	Irritable cries	4
Inappropriate words	Cries to pain	3
Incomprehensible words or nonspecific sounds	Moans to pain	2
No response	No response	1
<b>Motor Response</b>		
Obeys commands	Moves spontaneously and purposefully	6
Localizes painful stimulus	Withdraws to touch	5
Withdraws in response to pain	Withdraws in response to pain	4
Flexion in response to pain	Decorticate posturing (abnormal flexion) in response to pain	3
Extension in response to pain	Decerebrate posturing (abnormal extension) in response to pain	2
No response	No response	1

the evaluation in all but the completely asymptomatic and neurologically normal patient. Unenhanced, or noncontrast, CT is the initial and most reliable diagnostic tool, particularly for identifying bleeding.

Patients who are asymptomatic, fully awake and alert, and neurologically normal may be observed for several hours and safely discharged. It is imperative that they be discharged with a reliable caretaker and one who understands the signs and symptoms that should prompt emergent re-evaluation. Discharge instructions should be given in both written and verbal format. When appropriate, a follow-up visit should be scheduled with the patient's primary care provider. Admission to the hospital should be considered for patients with penetrating injuries, a history of loss of consciousness or a deteriorating level of consciousness, moderate to severe headache, intoxication, skull fracture, or lack of availability of CT. Additionally, all patients with a CSF leak or other significant associated injuries should be admitted for observation.

### Moderate TBI: GCS 9-13

Approximately 10% of patients presenting with TBI will fall into the moderate category. They should undergo the same initial examination as those presenting with

mild TBI but additionally will need laboratory studies and CT. All patients should be admitted to a facility with definitive neurosurgical care. Frequent re-evaluation of neurologic status is imperative. Approximately 90% of patients with moderate TBI will improve and will be discharged from the hospital. Ten percent experience deterioration of their condition and require management as described next for severe TBI. An emergent repeat CT should be performed in those whose condition deteriorates.

### Severe TBI: GCS 3-8

The treatment of severe TBI begins with the fundamentals of resuscitation previously described including restoration of an adequate circulating blood volume, blood pressure support, appropriate ventilation, and adequate oxygenation. Patients with severe head injury often have multisystem injuries and require a multidisciplinary team to aggressively identify and treat all injuries. An evidence-based approach to resuscitation and treatment of patients with severe brain injury is presented in [Figure 17-6](#).<sup>11</sup>

### Respiratory Monitoring and Management

Ensuring adequate oxygenation to avoid worsening of neuronal ischemia is essential. If the patient did not have an endotracheal tube placed in the field, the airway should be secured, with special attention paid to avoidance of hypoxia, hypercarbia, or hypocarbia. Ventilation should be provided with a goal PaCO<sub>2</sub> of 35 to 40 mm Hg. The cerebral vasculature is sensitive to changes in the PaCO<sub>2</sub>. In the head-injured patient, hypercapnia (PaCO<sub>2</sub> > 45 mm Hg) can cause significant elevation in ICP because of CO<sub>2</sub>-induced dilatation of the cerebral vasculature resulting in increased cerebral blood volume and flow. The immediate effect of hyperventilation is a reduction of ICP, although this response is neither universal nor sustained. Hyperventilation reduces ICP by causing cerebral vasoconstriction, with a subsequent reduction in CBF in reactive vascular beds. Hyperventilation should be reserved for those patients with obvious signs of brain stem herniation, often hallmarked by Cushing's triad (abnormal respiratory pattern, hypertension, and bradycardia) and nonreactive, dilated pupils.

### Patient Positioning

The head of the bed should be elevated at 15 to 30 degrees and the head maintained in the midline position to facilitate venous drainage from the head, thus allowing maintenance of cerebral perfusion. Temperature management will be discussed in more detail later; however, avoidance of hyperthermia is important in early brain resuscitation.<sup>43</sup> Moreover, patients who are identified early in resuscitation to have isolated head trauma and have hypothermia should undergo passive rewarming.

### Acute Surgical Management

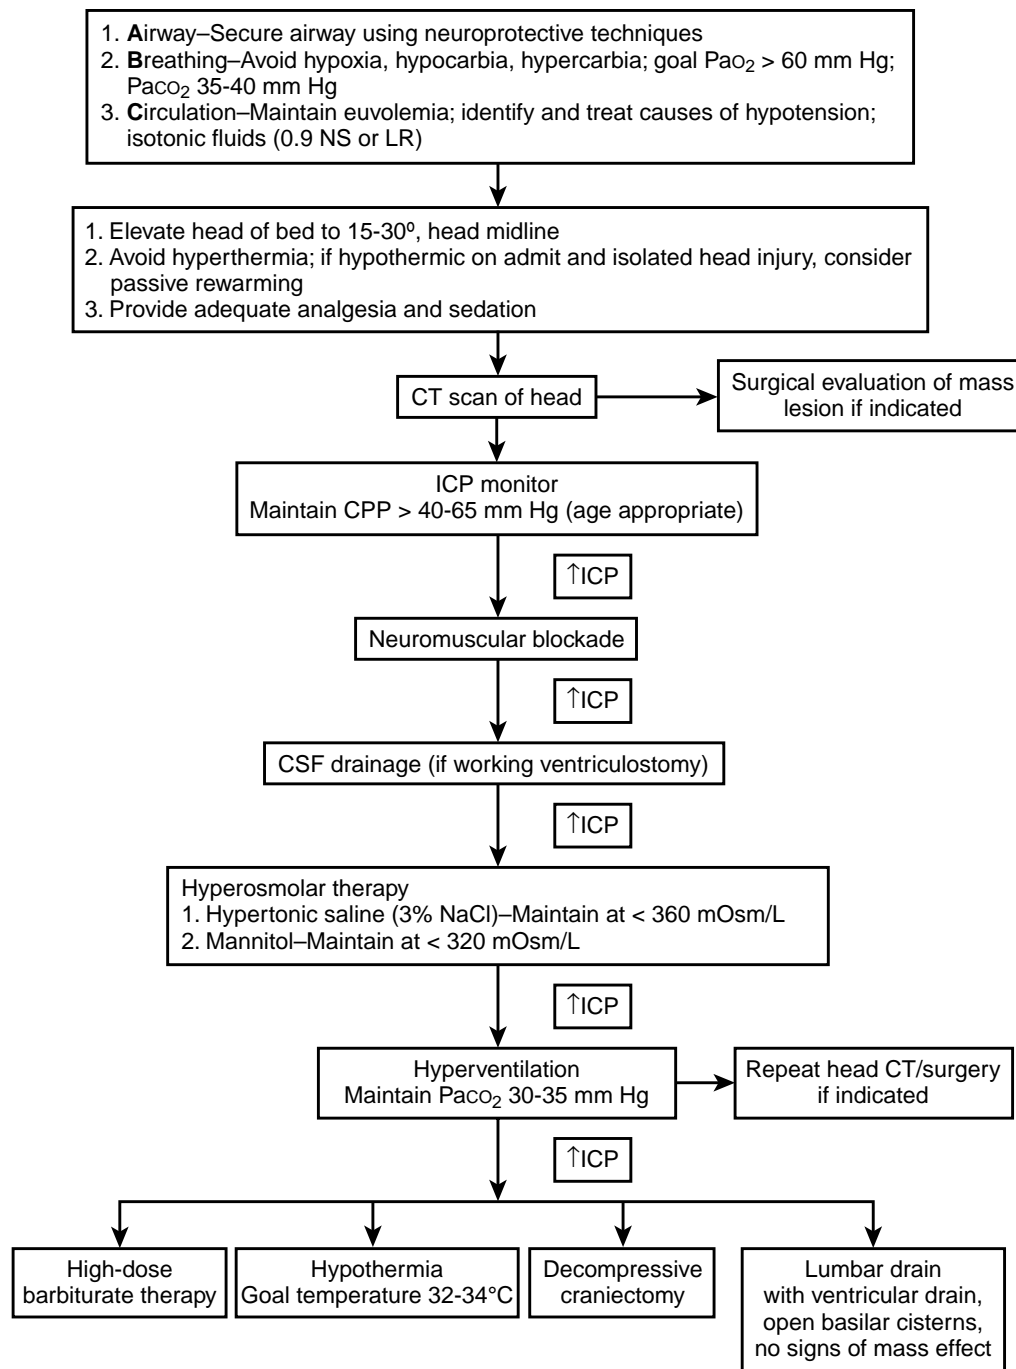

A CT scan should be obtained promptly in all patients after initial resuscitation and stabilization. Patients with intracerebral hematomas causing a mass effect should undergo prompt neurosurgical evacuation. The traditional definition of a significant mass effect has been greater than 5 mm of midline shift. Midline shift is measured on axial views of the CT scan. A line is drawn at the midline of the skull in the sagittal plane and then a perpendicular line is extended to the septum pellucidum. The basilar cisterns are also evaluated for compression.

### Sedation and Analgesia

Sedation and analgesia are commonly used in children with TBI. However, there is little clinical evidence guiding their use. Sedation and analgesia can help facilitate the care of the patient including maintenance of the airway and placement of invasive catheters or other monitoring devices. These measures can also facilitate the transport of the patient for diagnostic or therapeutic procedures. Sedation and analgesia may be useful in maintaining or decreasing ICP by decreasing the metabolic rate and thereby decreasing CBF. Studies have demonstrated a twofold to threefold increase in basal metabolic rate for oxygen accompanying painful or stressful stimuli. Noxious stimuli, such as suctioning, can increase ICP. Painful and noxious stimuli and stress can also increase sympathetic tone, resulting in hypertension and bleeding from operative sites.<sup>44,45</sup> However, these medications must be used with caution, because sedative or narcotic related vasodilatation may decrease CBF with resulting hypotension or conversely increase CBF by causing cerebral vasodilatation.

### Intracranial Pressure Monitoring and Management

The use of ICP devices has become standard in this country in the treatment of severe head injury, even in the absence of prospective, randomized clinical trials to establish efficacy in improving outcome. There are two lines of evidence to support the use of ICP monitoring in the pediatric TBI patient. There is strong evidence that supports the association between intracranial hypertension and poor neurologic outcome.<sup>46</sup> Second, ICP monitoring and aggressive treatment of intracranial hypertension are associated with the best reported clinical outcomes.<sup>47</sup> The "Guidelines for the Acute Management of Severe Traumatic Brain Injury in Infants, Children, and Adolescents" recommend that ICP monitoring may be considered in patients with a GCS score less than 8.<sup>11</sup> The guidelines also state that the presence of open fontanelles and/or sutures in an infant does not preclude the development of intracranial hypertension or negate the utility of ICP monitoring. The treatment threshold for intracranial hypertension is typically defined as an ICP

**Figure 17-6.** This algorithm provides an evidence-based approach for treatment of pediatric patients with severe head trauma. NS, normal saline; LR, lactated Ringer's; ICP, intracranial pressure; CSF, cerebrospinal fluid.

greater than 20 mm Hg. Age-specific and injury mechanism-specific ICP thresholds have yet to be defined. In more recent years, focus has switched from ICP-directed therapy to CPP-directed therapy and is discussed later.

Although there is no single ICP monitoring device that is superior to the others, intraventricular devices are effective monitors that allow CSF drainage as part of treatment of ICP. Ventricular CSF drainage may serve as a treatment option in the setting of refractory

intracranial hypertension. However, if not placed early after injury, placement may be difficult when damaged brain and cerebral edema have effaced the normal ventricle. Intraparenchymal monitors have fiberoptic or strain-gauge transducers that provide continuous pressure readings and can be placed, with relative ease, in any region of the brain. Newer monitors can measure brain tissue oxygen levels and permit manipulations to optimize regional oxygenation, including adjustments in the fraction of inspired oxygen ( $F_{iO_2}$ )

and blood transfusion. Coagulation abnormalities are a relative contraindication to the insertion of these devices. Therefore, prompt correction using plasma or activated factor VIIa should be considered before placement.<sup>48</sup>

The optimal CPP for a given individual is not clear. Global and/or regional cerebral ischemia commonly complicates brain injury. Studies have consistently shown that a CPP less than 40 mm Hg is associated with increased mortality.<sup>46,49</sup> A CPP between 40 and 65 mm Hg likely represents an age-related continuum with interindividual variability. Studies have suggested that avoidance of hypotension, rather than elevation of CPP, is beneficial.<sup>46</sup> Efforts to increase CPP in adults to a supernormal level with the use of fluids and vasoactive infusions are associated with significant risks, including pulmonary complications, fluid overload, pressor toxicity, and renal insufficiency. Furthermore, in cases of disrupted autoregulation, exacerbation of intracranial hypertension can result.

## Neuromuscular Blockade

Neuromuscular blockade is commonly used as a treatment strategy for patients with increased ICP. Neuromuscular blocking agents should be used only in those patients with a secure airway, who are mechanically ventilated and adequately sedated. The proposed mechanisms of neuromuscular blocking agents in reducing ICP include a reduction in airway and intrathoracic pressure with facilitation of cerebral venous outflow and prevention of shivering, posturing, or breathing against the ventilator.<sup>50</sup> Neuromuscular blockade should be reserved for the patient with increased ICP who is unresponsive to sedation and analgesia because its use has been associated with prolonged ICU stays and increased risk of nosocomial infections.

## Hyperosmolar Therapy

The use of hyperosmolar agents to decrease ICP was first described in the early 1900s. Hypertonic saline and mannitol were among the first agents used, and mannitol has become the mainstay of therapy over the past couple decades. The mechanism of action of mannitol has been well studied. However, its effect on survival and functional outcome after TBI has not been well demonstrated. Mannitol has two primary mechanisms. The first is an initial rheologic effect, resulting in a decrease in blood viscosity that occurs within minutes of administration. A resultant decrease in blood vessel diameter occurs as a result of autoregulation with reflex vasoconstriction that leads to a decrease in cerebral blood volume and ICP.<sup>51</sup> Second, mannitol acts as a potent osmotic diuretic, thus pulling fluid from the interstitial space into the intravascular space. Because of its diuretic effect, intravascular volume can be depleted with the risk of decreasing cerebral perfusion, resulting in secondary brain ischemia. Careful attention must be paid to promptly replenishing intravascular volume. Another reported risk of mannitol therapy is acute tubular necrosis. Monitoring

of serum osmolarity is recommended when using mannitol, with osmolar levels greater than 320 mOsm/L to be avoided. Most of the reports showing the development of renal damage occurred in the era of dehydration therapy for cerebral edema. It is unclear whether the same osmolar thresholds are valid in the current era of maintaining normal intravascular volume. The beneficial effects of mannitol are best achieved with rapid bolus administration, with dosage ranges of 0.25 to 1.0 g/kg. Chronic administration of mannitol has been associated with a reverse osmotic shift resulting in rebound cerebral edema and disruption of the blood-brain barrier.

More recently, hypertonic saline has re-emerged as a hyperosmolar agent and is the preferred agent in the TBI patient with hypovolemia.<sup>52,53</sup> Hypertonic saline includes 3% to 23.4% saline, with 3% saline the most studied in pediatrics. There is no evidence that one concentration is more effective than another for reducing intracranial hypertension. Similar to mannitol, hypertonic saline requires the presence of an intact blood-brain barrier to exert its effect. Hypertonic saline is an osmolar agent and it pulls fluid from the interstitium into the intravascular space, without a strong diuretic effect, thus maintaining blood volume and resultant cerebral perfusion. Hypertonic saline can be used as a bolus (3 to 5 mL/kg) or continuous infusion (0.1 to 1.0 mL/kg/hr titrated to the minimum dose needed to achieve a reduction in ICP). In addition to the hyperosmolar effect, hypertonic saline has been reported to have several other potentially beneficial effects for the trauma patient, including vasoregulatory, hemodynamic, neurochemical, and immunologic properties. Serum osmolarity of 360 mOsm/L has been reported with the use of hypertonic saline and has been well tolerated in the pediatric patient with a head injury.<sup>52</sup> The primary theoretical concerns associated with the risk of hypertonic saline include the development of central pontine myelinolysis (rapid shrinking of the brain associated with mechanical tearing of bridging vessels leading to subarachnoid hemorrhage), renal failure, and rebound intracranial hypertension (Table 17-2).

Prophylactic administration of mannitol or other hyperosmolar therapy either in the field or in the hospital is no longer routinely recommended. Hyperosmolar therapy should be reserved for those patients with documented intracranial hypertension or those with signs of impending herniation to avoid potential secondary injury and complications associated with hyperosmolar therapy.

## Anticonvulsant Prophylaxis

Anticonvulsants are often administered to patients with TBI. Current clinical evidence supports their use to prevent early post-traumatic seizures, which are typically defined as seizures occurring within the first 7 days after injury. Early post-traumatic seizures occur with a greater frequency in infants and children with severe TBI than adults. They may further increase brain metabolic demands, may increase ICP, and may

**Table 17-2** A Comparison of Mannitol and Hypertonic Saline (for Hyperosmolar Therapy)

	Mannitol	3% Hypertonic Saline
Bolus dosing guidelines	0.25-1.0 g/kg rapid bolus	3-5 mL/kg
Infusion guidelines	None	0.1-1.0 mL/kg/hr
Effectiveness	May wane with repeated administration	Effective after repeated administration; effective when mannitol efficacy has waned
Augmentation of MAP	Moderate	Greater, more prolonged
Rheologic properties	Yes	Yes
Diuretic effect	Osmotic diuretic, may necessitate volume replacement to avoid hypovolemia	Diuresis through action of atrial natriuretic peptide
Maximum serum osmolarity	320 mOsm/L	360 mOsm/L
Adverse effects	Renal failure, hypotension, rebound elevation in ICP	Rebound elevation in ICP, central pontine myelinolysis, bleeding, electrolyte abnormal
Proposed beneficial effects	Antioxidant effects	Restoration of resting membrane potential and cell volume, inhibition of inflammation

MAP, mean arterial pressure; ICP, intracranial pressure.

lead to secondary brain injury. Prophylactic anticonvulsants do not prevent late (occurring > 7 days from injury) post-traumatic seizures.

### Medically Refractory Intracranial Hypertension

It is estimated that 21% to 42% of children with severe TBI will develop refractory intracranial hypertension despite medical and surgical management.<sup>11</sup> In this population of children, therapies and interventions with higher risk profiles may need to be considered. Decompressive craniectomy, high-dose barbiturate therapy, hyperventilation, lumbar drain placement, and the use of moderate hypothermia should be considered in the patient with medically refractory intracranial hypertension.

#### Decompressive Craniectomy

Children are more likely than adults to have diffuse brain swelling after TBI and may be more amenable to a treatment strategy utilizing early decompressive craniectomy. Decompressive craniectomy should be considered in children with severe TBI and medically refractory intracranial hypertension in infants with abusive head trauma. The main goal of decompressive craniectomy is to control ICP, thereby maintaining CPP and cerebral oxygenation. Improved outcomes have been demonstrated in several small single-center studies, and it appears to be most effective when done early, before the development of extensive secondary brain injury.<sup>54,55</sup>

#### Barbiturate Therapy

High doses of barbiturates are known to reduce ICP and have been used in the management of increased ICP for decades. Their side effects limit their current use to those patients with injuries refractory to first-line therapies. Barbiturates are effective in lowering

ICP by suppression of brain metabolism and altering vascular tone. In addition to the ICP-lowering benefits, barbiturates also inhibit free radical-mediated lipid peroxidation and have membrane-stabilizing effects. Small case series of children with severe TBI suggest that barbiturates may be effective in lowering ICP in the setting of refractory intracranial hypertension.<sup>56,57</sup> Their use is associated with myocardial depression, increased risk of hypotension, and the need for blood pressure support with intravascular fluids and inotropic infusions. It is important that barbiturates be used in the setting of systemic monitoring with the ability to rapidly detect hemodynamic instability.

#### Hyperventilation

Hyperventilation has been a mainstay in the management of severe TBI, but more recent concerns about its role in cerebral ischemia have lessened its use. As discussed previously, the cerebral vasculature is sensitive to changes in PaCO<sub>2</sub>, with hypocarbia producing cerebral vasoconstriction and a resultant decrease in CBF. Historically, hyperemia, or excessive CBF, was thought to be the primary mechanism resulting in cerebral edema after TBI, thus making hyperventilation a reasonable approach to the management of the patient with severe TBI. More recent pediatric studies have demonstrated that hyperemia is uncommon after severe TBI. Hyperventilation may decrease cerebral oxygenation, resulting in secondary brain ischemia.<sup>58,59</sup> Aggressive hyperventilation (PaCO<sub>2</sub> < 30 mm Hg) may be considered for refractory intracranial hypertension. Monitoring of CBF, jugular venous oxygen saturation, or brain tissue oxygenation may help identify cerebral ischemia in this setting.

#### Lumbar Drain

Placement of a lumbar drain can be considered in patients with refractory intracranial hypertension that

is unresponsive to the first-line therapies. It is recommended that the patient have a working ventriculostomy in place or documentation of open basilar cisterns on CT.

### *Therapeutic Hypothermia*

The avoidance of hyperthermia and use of therapeutic hypothermia after TBI is based on the rationale that temperature plays an important role in mechanisms contributing to secondary brain injury (excitotoxicity, free radical formation). Despite evidence in animal models demonstrating efficacy of therapeutic moderate hypothermia (32°-34°C), large randomized clinical studies in both adults and children have been unable to prove the effectiveness of hypothermia on improved outcome after TBI.<sup>60-65</sup> Studies extrapolated from the adult literature indicate that hyperthermia adversely

affects outcome, and it may be advisable to consider passive rewarming of the mild to moderately hypothermic trauma patient with isolated head injury.<sup>43</sup>

---

## CONCLUSION

With continued advancements in medical care, more children are surviving TBI.<sup>10</sup> The highest mortality rates occur in children younger than 2 years of age and older than 15 years of age. Survivor outcomes range from full recovery to severe physical and/or mental disabilities. Generally, children and adolescents recover better than those older than 21 years. The immature brain is very susceptible to secondary brain injury, and an open fontanelle may mask signs until rapid decompensation occurs.

# PEDIATRIC ORTHOPEDIC TRAUMA

Gregory A. Mencio, MD • Michael T. Rohmiller, MD • Neil E. Green, MD

Musculoskeletal trauma is the most common emergency condition in children.<sup>1</sup> In children ages 1 to 14, accidents are the leading cause of death.<sup>2</sup> However, most orthopedic injuries sustained by children are not life threatening. The chance of a child sustaining a fracture before age 16 is 42% for boys and 27% for girls.<sup>3</sup> It has been estimated that between 1% and 2% of children present with a fracture each year.<sup>4</sup> As participation in sporting and recreational activities increases, the number of fractures is likely to increase. A 2006 study looking at the impact of trauma on an urban pediatric orthopedic practice demonstrated that fracture treatment (both operative and nonoperative) accounted for approximately one third of the total work-related relative value units generated by this group.<sup>5</sup> The most common fractures seen were of the distal radius (23%), forearm (14%), tibia (13%), and elbow (10%). The most common fracture-related operations were performed on the elbow (23%), tibia (12%), femur (9.8%), forearm (5.5%), and the distal aspect of the radius (5%).

Patient gender, age, climate, time of day, and social situation in the home have been shown to impact the frequency of orthopedic injuries. In children, boys sustain fractures at 2.7 times the rate of girls.<sup>6</sup> However, as girls become more involved in athletic events, this margin may narrow. It has been shown that fracture location varies with chronologic age, a finding that is probably due to a combination of the anatomic maturation of the child and the age-specific activities of childhood.<sup>3</sup> Several authors have shown that fractures are more common during the summer months when children are out of school.<sup>4,6,7</sup> It has also been shown that there is a strong association between sunshine and fractures and a negative association between rain and fractures.<sup>8</sup> Likewise, two studies have documented that the afternoon is the most frequent time for fractures to occur.<sup>9,10</sup> This correlates with the time of peak activity for children. Injuries in the home during the late afternoon and evening account for more than 83% of all injuries to children.<sup>11</sup> Moreover, the overall incidence of fractures occurring at home increases with the age of the child.<sup>4,12</sup> In a Swedish study, the physical quality of the home environment did not correlate well with the fracture incidence.<sup>13</sup> The major correlation was

with the degree of social handicaps such as welfare or alcoholism in the family. Similarly, a study from Manitoba elicited the social situation at home as a major influence of children's injuries.<sup>14</sup>

No discussion of pediatric orthopedic trauma is complete that does not include a discussion of nonaccidental trauma. The incidence of physical abuse to children is estimated to be 4.9 per 1000. Of those abused, 1 of every 1000 will ultimately die as a result.<sup>15</sup> Early recognition and reporting of nonaccidental trauma is essential because children who return home after hospitalization with unrecognized abuse have a 25% risk of serious injury and a 5% risk of death.<sup>16</sup> Children at highest risk for abuse are first-born children, premature infants, stepchildren, and handicapped children.<sup>17</sup> Most cases of child abuse involve children younger than 3 years of age. Any child presenting with fractures, particularly if they involve the long bones, should be viewed with circumspection as to the cause.<sup>18</sup>

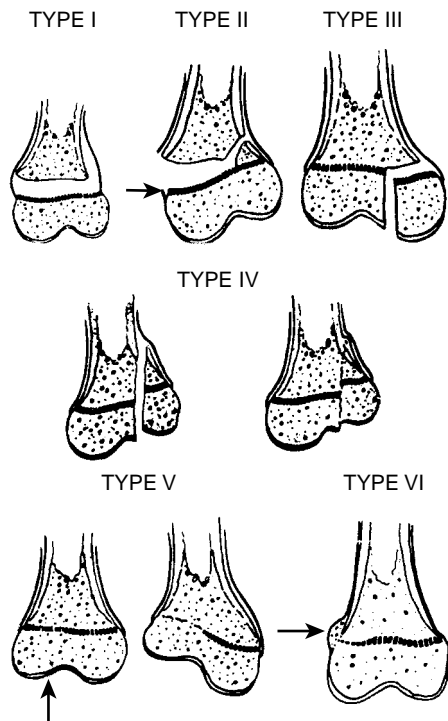

## PATHOPHYSIOLOGY

The major difference between children and adults is that children are constantly growing. In the immature skeleton, longitudinal and appositional growth takes place through the physes (growth plates) that are located at the ends of the long bones, in the end plates of the vertebral bodies, or at the periphery of the round bones in the feet and hands. Thus, the physis is essential for normal skeletal growth but is also the weakest portion of the bone in children. Consequently, fractures in children frequently involve this structure. It is estimated that in children approximately 30% of fractures of the long bones include an injury to the physis.<sup>19-21</sup> Most fractures that involve the growth plates heal without consequence. However, some injuries can result in permanent damage with significant sequelae such as angular deformity or complete cessation of growth.

The ends of every long bone consist of an epiphysis (near the joint), physis, and metaphysis (area of newly formed bone). At the time of skeletal maturity, the physis closes, which means there is no further

longitudinal growth. Fracture healing in children is rapid and the potential for remodeling is great due to the growth potential and dynamism of the immature skeleton. These characteristics allow for nonoperative treatment of some fractures in children that demand operative treatment in skeletally mature patients. Remodeling of fractures predictably occurs in the plane of primary motion of the adjacent joint (usually flexion/extension), to a lesser degree in the coronal plane (varus and valgus deformities), and is virtually nonexistent in the transverse plane with rotational malalignment.<sup>22</sup>

Classification of fractures is done to predict outcome and guide treatment. Fractures in children are classified according to the pattern of involvement. Currently, most orthopedic surgeons use the Salter-Harris classification (Fig. 18-1).<sup>23</sup> Type I injuries involve the physis only and may be missed on radiographs if they are not displaced. Type II injuries start in the physis and exit the metaphysis. Type III injuries involve the physis and epiphysis, exiting into the joint, and type IV fractures involve both the epiphysis and metaphysis. Classic teaching states that type I and II injuries heal without growth abnormalities if reduced appropriately. More recent literature disputes some of this dogma.<sup>24-26</sup> Type III and IV injuries usually occur in older children and require anatomic realignment via open reduction to restore congruity of the joint to minimize the risk of arthritis. Also, it restores continuity of the physis to decrease the risk of growth disturbance. Type V injuries are crush injuries and are not usually recognized at presentation, but this pattern carries a high risk of growth arrest.<sup>27</sup>

**Figure 18-1.** Salter-Harris classification of physeal injuries with Rang modification. (From Rang ML [ed]: *The Growth Plate and Its Disorders*. Edinburgh, E&S Livingstone, 1969, p 139.)

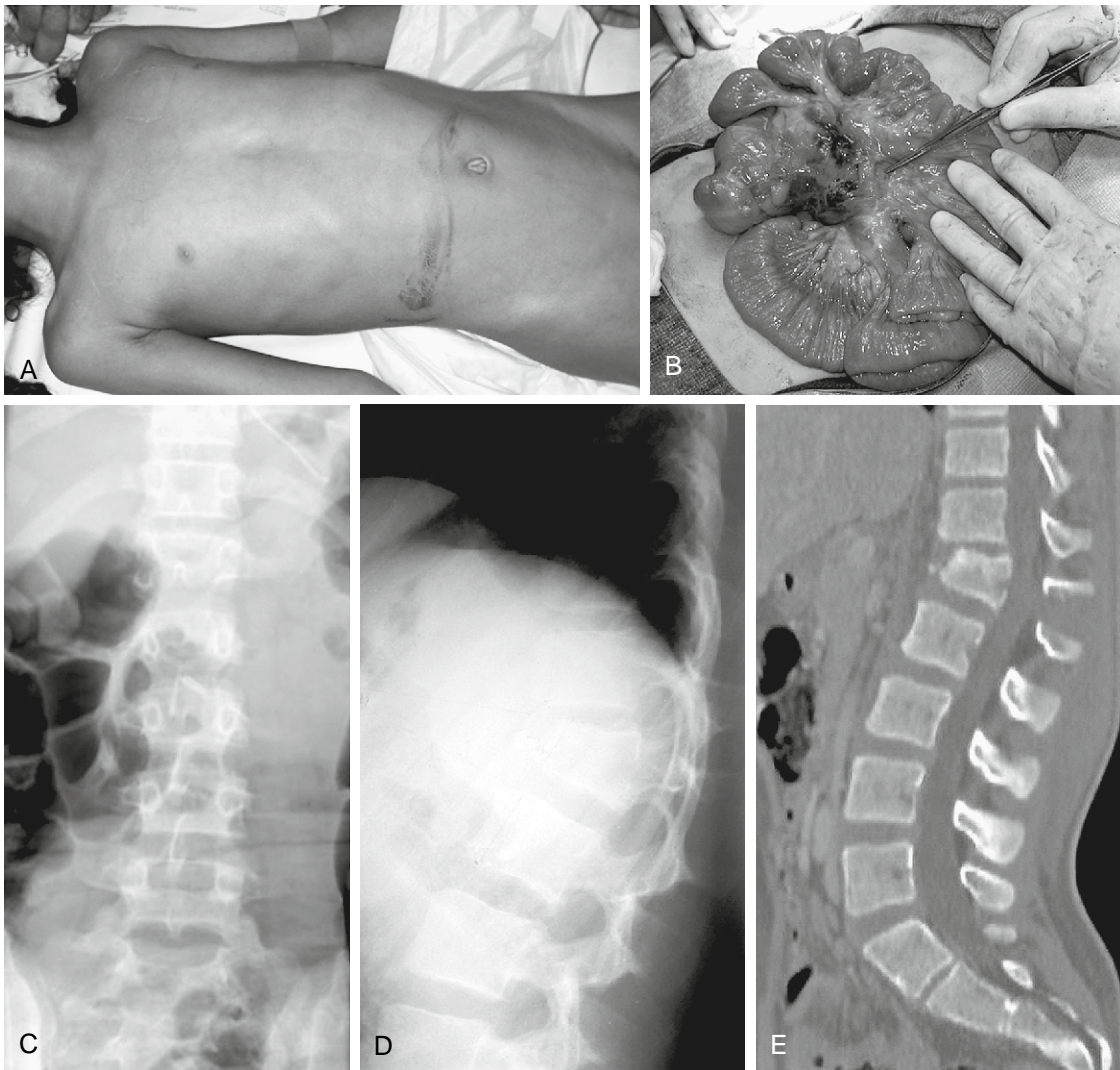

## COMPLEX INJURIES

Children sustain injuries that are different from adults owing to their size and activities. A common example is a pedestrian struck by a car. An adult will frequently sustain an injury to the tibia or knee from the car's bumper. However, the same mechanism will result in a fracture of the femur or pelvis and a chest or head injury in a small child.<sup>28</sup> Motor vehicle accidents (MVAs) are the most common cause of multiple injuries to children, both as occupants and pedestrians.<sup>28,29</sup> Although not restricted to MVAs, spine trauma is frequently seen in the child with multiple injuries. Awareness of the possibility of cervical spine trauma is mandatory in any child who presents with facial injuries.<sup>30,31</sup> Likewise, ecchymosis in the lower abdomen consistent with the lap belt portion of the seat belt should alert the physician to the possibility of significant intra-abdominal and/or spine injury.<sup>32-34</sup> Frequently seen with the use of lap belts without shoulder restraint, the lap belt syndrome consists of flexion-distraction injuries to the lumbar spine (Chance fracture), hollow viscus rupture, and traumatic pancreatitis (Fig. 18-2).<sup>35</sup> This terminology has evolved to include a wider spectrum of intra-abdominal hollow viscus, solid organ, and vascular injuries that can occur in conjunction with a characteristic flexion-distraction injury to the spine. This injury occurs when a car lap belt restraint acts as a fulcrum over which the torso is violently flexed anteriorly and distracted posteriorly.

Open fractures are considered one of the true orthopedic emergencies in children.<sup>36</sup> These injuries usually result from high-energy mechanisms and are often seen in the setting of multiple trauma. Open fractures in children and adults are classified according to the system of Gustilo-Anderson (Table 18-1).<sup>37-39</sup> The four goals of treatment of open fractures are prevention of infection, bony union, prevention of malunion, and return to function of limb and patient.<sup>36,40</sup> To attain these goals, open fractures must be treated by early irrigation and débridement along with broad-spectrum antibiotic therapy.<sup>37-39</sup> Kindsfater and Jonassen found that early treatment of tibial shaft fractures in children resulted in fewer cases of osteomyelitis when compared with those treated later.<sup>41</sup> As a counterpoint, data from our institution demonstrated no difference in infection or nonunion rates in 390 open fractures of the lower extremities in adults.<sup>42</sup> However, there is no consensus on the effect of delaying surgical treatment of open fractures in regard to rates of infection and need for secondary surgical procedures to promote bone healing.<sup>36,43-49</sup>

## FRACTURES OF THE LOWER EXTREMITY

Because of the high energy required, fractures of the pelvis and proximal femur are rare but serious injuries in children. Approximately two thirds of patients with pelvic fractures have associated injuries, and approximately one third have residual, long-term morbidity.<sup>50,51</sup> Pelvic fractures rank second to head

**Figure 18-2.** A, A 12-year-old girl was involved in a motor vehicle accident resulting in ecchymosis in the lower abdomen caused by the lap belt portion of a three-point restraint. This child had a laceration of the omentum discovered at laparotomy (B) and a flexion-distraction fracture of L1 with disruption of all three columns of the spine (C-E) that required surgical stabilization.

Grade	Description
I	Wound < 1 cm
II	Transitional wound (1-10 cm)
III	Wound > 10 cm
IIIA	Extensive soft tissue injury
IIIB	Reconstructive soft tissue injury
IIIC	Vascular injury

From Gustilo RB, Mendoza RM, Williams DN: Problems in the management of type III (severe) open fractures: A new classification of type III open fractures. *J Trauma* 24:747-796, 1984; Gustilo RB, Anderson T: Prevention of infection in the treatment of 1025 open fractures of long bones: Retrospective and prospective analyses. *J Bone Joint Surg Am* 50:453-458, 1976.

injuries in terms of complications, including life-threatening visceral injuries. The mortality rate from pelvic fractures is between 9% and 18%, which is lower than in adults.<sup>50</sup> Children with multiple injuries should be checked carefully for fractures of the pelvis. Some common findings for pelvic fractures are the presence of a hematoma beneath the inguinal ligament (Desot's sign), decreased distance between the greater trochanter and anterior superior iliac spine on the affected side in lateral compression injuries (Roux's sign), and the presence of a bony prominence or hematoma on rectal examination (Earl's sign). An anteroposterior radiograph of the pelvis is usually sufficient as the initial screening study, although increasingly these injuries are diagnosed by spiral tomography that is performed as part of the initial trauma evaluation.<sup>52</sup> Most pediatric pelvic fractures, even those in which the pelvic ring is disrupted, can be treated nonoperatively with good outcomes.<sup>51</sup>

Fractures of the femoral neck are serious injuries that typically require operative treatment.<sup>53-62</sup> Osteonecrosis caused by disruption of the blood supply to the femoral

epiphysis is a dreaded complication of this fracture that occurs in up to 75% of children after this injury.<sup>53-58,62-65</sup> The risk of developing osteonecrosis correlates with a higher anatomic location of the fracture in the femoral neck, extent of displacement, and delay in reducing the fracture. Accordingly, fractures and dislocations of the proximal femur are treated as orthopedic emergencies. They require immediate anatomic reduction, which may be achieved by closed or open techniques, and internal fixation (Fig. 18-3).<sup>55,59,62,66-69</sup>

Pediatric femoral shaft fractures are common injuries. The incidence and mechanism of pediatric femoral shaft fractures vary with patient age and gender. Child abuse accounts for up to 67% of femur fractures in children younger than age 1, but only 11% of fractures in children between ages 1 and 2 years old.<sup>70-72</sup> Classic teaching states that spiral fractures in preambulatory children are pathognomonic for abuse. However, other studies have demonstrated that any fracture pattern can occur as the result of abuse.<sup>71</sup>

**Figure 18-3.** A, Anteroposterior radiograph of the pelvis of a 12-year-old girl injured as the result of a fall shows a displaced transcervical fracture of the left femoral neck. The fracture was treated as an emergency with closed reduction and internal fixation with two cannulated screws. B and C, Intraoperative fluoroscopic images demonstrate anatomic reduction of the fracture. D and E, Radiographs 1 year later show healing of the fracture and no evidence of osteonecrosis.

Falls are the leading cause of femur fractures in children aged 2 to 3 years, and MVAs are the most common cause in older children.<sup>70</sup> Although bleeding after a femur fracture can be fairly extensive, transfusion in isolated, closed injuries is rarely needed. Therefore, other causes of blood loss must be considered if there is hemodynamic instability or a falling hematocrit at 24 hours after injury in a patient with a femur fracture, especially in the setting of multiple trauma.<sup>73</sup>

Treatment of femur fractures also varies with age.<sup>72</sup> Younger children (<4-5 years) are usually treated nonoperatively by closed reduction and immediate spica cast immobilization.<sup>74-77</sup> Older children (4-10 years) are treated with flexible nails<sup>78-85</sup> or plates.<sup>86-88</sup> Adolescents (>10 years or >100 lbs) and teenagers may be treated as adults with solid, reamed, femoral nails, which should be introduced through the tip of the greater trochanter, rather than through the piriformis fossa, to avoid injury to the vascular supply to the femoral head. In contrast to adults, the timing of femur fracture stabilization in children, even in the setting of multiple trauma, does not appear to have an effect on the development of pulmonary complications.<sup>89</sup> The implications are that surgery can be deferred until the general medical condition of the child permits, with the caveat that expeditious stabilization of femur (as well as other long bone) fracture(s) will facilitate mobilization and nursing care in the overall management of the child.

Knee injuries in children differ from those in adults. In children, the cartilage of the physes, apophyses, menisci, and articular surface are weaker than the knee ligaments and are thus more prone to injury.<sup>90</sup> Therefore, fractures about the knee occur more commonly than ligamentous injuries in skeletally immature individuals.<sup>91</sup> The distal femoral physis is the largest and fastest growing physis. It is often injured as a result of a direct blow and is a common injury in American football players. Most fractures are Salter-Harris type I or II injuries. These fractures can usually be treated by closed reduction and percutaneous, cross-pin stabilization. Fractures extending into the articular surface (type III and IV injuries) require open reduction and internal fixation if displacement of the articular surface is greater than 2 mm. Because of the size of this growth plate, its complex, undulating anatomy, and the forces required for displacement, fractures of the distal femoral physis, even type I and II injuries, may result in permanent growth disturbance in up to 50% of cases.<sup>92</sup> All of these fractures should be followed for a minimum of 1 year to evaluate for sequelae of complete (limb-length inequality) or partial (angular deformity) growth arrest.

Proximal tibial physeal injuries are uncommon owing to the reinforcement provided by the knee joint capsular attachments and collateral ligaments. However, vascular compromise of the lower leg due to a popliteal artery injury is possible with displaced fractures of the proximal tibial physis, particularly with extension-type injuries in which the proximal portion of the tibial metaphysis is displaced posteriorly. Such injuries tent the popliteal artery at the level of the physis and proximal to the trifurcation, where it is relatively tethered by the peroneal branch as it courses through

the fascia entering the anterior compartment of the leg (Fig. 18-4). Close attention to the vascular examination of the lower extremity is critical after injuries to the proximal tibia. Intra-articular injuries including patellar fractures, tibial spine/plateau fractures, osteochondral fractures, and ligamentous/meniscal injuries typically present as a hemarthrosis. These fractures are not typically emergencies and can be splinted initially and then treated definitively at a later time.

Nonphyseal fractures of the tibia and fibula are among the most common injuries involving the lower extremity in children.<sup>93,94</sup> Fortunately, most of these injuries are low energy and can be treated nonoperatively with good long-term results and few complications. However, one must always be cognizant of the possibility of compartment syndrome after closed or open fractures of the tibial shaft.<sup>95</sup> Indications for operative treatment of tibial shaft fractures include open fractures, fractures with neurovascular injury or impending compartment syndrome, those with unacceptable alignment after closed reduction, and fractures occurring in the setting of multiple trauma.

Foot and ankle fractures are typically caused by indirect, torsional forces. Injuries to the distal tibial and fibular physes account for 25% to 38% of all children's physeal injuries.<sup>96,97</sup> Sports injuries account for up to 58% of physeal fractures about the ankle.<sup>98</sup> Nonoperative treatment has historically been the treatment of choice except for intra-articular fractures and those unable to be adequately reduced by closed means. Recent data suggest improved results with open reduction of distal tibial physeal injuries.<sup>24</sup> Computed tomography (CT) is very useful in defining the pathoanatomy of fractures with intra-articular involvement or unusual patterns, and has proved to be very helpful in making management decisions as well as in preoperative planning.<sup>99</sup> Foot fractures are uncommon and infrequently cause problems for the child. Most foot fractures can be treated nonoperatively with immobilization and restricted weight bearing with good functional results. More complex problems that require operative intervention include fractures of the talar neck and calcaneus, fractures or dislocations of the tarsometatarsal (Lisfranc) joint, and open fractures and lawn mower injuries.<sup>99</sup>

## SPINE INJURIES

### Cervical Spine Injuries

Cervical spine injuries in children are relatively uncommon but potentially catastrophic. Accurate diagnosis requires an awareness of the injury patterns, anatomic characteristics, and radiographic variants of the immature cervical spine.<sup>100</sup> These injuries account for approximately 1% of all pediatric fractures and only 2% of all spine fractures.<sup>101-103</sup> Pediatric cervical spine injuries are fundamentally different from their adult counterparts owing to the anatomic characteristics of the immature spine and, to a lesser extent, the differences in the mechanisms of injury between adults and children.<sup>104</sup> The cervical spine in children is inherently

**Figure 18-4.** Anteroposterior (A) and lateral (B) radiographs of a 13-year-old boy showing a Salter-Harris type I fracture of the proximal tibial physis with posterior displacement of the distal fragment after an extension-type injury. C and D, Distal pulses were diminished before and after closed reduction and stabilization of the fracture. E, Arteriogram shows occlusion of the popliteal artery at the level of the fracture. Vascular repair with an interposition graft was performed successfully. F, Drawing shows the relation of the popliteal artery to the proximal tibial physis and the mechanism of vascular injury in this fracture. (From Green NE: Fractures and dislocations about the knee. In Green NE, Swiontkowski MF [eds]: *Skeletal Trauma in Children*. Philadelphia, WB Saunders, 2003.)

mobile because of a generalized laxity in the interspinous ligaments and joint capsules, underdeveloped neck musculature, thick cartilaginous end plates, incomplete vertebral ossification (wedge-shaped vertebral bodies), and shallow-angled facet joints, particularly in the upper segments (between the occiput and C4).<sup>104</sup>

In infants and young children, injuries to the upper cervical spine (above C3) predominate because the head is disproportionately large and creates a large bending moment in the upper cervical spine. In an 11-year experience with 122 pediatric neck injuries, none of the 21 patients age 8 years or younger had evidence of injury below C3.<sup>105</sup> Also, multiple-level spinal injuries are more common, occurring in approximately

25% of children with cervical spine fractures.<sup>105-108</sup> Spinal cord injury without radiographic abnormality (SCIWORA) occurs more frequently in children than in adults.<sup>102,104</sup> After age 8 to 10 years, the anatomic and biomechanical characteristics of the cervical spine are more like an adult and injuries to the cervical spine are much more likely to occur in the subaxial region (below C3). Evaluation and treatment of these injuries are essentially the same as in an adult.<sup>100,102,104,109</sup>

Mechanisms of injury vary somewhat with age. In neonates, birth trauma is the most common cause of cervical spine injury and occult spinal cord injury has been demonstrated at necropsy in 30% to 50% of still-borns. Excessive distraction and/or hyperextension of

**Figure 18-5.** A, Drawings of an adult and a child on a normal spine board contrasting the differences in position of the head and neck during emergency transport. Because of the disproportionate head-to-body ratio in children, the child's cervical spine is flexed. B, Two methods of modifying the traditional spine board for pediatric patient transport are shown. In the upper illustration, a cutout in the board allows the occiput to be recessed. In the lower illustration, the area under the thorax is built up with padding. Both methods effectively allow the head to translate posteriorly, creating more normal alignment of the cervical spine. (Reprinted from Herzenberg JE, Hensiger RN, Detric DK: Emergency transport and positioning of young children who have an injury to the cervical spine. *J Bone Joint Surg Am* 71:15-21, 1989.)

the cervical spine are thought to be the most common mechanisms of injury and may be associated with abnormal intrauterine position (transverse lie) or a difficult cephalic or breech delivery.<sup>110,111</sup> In infants and young children, nonaccidental trauma is a significant cause of injury to the cervical spine. Avulsion fractures of the spinous processes, fractures of the pars or pedicles (most commonly C2), or compression fractures of multiple vertebral bodies are the most common patterns of injury and are thought to result from severe shaking or battering.<sup>112,113</sup> These injuries may be associated with other signs of nonaccidental trauma, including fractures of the skull, ribs, or long bones, and superficial ecchymoses. In older children (up to about age 10), the most common causes are pedestrian-MVAs and falls. In children older than 10 years of age, the most common causes are passenger-related MVAs, sports-related injuries, and diving accidents.

Appropriate methods of immobilizing children for transport and evaluating them clinically and radiographically are crucial to avoid detrimental outcomes. The goal of immobilization during transport of the injured child with potential spine trauma is to avoid excessive angulation of the spinal column so as to avoid causing or exacerbating spinal cord injury. Immobilization of children younger than 8 years of age on a standard spine board during emergency transportation has been shown to cause excessive flexion of the cervical spine due to the disproportionately large diameter of the head relative to the torso. It has been recommended that the child's spine board be modified by building up the area under the torso with padding to allow the head to fall back slightly or cutting out the area under the occiput to recess the skull (Fig. 18-5).<sup>114</sup> In addition to proper spine board immobilization, an appropriately fitting cervical collar is necessary to achieve neutral alignment of the cervical spine after injury.<sup>115</sup>

Clinical evaluation of a child suspected of having an injury to the cervical spine is often hampered by an inability to obtain an accurate history and the unreliability of the physical examination.<sup>100,102,109,116-118</sup> Historically, overt or occult injury to the cervical spine is more likely to occur as a result of falls from a height of more than

4 feet, pedestrian- or cyclist-MVAs, and unrestrained occupant-MVAs. Head or facial trauma, altered mental status, and/or loss of consciousness are also risk factors. Neck pain, guarding, and torticollis are the most reliable signs of an injury to the cervical spine in children. Extremity weakness, sensory changes (numbness or tingling), bowel and bladder dysfunction, and, less frequently, headaches, seizures, syncope, and respiratory distress are signs of injury to the spinal cord.<sup>31,100,101,106,119-127</sup> When these conditions are present, the cervical spine should be immobilized until imaging studies can be completed and the spine cleared (Table 18-2).<sup>100</sup>

Radiographic evaluation of the cervical spine in children is hampered by the presence of normal anatomic variants that can be mistaken for trauma. Synchondroses and incompletely ossified, wedge-shaped vertebral bodies can simulate fractures.<sup>128-131</sup> Anterior angulation of the odontoid is a normal variant in approximately 5% of children and may be mistaken for a Salter-Harris type I fracture of the dens. Physiologic subluxation of C2 on C3 or C3 on C4 of up to 3 mm is a normal variant (pseudosubluxation) in about 40% of children younger than age 8 years that is often misinterpreted as pathologic instability.<sup>130,132</sup> Focal kyphosis of the midcervical spine is a normal

**Table 18-2** Risk Factors for Cervical Spine Injury

Mechanism of injury
Pedestrian/ or cyclist/motor vehicle accident
Unrestrained occupant/motor vehicle accident
Fall > 4 feet
Loss of consciousness
Neck pain, limited range of motion, torticollis
Abnormal neurologic examination
Numbness, tingling
Extremity weakness
Head or facial trauma

variant in about 15% of children younger than age 16 years that can also be misinterpreted as pathologic.

Initial radiographic evaluation should include cross-table lateral and anteroposterior radiographs. On the lateral view, it is essential to see the C7-T1 disc space. Oblique films are additionally helpful in defining detail of the pedicles and facet joints.<sup>128</sup> Open-mouth odontoid images are technically difficult to perform and rarely helpful.<sup>133</sup> CT is a much better way to image the upper cervical spine and also provides excellent definition of known fractures, confirmation of suspicious areas, and excellent visualization of the cervicothoracic level, which can be difficult to adequately image with plain radiography. CT evaluation of the cervical spine has been shown to be more efficacious than conventional images in evaluating the cervical spine in adult and pediatric trauma and to lower institutional costs and complications in urban trauma centers.<sup>126,134,135</sup> Magnetic resonance imaging (MRI) is the preferred study to evaluate the spinal cord and soft tissue structures, including ligaments, cartilage, and intervertebral discs.

Once a cervical collar has been placed on a child or the neck immobilized, either at the scene of an accident or in the emergency department, formal clearance of the cervical spine is necessary before immobilization is discontinued.<sup>117</sup> In general, the cervical spine may be cleared based on clinical examination alone if the child is awake, alert, and cooperative; if there are no signs of cervical injury; and if the mechanism of injury is not consistent with cervical trauma.<sup>100,117</sup> For children younger than age 8 to 10 years who are obtunded or otherwise unable to be examined, and all those with a profile suggestive of injury to the cervical spine, clearance may be based on a five-view cervical spine radiographic series, consisting of anteroposterior, lateral, open-mouth odontoid, and two oblique views, and CT of the axial region of the spine, from the occiput to C2. In a study at our institution in which this protocol was followed, 8 of 112 children were diagnosed with cervical spine injuries. Two of 6 children with bony injuries (33%) were diagnosed only by the CT scan. No injuries were missed, and cervical immobilization was discontinued in a timely fashion.<sup>136</sup> The rationale for CT includes the predisposition for injuries to occur in the upper cervical region in children younger than

8 years old and the technical difficulty of imaging this area with plain radiographs.<sup>100</sup> In a subsequent study from our institution, helical CT was shown to have higher specificity, sensitivity, and negative predictive value than conventional radiographs in evaluating the cervical spine in children with blunt trauma.<sup>135</sup>

Others have advocated a definitive role for MRI as an adjunct to plain films and CT, particularly in identifying soft tissue injury.<sup>137-139</sup> In one study of 79 children, MRI revealed injuries in 15 patients with normal radiographs and excluded injuries suspected on plain radiographs and CT scans in 7 and 2 patients, respectively.<sup>137</sup> In 25 obtunded or uncooperative children, MRI demonstrated 3 with significant injuries.

Halo vest immobilization is being used with increasing frequency in children with cervical spine injuries. It affords superior immobilization to a rigid cervical collar and is easier to apply and more versatile than a Minerva cast. It permits access for skin and wound care while avoiding the skin problems (maceration, ulceration) typically associated with both hard collars and casts. However, complication rates associated with pediatric use of halo vest immobilization as high as 68% have been reported.<sup>140</sup> Pin site infections are the most common problems, but pin perforation, cerebrospinal fluid leaks, and brain abscesses have also been described.<sup>109,140</sup> In children younger than age 6 years, a CT scan of the skull to measure calvarial thickness can be helpful in determining optimal sites for pin placement.<sup>141</sup> In children older than age 6 years, the standard adult halo construct utilizing four pins (two anterolaterally, two posterolaterally) inserted at standard torques of 6 to 8 inch-pounds generally works well (Fig. 18-6A). In younger children, more pins (up to 12) placed with lower insertional torques (2-4 inch-pounds) have been advocated (see Fig. 18-6B).<sup>140,141</sup> Standard pediatric halo rings fit most children, but infants and toddlers usually require custom rings. Although standard pediatric halo vests are available, custom vests or body casts generally provide superior immobilization.<sup>142</sup>

The possibility of SCIWORA should be considered in children, particularly in those younger than 8 years old.<sup>143-146</sup> MRI may be diagnostic in demonstrating spinal cord edema or hemorrhage, soft tissue or ligamentous injury, or apophyseal or disc disruption but is completely

**Figure 18-6.** A, Six-year-old immobilized in standard halo construct with four pins (two anterolateral, two posterolateral) inserted at torques of 6 to 8 inch-pounds. B, Three-year-old child with halo ring with 10 pins inserted at low torque, in contrast to the usual four-pin configuration used in older children and adults. (From Weiser ER, Mencia GA: Pediatric cervical spine injuries: Assessment and treatment. *Semin Spine Surg* 13:142-151, 2001.)

normal in approximately 25% of cases. SCIWORA is the cause of paralysis in 20% to 30% of children with injuries of the spinal cord. Potential mechanisms of SCIWORA include hyperextension of the cervical spine, which can cause compression of the spinal cord by the ligamentum flavum, followed by flexion, which can cause longitudinal traction. Other mechanisms include transient subluxation without gross failure or unrecognized cartilaginous end plate failure (Salter-Harris type I fracture).

Regardless of the specific mechanism, injury to the spinal cord occurs because of the variable elasticity of the elements of the spinal column in children.<sup>147</sup> Experimentally, it has been shown that the bone, cartilage, and soft tissue in the spinal column can stretch about 2 inches without disruption but the spinal cord ruptures after one-fourth inch.<sup>111,146,148</sup> Spinal cord injury occurs when deformation of the musculoskeletal structures of the spinal column exceeds the physiologic limits of the spinal cord.<sup>147</sup> Injury may be complete or incomplete and may occur at more than one level.<sup>149</sup> Partial spinal cord syndromes reported in SCIWORA include Brown-Séquard and anterior and central cord syndromes as well as mixed patterns of injury.<sup>143-145,147</sup>

Prognosis after SCIWORA is correlated to MRI findings, if any are present, and to the severity of neurologic injury.<sup>143-145</sup> Effective management demands careful evaluation of the cervical spine to exclude osseous or cartilaginous injury or mechanical instability. In addition, stabilization of the spine is needed to prevent recurrent injury.<sup>143-146</sup> Immobilization with a rigid cervical collar for 2 to 3 months is usually adequate treatment for SCIWORA. There are no reports of recurrent spinal cord injury when the cervical spine has been immobilized in this manner. Surgery is occasionally necessary for unstable injury patterns. The prevalence of scoliosis after infantile quadriplegia is over 90%. Therefore, long-term follow-up is necessary to monitor for vertebral column deformity.

Administration of high-dose corticosteroids within the first 8 hours of spinal cord injury has been shown to improve the chances of neurologic recovery in adults.<sup>150-153</sup> According to guidelines from the third National Acute Spinal Cord Injury Study (NASCIS), when treatment is initiated within 3 hours of injury, methylprednisolone should be administered as an intravenous bolus of 30 mg/kg over 15 minutes followed by a continuous infusion of 5.4 mg/kg/hr over the next 23 hours. Also, if treatment cannot be started until more than 3 to 8 hours after injury, the corticosteroids should be given for 48 hours. After 8 hours, there is no benefit and corticosteroids should not be administered.<sup>152,153</sup> Although the effect on younger children (<13 years old) is not known, we universally initiate this protocol in all patients with spinal cord injuries at our institution.

### Thoracic, Lumbar, and Sacral Spine Injuries

Thoracic, lumbar, and sacral fractures are also relatively uncommon in children. MVAs or falls cause the majority of these injuries. Child abuse can be a cause in younger children.<sup>122,154-158</sup> The most common injuries are compression fractures and flexion-distraction

injuries. Compression fractures are caused by a combination of hyperflexion and axial compression. Because the disc in children is stronger than cancellous bone, the vertebral body is the first structure to fail. It is common for children to sustain multiple compression fractures. Compression rarely exceeds more than 20% of the vertebral body. In the multiply injured patient, helical CT is increasingly becoming the preferred imaging modality for diagnosing and characterizing these fractures.<sup>52,159</sup> These fractures are managed conservatively with rest, analgesics, and bracing.<sup>158</sup>

Flexion-distraction injuries (seat belt injuries) occur in the upper lumbar spine in children wearing a lap belt.<sup>35,160-167</sup> With sudden deceleration, the seat belt slides up on the abdomen where it provides an axis about which the spine rotates. As a result, the torso is forcibly flexed and the spinal column fails in tension, resulting primarily in disruption of the posterior column with variable patterns of extension into the middle and anterior columns. These injuries may be missed on axial CT because of the transverse plane of orientation of the fracture. A lateral radiograph showing widening of the interspinous distance (see Fig. 18-2D) and a CT with sagittal reconstruction (see Fig. 18-2E) are the most helpful studies in diagnosing this fracture. Approximately two thirds of patients have an injury to a hollow viscus, a solid organ injury, and even an injury to the abdominal aorta. These injuries often result in greater morbidity than the spine fracture and may be life threatening, particularly if unrecognized initially.<sup>35,168,169</sup> Fortunately, neurologic injury is unusual. Lap belt injuries with mostly bony involvement and kyphosis less than 20 degrees can be treated with hyperextension casting. Those with posterior ligamentous disruption and soft tissue injury require surgical stabilization with compression instrumentation and posterior arthrodesis.

Fracture-dislocations of the spine are unstable injuries that usually occur at the thoracolumbar junction and often are associated with neurologic deficits. They are rare injuries in children that require surgical stabilization and fusion. Burst fractures are also rare injuries in children that result from axial compression and typically occur at the thoracolumbar junction or in the lumbar spine.<sup>170</sup> The need for operative treatment is determined by the stability of the fracture and the presence of neurologic deficits. Fractures of the sacrum are usually associated with pelvic fractures. Fractures that involve the sacral foramina or central sacral canal are associated with neurologic deficits in 28% and 50% of patients, respectively. Decompression of the sacral nerve root(s) and stabilization of the sacral fracture may be necessary to improve neurologic function. In most instances, however, fractures of the sacrum can be treated nonoperatively.

### FRACTURES OF THE UPPER EXTREMITY

Fractures of the clavicle are among the most common injuries in children. They are usually uncomplicated and require little, if any, treatment other than sling

immobilization for comfort. Distal clavicular fractures in the immature child may mimic acromioclavicular separation. The trauma surgeon should be aware of this injury and not mistake it for a true acromioclavicular dislocation. The periosteal sleeve of the distal clavicle remains intact with the coracoclavicular ligaments attached.<sup>21,171-173</sup> The fracture heals very rapidly with an enormous amount of callus and requires no treatment other than sling immobilization for comfort. There will be complete remodeling of the bone.

Injuries to the medial end of the clavicle are somewhat rare but potentially problematic from the standpoint of recognition and neurovascular complications. The medial clavicle consists of the clavicle and its medial growth plate plus the ligaments of the sternoclavicular joint. The physis of the medial clavicle is the last one in the body to close, and frequently does not close until after age 21.<sup>21,173,174</sup> The so-called dislocation of the sternoclavicular joint in the teenager and young adult is almost always a type I physeal fracture. It is important to recognize this distinction because a true dislocation likely would be unstable, whereas a type I fracture of the physis is a stable injury once reduced.

Anterior or posterior displacement of the medial end of the clavicle may occur as a result of indirect trauma to the shoulder with a secondary force vector that determines the final resting position of the bone. Posterior displacement almost always occurs by a direct mechanism such as when one falls on something such as a football and others land on top of him. The medial portion of the clavicle is pushed posteriorly, resulting in an injury directly through the growth plate of the medial clavicle. The patient presents to the emergency department with pain and swelling about the sternoclavicular joint. The shoulder is usually held forward. There is no pain about the distal clavicle or the shoulder joint. Although uncommon, compression of the mediastinal structures is the most devastating complication of this injury.

Diagnosis of the injury requires awareness of the injury and a CT scan to confirm the diagnosis. Radiographs may show the posterior dislocation, but it is most clearly seen on CT scan with thin cuts through the medial clavicle and sternoclavicular joint (Fig. 18-7A). Treatment of this type I fracture of the medial clavicular growth plate is usually easily handled by

closed reduction under general anesthesia (see Fig. 18-7B). Although open reduction is rarely necessary, internal fixation with a large, nonabsorbable suture placed through the thick periosteal sleeve is usually sufficient. Smooth pins should be avoided because of the risk of migration. Open reduction should be performed in conjunction with a general, vascular, or thoracic surgeon assisting or available in the event of unrecognized or iatrogenic injury to the great vessels. However, the most common problem associated with persistent posterior displacement is dysphagia.

Once the fracture (posterior dislocation) is reduced, alignment is maintained with a hard figure-of-eight bandage. This should be applied in the operating room with the patient still asleep using cast padding applied in a criss-crossing, figure-of-eight manner with the shoulders abducted. This bandage is then covered with fiberglass to keep the shoulders in that position. This injury should be stable enough within 3 to 4 weeks to discontinue the immobilization and begin gentle motion of the shoulder. Healing is rapid, and return of function is expected.

Fractures about the proximal humerus can usually be treated nonoperatively. In all age groups, the tremendous arc of motion in the shoulder joint allows a fairly large margin for fracture alignment. In the younger child, the rapid growth of the proximal humeral physis, which accounts for about 80% of the length of the bone, also contributes to rapid and predictable remodeling of all but the most angulated fractures. In these children, no treatment other than immobilization for comfort is necessary.<sup>175,176</sup> Markedly displaced fractures in the teenager, however, may not remodel because there is not sufficient remaining growth.<sup>176-178</sup> Most injuries in this age group are Salter-Harris type II fractures of the proximal humerus physis, which are usually not stable in addition to being significantly angulated and displaced. These fractures need to be reduced and usually require fixation. Generally these fractures can be stabilized with percutaneous Steinmann pins or cannulated screws inserted from the distal fragment into the proximal fragment using C-arm visualization.<sup>179,180</sup> Internal fixation should be supplemented with a sling and swathe. If pins are used, they should remain for 3 to 4 weeks after which gentle range of motion may begin. The fracture will heal very

**Figure 18-7.** A 16-year-old boy injured his right clavicle when he was checked into the board while playing hockey. He complained of difficulty swallowing. Anteroposterior radiograph of the right clavicle appeared normal. **A**, CT scan with thin cuts through the sternoclavicular joint shows posterior displacement of the medial end of the clavicle (arrow). **B**, Note restoration of alignment after closed reduction.

quickly. Permanent injury to the growth plate is not an issue because this fracture generally occurs very close to the end of skeletal growth.

Fractures about the elbow in children can be difficult to diagnose because the anatomy of the immature elbow is confusing owing to the presence of numerous centers of ossification. Knowledge of the sequence of appearance and maturation of the secondary ossification centers is mandatory. A comparison radiograph of the contralateral elbow is often helpful in correctly identifying the nature of the injury.<sup>181</sup>

The most common fracture about the distal humerus in the child is a supracondylar fracture. These fractures are classified according to the amount of displacement. Type III fractures are the most severe, with both fragments completely displaced. The injury usually occurs from a fall on the outstretched hand. In children who are ligamentously lax, the elbow will hyperextend and shear off the distal portion of the humerus through the olecranon fossa.<sup>182</sup>

The major problems with this injury are swelling and nerve and/or vascular injury. In the past, it has been thought that this fracture should be treated immediately. However, we now recognize that this fracture does not need immediate operative stabilization unless

there are other extenuating circumstances, such as vascular injury, compartment ischemia, or an open wound. Currently, the general policy is to delay treatment until the next day if the patient presents in the middle of the night and correct the fracture during the daylight hours with operating room personnel who are familiar with the procedures required. Initially, the elbow is splinted in less than 90 degrees of flexion with a loose bandage over a posterior splint.<sup>183,184</sup> These fractures can usually be reduced by closed manipulation and stabilized by percutaneous pins (Fig. 18-8). Occasionally, open reduction and pinning of this fracture is necessary if a perfect anatomic reduction is not possible, or if there are other extenuating circumstances such as an open fracture or a vascular injury that requires exploration.

There has long been a controversy as to the treatment of the pulseless extremity in patients who have sustained a supracondylar fracture. Absence of the pulse with this fracture is not uncommon. It is believed that the absence of the pulse may either be the result of vascular spasm and/or direct vascular injury. However, the collateral circulation about the elbow is so rich that the circulation to the forearm and hand usually remains normal. Treatment of the vascular injury has been debated for decades in the orthopedic and

**Figure 18-8.** A 6-year-old fell while horseback riding and landed on his outstretched left arm. Anteroposterior (A) and lateral (B) radiographs show a completely displaced (type III) supracondylar humerus fracture. Neurovascular status of the extremity was intact. C and D, The child was treated with closed reduction and percutaneous fixation with smooth Steinmann pins.

vascular surgery literature. The current practice is observation as long as circulation to the hand and forearm is clinically normal.<sup>182,183,185</sup> It has been shown by follow-up studies that vein grafts for these vascular injuries will frequently clot because of the excellent collateral circulation about the elbow.<sup>186</sup> The only true indication for vascular exploration is the pulseless, ischemic extremity, which is a true surgical emergency. In this instance, the fracture should be reduced and stabilized with crossed pins before vascular repair.<sup>187,188</sup>

Compartment syndrome is a feared complication that is actually quite uncommon in the modern era of treatment. By stabilizing the fracture with internal fixation, the need to immobilize the elbow in hyperflexion, which has been shown to increase the risk of vascular compression and forearm compartment swelling, is avoided.<sup>182</sup>

The signs of compartment syndrome are well known, but the main one is pain that is out of proportion to the fracture itself. Once this fracture is stabilized, the child should be comfortable and not have significant pain. Passive extension of the fingers should be possible to a neutral position. If not, it suggests the need for investigation of a compartment syndrome by removal of the splint, palpation of the forearm compartment, and pressure measurements, if necessary. If

the pressures are elevated, consistent with a forearm compartment syndrome, fasciotomy should be performed quickly.

Salter-Harris type I fractures of the distal humerus are less common than other injuries about the elbow. However, they are frequently misdiagnosed. For that reason alone, it is an important fracture to understand. Equally important is the recognition that in very young children this fracture often occurs as the result of non-accidental trauma. Therefore, this injury should trigger investigation into the possibility of abuse as the mechanism of occurrence.<sup>189</sup> The differential diagnosis of this injury requires an understanding of the anatomy of the distal humerus and the pathology of the lesion itself. With a type I fracture of the distal humerus, the entire epiphysis moves away from the rest of the humeral shaft and is displaced in a medial (more typical) or lateral direction. This fracture usually occurs in very young children in whom only the capitellum is ossified. Radiographically, in the type I fracture, the capitellum appears displaced from its normal position relative to the distal humerus and is distinguished from dislocation of the elbow by the fact that the radius and ulna remain in line with the capitellum and all three structures are displaced relative to the distal humerus (Fig. 18-9). In an elbow dislocation, the radius and

**Figure 18-9.** An 11-month-old infant, ultimately determined to have been the victim of abuse, presented with a swollen arm. **A**, On the anteroposterior radiograph of the elbow, the capitellum, the proximal radius, and the ulna are displaced from their normal positions relative to the distal humerus (*arrows*), consistent with a fracture-separation of the distal humeral epiphysis. In an elbow dislocation, the radius and ulna are displaced relative to the distal humerus but the capitellum is not displaced from its normal position in the distal humerus. **B**, The lateral radiograph of the elbow shows a small metaphyseal fragment (*arrow*), also consistent with a fracture of the distal humeral physis and not with dislocation of the elbow. This fracture was treated with cast immobilization. **C** and **D**, Note the exuberant fracture callus 3 weeks after the injury.

ulna are displaced relative to the distal humerus and are not in line with the capitellum. Also, the capitellum is not displaced from its normal position in the distal humerus.<sup>182</sup>

This fracture may also occur in newborns as a result of birth trauma. In this instance, the fracture is usually stable, will heal in a few days, and requires only splint immobilization for comfort. In the child, this fracture may require closed manipulation and pinning if the fracture is expediently diagnosed before some healing has occurred. Unfortunately, especially in instances of nonaccidental trauma, the child is usually seen well after this injury has already begun to heal and manipulation of the fracture is either not possible or ill advised.

Fractures of the lateral condyle of the humerus must also be distinguished from the Salter-Harris type I fractures of the distal humeral physis. With fractures of the lateral condyle, the radius and ulna remain aligned with the humerus but the capitellum is displaced from its normal position (Fig. 18-10). If the condylar fracture is displaced at all, it requires open reduction and pin fixation because the risk of nonunion is high when

it is treated nonoperatively. Nonunion will result in a progressive valgus deformity of the elbow with an ulnar nerve palsy.<sup>190-192</sup>

Forearm fractures have traditionally been treated with closed manipulation and casting. In most instances, especially with distal fractures, this treatment is highly successful and results in normal function of the extremity. Our preference is to perform closed reduction of these fractures in the emergency department using intravenous ketamine (2 mg/kg) or other methods of conscious sedation. Ketamine has proved to be an excellent drug for sedation in the ambulatory management of these and other fractures because it has a fast onset of action, particularly after intravenous administration, has a very short half-life, and does not cause respiratory depression or suppression of the gag reflex. The child is monitored with electrocardiography and pulse oximetry by a nurse or physician who is not involved in the management of the fracture according to the guidelines for conscious sedation from the American Academy of Pediatrics. Midazolam (Versed) is also frequently used to prevent emergence reactions that are sometimes seen with ketamine, especially in the older child.<sup>193,194</sup>

**Figure 18-10.** A 7-year-old child fell from a bunk bed, resulting in a fracture of the lateral condyle of the humerus. Anteroposterior (A) and lateral (B) radiographs show displacement of the capitellum (arrow), whereas the radius and ulna remain aligned with the humerus. Even if they were minimally displaced, the risk of joint incongruity and nonunion is high after nonoperative treatment of this fracture. Anteroposterior (C) and lateral (D) radiographs of the elbow after open reduction and pin fixation show anatomic alignment.

**Figure 18-11.** Anteroposterior (A) and lateral (B) radiographs show diaphyseal fractures of the radius and ulna in a 6-year-old, with angulation after closed treatment. C and D, Fractures were treated with internal fixation by using flexible titanium nails inserted via 1-cm incisions, distally in the radius and proximally in the ulna, and advanced across the fracture under fluoroscopic visualization.

The use of a portable fluoroscopy unit is essential in treating pediatric forearm fractures, both to guide reduction of the fracture and to confirm alignment after immobilization. After manipulation of the fracture, the extremity is immobilized in a sugar tong splint that will allow for swelling. When swelling is no longer a concern, the sugar tong splint is incorporated into a long-arm, fiberglass cast. After 3 weeks, a short-arm cast is applied for another 3 weeks, after which progressive use and motion is started.

Fractures of the shaft of both bones of the forearm, especially from the midportion of the forearm proximally, are poorly treated with cast immobilization

alone, especially in children older than the age of 8 or 9 years. It is difficult to maintain reduction of these fractures in a cast or splint. Also, angulation or malrotation in the diaphysis of either the radius or ulna will result in loss of rotation in the forearm (Fig. 18-11). For this reason, fractures of the shafts of the radius and ulna are being treated by internal fixation using flexible titanium nails with increasing frequency.<sup>195-203</sup> These fractures can usually be reduced by closed manipulation (although open reduction may occasionally be required) and by percutaneous insertion of titanium or stainless steel intramedullary nails.

## BRAIN TUMORS

Brain tumors are rare in the first year of life, with an incidence of 1 per 100,000 infants.<sup>1</sup> This incidence increases with age. By the age of 2 years, central nervous system (CNS) tumors occur in 2 to 5/100,000 children. Brain tumors represent the most common solid tumors in the pediatric population.<sup>2</sup>

In the group of brain tumors considered congenital, the most common are teratomas (37%), followed by primitive neuroectodermal tumors (PNETs) (12%), astrocytomas (10%-15%), and choroid plexus tumors (8%).<sup>3</sup> In a slightly older population of children, teratomas become less frequent and other neoplasms become relatively more common, including astrocytomas (34% of brain tumors in children younger than 24 months of age), PNETs (23%), and ependymomas (11%). There is also a group of tumors that are sometimes considered non-neoplastic. These include developmental tumors, which derive from aberrant proliferative growth during embryonic brain development and include craniopharyngiomas, lipomas, dermoids, and colloid cysts.<sup>4</sup>

### Cerebellar Astrocytomas

Low-grade astrocytomas occur throughout the CNS and constitute a fourth of all pediatric brain tumors. Cerebellar astrocytomas are common (12%-17% of pediatric CNS tumors), and their treatment has the most favorable outcome of all intra-axial neoplasms in the CNS.<sup>5</sup> Most of these tumors are found in children younger than the age of 10 years. The symptoms of cerebellar astrocytomas include headache (80%), vomiting (80%), gait disturbance, and decreased level of consciousness. Signs include ataxia in 80%, papilledema, cranial nerve palsies (including blindness and diplopia), and dysmetria. The rapid progression of signs and symptoms is often a function of cerebrospinal fluid (CSF) obstruction because the tumor occupies

the fourth ventricle or the aqueduct and causes hydrocephalus. Treatment of the hydrocephalus is often required urgently in very sick children. Temporary diversion of CSF via external ventriculostomies or shunts often precedes removal of the tumor.

Many of the signs and symptoms of posterior fossa neoplasms have an indolent progression. It is not unusual for headache and vomiting and ataxia to continue for many months in patients who are treated for otitis, viral syndromes, gastrointestinal disorders, or failure to thrive. It is the experience of many neurosurgeons that nearly all brain tumors in young children are misdiagnosed initially, sometimes for long periods of time. The relentlessness and progression of symptomatology is the decisive factor that leads to diagnostic studies.

Surgical removal of these tumors is often possible, but new neurologic deficits can occur in 30% of patients, although at least half of these new deficits are transient.<sup>6</sup> Neurologic trauma during surgery occurs because of the proximity of vital brain stem and delicate cranial nerve structures to the tumor, which is often large and firm. Postoperative pseudomeningocele (the bulging of skin at the occipital incision site) and hydrocephalus are not uncommon (10%-26%) and require additional treatment. Temporary continuation of postoperative CSF diversion via external ventriculostomy is favored by many surgeons to reduce the likelihood of permanent ventriculoperitoneal shunts.

The unambiguous goal of surgical therapy for low-grade tumors remains complete removal. When total resection of these tumors is confirmed, the long-term survival without recurrence occurs in about 90% of cases but much depends on the biologic aggressiveness of the tumor. Some histologic features such as mitosis, endothelial proliferation, and necrosis suggest a high-grade lesion with a much poorer prognosis. In cases of "low grade" astrocytomas with unanticipated rapid recurrence, additional treatment can be attempted,

including further surgery and adjunctive chemotherapy and/or radiotherapy. Frequent follow-up scans continue for at least 5 years after the operation.

## Ependymomas

Ependymomas represent about 10% of pediatric brain tumors and are slightly less common than PNETs and astrocytomas. More than two thirds of ependymomas in children occur in the posterior fossa (Fig. 19-1) and the symptoms they cause are similar to posterior fossa or cerebellar astrocytomas: headache, vomiting, lethargy, and ataxia. These symptoms result from a

combination of compression along the dorsal brain stem and hydrocephalus. Many extend from the obex (in the inferior aspect of the fourth ventricle) and then extrude through the lateral opening of this ventricle (foramen of Luschka) into the cerebellopontine angle. Here they invade and compress cranial nerves with resulting facial weakness, diplopia, swallowing dysfunction, and hearing loss. When large, they often extend beyond the foramen magnum and can compress the cervical cord. In regard to their cell of origin, they are not limited to the ependymal layer of the ventricle but can arise from cerebellar, cerebral, or spinal cord parenchyma.

**Figure 19-1.** MR image of a posterior fossa ependymoma. The tumor involves the lateral aspect of the posterior fossa and contains calcifications typical of ependymomas. The brain stem is severely distorted by the mass effect of the tumor. The tumor also compresses cranial nerves on the right side, making complete tumor removal problematic. This patient had right facial weakness, diplopia, and mild left hemiparesis postoperatively.

Aggressive surgical resection has been the goal of neurosurgical treatment of these difficult tumors, but there is high probability of new or worsening neurologic deficits as a result of surgical trauma. Modern surgical results have clearly demonstrated a correlation between postoperative residual tumor and tumor recurrence and/or progression. In the 30% of children where the tumor is totally resected, there is still a 20% to 40% possibility of recurrence, even after conventional radiotherapy.<sup>7</sup> In cases of near-total resection, the rate of progression-free survival falls to 30%.<sup>8</sup> Most of the recurrences are local and radiation therapy has become the mainstay of treatment, even with complete resection. Very small children, usually younger than age 3 years, are faced with comparatively greater morbidity from conventional radiotherapy, and radiation therapy is often deferred. Chemotherapy has been used with some success in this group of patients. The role of chemotherapy without irradiation has generally not been favorable in other groups. Retrospective studies have failed to prove substantial benefit in survival when chemotherapy is added to surgery and radiation therapy for newly diagnosed ependymomas.

Treatment of ependymomas has remained problematic. Large, invasive tumors are clearly difficult to remove without significant risk to the patient, and residual tumors are largely refractory to chemotherapy and radiation. Some surgeons have suggested staged surgical attacks with an initial subtotal debulking followed by a second aggressive approach after chemotherapy. Whether this approach provides durable survival has not been established. Surveillance of treated patients with ependymomas must continue for many years, independent of histologic grading and extent of resection. Radiosurgery is also being used to treat focal areas of recurrent or unresectable tumor.

## Medulloblastomas

Medulloblastomas are the most common malignant solid tumor in children and constitute 20% of pediatric brain tumors.<sup>9</sup> They are usually located in the posterior fossa and they are also referred to as primitive neuroectodermal tumors (PNETs) because they are histologically identical to tumors (pineoblastomas, neuroblastomas, and retinoblastomas) located in other locations that are believed to have derived from progenitor subependymal neuroepithelial cells undergoing malignant transformation. Nearly half of medulloblastomas have chromosomal abnormalities, particularly the deletion of 17p chromosome that contains the tumor suppressor gene *TP53*.<sup>10</sup>

Hydrocephalus often occurs with medulloblastomas because of their location within the cerebellar vermis (a midline structure), often filling the fourth ventricle (Fig. 19-2). Children with this tumor often have symptoms of elevated intracranial pressure (ICP) (obtundation, headache, nausea/vomiting, irritability) and have signs suggestive of posterior fossa compression (dysmetria, ataxia, diplopia, head tilt, and papilledema). Lumbar puncture should not be done after

computed tomography (CT) or magnetic resonance imaging (MRI) has established the presence of a posterior fossa tumor and obstructive hydrocephalus. CSF diversion treatments (usually via an external drain) are usually done either before or in conjunction with craniotomy. Conversion of these temporary devices to permanent ventriculoperitoneal shunts is not uncommon in children with large tumors and marked preoperative ventriculomegaly.

Complete resection of medulloblastomas is often possible, although permanent postoperative deficits can occur in as many as 14% of patients with worsening of preoperative deficits after aggressive surgery.<sup>6</sup> The “posterior fossa syndrome” that can occur in up to 13% of children after surgery is characterized by mutism, drooling and swallowing difficulties, ocular palsies, and increasing ataxia.<sup>11</sup> These problems resolve entirely in most patients after several months. Improvement is thought to occur with resolution of swelling within the inferior vermis.

Staging is important with medulloblastomas because patients have a predictable outcome depending on age, metastases, pathology, and extent of surgical resection. Poor survival is correlated with age younger than 4 years, residual tumor measuring more than 1.5 cm,<sup>2</sup> and tumor dissemination, particularly “drop” metastasis along the spinal column. After craniospinal radiation in eligible patients, survival occurs in 50% to 70% of patients with standard or low-risk medulloblastomas. Newer treatment protocols include chemotherapy first, which is followed by radiotherapy consisting of lowered cumulative craniospinal doses (24 to 36 Gy to the entire brain) with hyperfractionated delivery, usually 1 Gy twice daily. Survival in these “good risk” patients is nearly 90% after 5 years. Survival in high-risk patients is 60% to 65% with current multimodality therapy, with the worst outcomes in affected infants. Children younger than 3 years of age are usually treated first with chemotherapy, with irradiation deferred for 1 to 2 years. Radiation is sometimes avoided altogether in the 40% with progression-free survival.<sup>12</sup>

Recurrent medulloblastoma after surgery and radiotherapy is not amenable to cure, but a combination of aggressive therapies can allow remission of disease. These treatments include reoperation, radiosurgery, and high-dose chemotherapy with autologous stem cell rescue. Each of these treatments carries significant morbidity, including loss of cognitive skills, growth retardation, endocrine problems, and the risk of second tumors and vascular malformations in previously irradiated areas.

## Supratentorial Nonglial and Glial Neoplasms

There are multiple nonglial tumors involving the cerebral hemisphere. Supratentorial tumors are fairly common, and the majority of these are glial in origin, usually designated in ascending order of malignancy as astrocytomas, anaplastic astrocytomas, or glioblastoma multiforme. Nonastrocytic tumors include

**Figure 19-2.** MRI and MRS (magnetic resonance spectroscopy) of a posterior fossa medulloblastoma, with compression of fourth ventricle. The MRS profile (*bottom left*) shows a choline peak with depression of *N*-acetyl aspartate (NAA) typical of aggressive tumors.

PNETs (including cerebral neuroblastomas), choroid plexus tumors (papillomas and carcinomas), teratomas (including dysembryoplastic neuroepithelial tumors [DNETs], germinomas, oligodendrogliomas, meningiomas, and gangliogliomas). In this latter grouping, operative resection is the requisite initial treatment. In the last three tumors, adjunctive therapies are not recommended after gross total resection if the tumor is relatively benign.

Seizures are much more common with supratentorial tumors because they affect the eloquent neocortex, particularly tumors in the medial or lateral temporal cortex. Older individuals are afflicted with these tumors and can present with personality changes, cognitive difficulties, headache, and growth deficits.

Germ cell tumors are composed of germinomas and teratomas and arise in pineal and suprasellar regions

predominantly. Germ cells tumors often metastasize and cannot be surgically cured. Therefore, they are often best treated with radiation and chemotherapy. This combination of therapies is often quite successful with the majority of germ cell neoplasms.

Ependymomas that occur in the cerebral hemispheres remain problematic in terms of treatment, although hemispheric tumors generally have comparatively better outcomes. Incomplete resection (often because of diffuse involvement within critical brain regions) and leptomeningeal spread are significant adverse risk factors. Age is also a factor. Children younger than 3 years of age have significantly diminished progression-free survival (10%-15%) compared with older children.<sup>13</sup>

As with medulloblastoma, glial and nonglial tumors often have genetic abnormalities, with chromosomal

abnormalities and gene mutations. Many low-grade lesions progress to become more malignant. The pathway to this malignant progression is complex. Chromosomal translocations and mutations occur as initiating events before the amplification of deleterious genes that support tumor progression. In medulloblastomas, the loss of regulation of the Sonic hedgehog developmental signaling pathway causes inactivation of the retinoblastoma tumor-suppressor gene and thereby induces the proto-oncogene *MYCN*.<sup>14</sup> *MYCN* is a key transcription factor that leads to proliferation of neuronal progenitor cells, and its overexpression is common in medulloblastomas. In 50% to 60% of malignant gliomas, mutations of the *TP53* suppressor gene on chromosome 17 result in malignant differentiation of glial cells and the loss of normal apoptosis. Multiple cells in the adult brain, including neural stem cells and glial progenitor cells, are self-renewing and have robust proliferative potential. As such, even small numbers of these cells can undergo malignant transformation and lead to the development of gliomas. Additionally, aberrant regulation of gene transcription can independently lead to tumor progression, either by amplification or loss of inhibition of genes involved in cell division. Extracellular growth factor activation such as vascular endothelial growth factor (VEGF) can lead to malignant transformation by phosphorylation of tyrosine kinases that deregulate signaling pathways. The interaction of VEGF and its receptor leads not only to increased endothelial proliferation but also to cell migration, cell proliferation, vascular permeability, and the loss of apoptosis.<sup>15</sup>

There is a growing appreciation of the myriad causes of neoplastic growth, often by agents that do not directly alter DNA but cause subtle changes in gene expression. For example, hypermethylation (adding a methyl group to cytosines that precede guanines) of promoter regions of tumor-suppressor genes or DNA repair genes can lead to transcriptional silencing of regulatory regions in glioma cells, leading to tumor development.<sup>16</sup> Even microRNA genes, composed of 21-23 nucleotides, are important regulators of gene expression and can function as oncogenes when they downregulate tumor suppressor genes. The precise regulation of cell-cycle control is disrupted in all instances of glial tumorigenesis. The highly complex causes of this loss of regulation remain an enigma.

For surgical treatment of brain tumors there exists a strong association between resection extent and outcome. From the neurosurgical viewpoint, maximal resection should be attempted without inordinate surgical morbidity. The advent of frameless stereotaxy for precise tumor localization, “functional” localization with intraoperative monitoring (e.g., somatosensory evoked potential mapping to determine the location of the motor cortex), presurgical functional MRI to determine location of speech areas, and intraoperative scanning (via real-time ultrasonography, CT, or MRI) have each added considerably to the safety of surgery. Nonetheless, surgery can only achieve resection of targeted areas. Infiltrative tumors (which typically extend well beyond the target borders) cannot be ablated

using current surgical technology. The roles of chemotherapy, molecular manipulation, and conformal radiation therapy remain essential to the goal of controlling high-grade brain neoplasms partially treated with surgery. Unfortunately, high-grade brain lesions remain stubbornly resistant to the intensive multimodality treatments that follow surgical resection. Survival curves for highly malignant brain lesions have not changed substantially in the past several decades.

## Radiotherapy for Pediatric CNS Tumors

The target for radiation therapy is cellular DNA. Ionizing radiation damages double-stranded DNA, leading to cell death. Unlike normal cells, which have a preserved ability to repair radiation damage, neoplastic cells often are replicating at abnormally high rates and radiation interferes with their mitotic or proliferative ability. With slowly growing tumors such as cranio-pharyngiomas, the response to radiation is subtle and such tumors may take many months to show a clinical response. The critical sublethal dose required to preserve normal tissue but damage brain tumors, the so-called therapeutic window, is quite well understood and depends on a number of factors, including vulnerability of affected tissue (which can depend on the age of the patient and locale of the target; optic nerve radiation, as an example, is poorly tolerated), tumor vulnerability, volume irradiated, total dose, fraction size, and interfraction interval. As total volume of irradiation increases, the cumulative radiation dose must necessarily decrease to reduce the morbidity of treatment. The conventional cumulative radiation dose for most pediatric CNS tumors is in the 50- to 60-Gy range, although some tumors (e.g., germinomas) are much more sensitive to radiation and can respond to treatment in the 30- to 50-Gy range.<sup>17</sup> Identification of tumor type is therefore an important determinant of radiation therapy, and biopsy is often a prerequisite for treatment.

Radiotherapy has enjoyed significant technologic advances with the advent of improved radiologic definition of tumors and sophisticated computer-assisted planning in three-dimensional systems. Stereotactic radiosurgery (SRS) has become routine in the United States, and single high-dose fractions can be delivered with great precision using high-energy photons produced either by linear accelerators or cobalt sources (gamma knife). Proton-beam therapy utilizes charged nuclear particles to deliver energy in discrete target points after the proton has nearly come to rest. As such, the proton can traverse normal brain without losing energy. As it comes to rest, it gives off most of its energy in less than 1 cm in the form of a Bragg “peak,” providing a distinctively sharp rise in absorbed energy at the targeted tissue.

All these stereotactic methods are very precise and ideal for small targets, which are usually noninfiltrative lesions with well-delineated borders. The complications arising from targeting structures larger than 3.5 cm limit the radiosurgical approach. As such, the

utility of treating small noninfiltrative tumors is optimal with single-fraction radiosurgery. For larger lesions in vulnerable areas of the brain (e.g., brain stem, retina, or cranial nerves), fractionation can be used with either repeat head fixation or localization systems to minimize complications of SRS therapy. In pediatric patients, SRS is mainly used as a boost to tumors that have recurred or persisted after conventional fractionated radiation therapy.

Stereotactic radiotherapy is distinct from radiosurgery in that it utilizes SRS techniques (usually with radiation from linear accelerators, with computer-assisted planning and delivery devices) using fractionation such as limited radiation of delivery of less than 200 cGy per day. The targets of this therapy are usually discrete and spare nearby normal structures (e.g., the optic nerve, the optic chiasm, the hypothalamus) that cannot tolerate the radiation delivered with single-dosing methods such as the gamma knife. This conformal radiation provides the radiobiologic advantages of fractionation along with the precision and control of SRS. Tumors typically treated in this manner are craniopharyngiomas, optic system tumors, and pituitary adenomas.

## TREATMENT OF SPASTICITY AND MOVEMENT DISORDERS

Spasticity is defined as an abnormal response to passive muscle stretch. As the velocity of passive movement of a joint is increased, increased resistance develops. During examination of an affected extremity, there can be as little as a “catch” to passive movement or, in more severe cases, no movement at all. Spastic children often have muscle stiffness, fatigue, and pain. If the condition is severe and chronic, muscle contractures and joint dislocation can occur, particularly in the flexor muscles and internal rotator muscles. In children with spastic quadriplegia, the typical stance is one of flexed elbows and wrists, with standing and walking on toes, the knees and hips flexed, and the legs internally rotated.

Spasticity occurs because of an imbalance of excitatory Ia afferents from muscle spindles into the spinal cord and inhibitory descending impulses from the basal ganglia and cerebellum. In most children, the inhibitory impulses are diminished because of early CNS injury or injury to the spinal cord, which conducts the descending inhibitory impulses. Hence, treatment is directed toward either increasing the inhibitory neurotransmitters (usually  $\gamma$ -aminobutyric acid [GABA]) or reducing the afferent excitatory transmission from muscle spindles. Baclofen achieves the former, and dorsal rhizotomy (via cutting afferent nerve roots) interrupts the reflex transmission from muscle spindles.<sup>18,19</sup>

The children most susceptible to spasticity are those with low birth weight due to prematurity who have suffered a variety of cerebral insults, particularly hypoxic-ischemic encephalopathy with its predilection for causing periventricular white matter loss. Other affected infants have antepartum or intrapartum

insults that lead to specific brain injuries that interrupt pyramidal pathways that mediate the inhibitory spinal pathways.

Treatment of spasticity should aim to improve function and facilitate care. Multidisciplinary clinics usually assess the potential candidate for surgical treatment. The best candidates for lumbosacral rhizotomy are motivated, older children (age 5-6 years) with spastic diplegia (affecting the legs predominantly) who lack severe contractures and have relatively good leg strength. Children with weak legs and spasticity can lose function with rhizotomy because they depend on their increased tone to maintain marginal ambulatory function. Rhizotomy can produce, to their detriment, a nonadjustable and permanent decrease in spasticity. Very young children are not good candidates for baclofen pumps because of the size of the device. Oral baclofen can be most useful in these very young children. Baclofen pumps are advantageous in children with severe spasticity that interferes with their care and in children with quadriplegia, often with a greater reduction of spasticity in the legs than the arms. The treatment is not permanent and nonablative, and the dosing is amenable to adjustments. It is particularly useful in children with spinal cord insult from trauma or inflammatory processes (transverse myelitis) and in patients with familial spastic paraparesis.

Botulinum toxin produces neuromuscular blockade and thereby reduces muscle contractions and spasticity. It is typically injected into spastic muscles and for a period of several months will decrease spasticity and increase range of motion. These injections are often used to extend the period of time until a definitive procedure can be done in very young children, often decreasing the risk of developing muscle contractures that are fixed deformities not amenable to any spasticity treatments.<sup>20</sup>

## EPILEPSY SURGERY

Epilepsy affects about 1% of the population and starts commonly in the first decade of life. Surgical control of epilepsy is a well-established therapy when medical control of seizures cannot be achieved. Temporal lobectomy has been a mainstay of pediatric neurosurgical care for more than 40 years, and temporal resections constitute more than half of the epilepsy interventions currently performed in pediatric patients. The efficacy of surgery for temporal lobe epilepsy is well established. In a randomized, controlled trial of surgery versus medical therapy, 64% of patients were free of disabling seizures after surgery compared with only 8% of those in the medical arm.<sup>21</sup> Surgery additionally may curtail the cognitive and psychosocial disabilities that can occur with medically intractable seizures, particularly in remediable syndromes that begin in infancy, before the acquisition of language and social skills. The quality of life for patients with epilepsy is unambiguously related to the recurrence of seizures, and uncontrolled seizures carry a substantial risk of disability and death.

Drug-resistant epilepsy is thought to be reasonably predicted after only two antiepileptic medications have proven ineffective. After the failure of a third medication, the probability of being seizure free is less than 10%. Therefore, despite the invasiveness of surgery, it is highly reasonable to consider operative intervention 1 or 2 years after the onset of disabling epileptic seizures, particularly in the 30% of epileptic children who have complex partial seizures emanating (unilaterally) from the temporal area. Surgery requires comprehensive preoperative evaluation by epilepsy specialists, along with multiple imaging and monitoring studies. Invasive monitoring is fairly common in pediatric patients, who tend to have seizures that are multilobar. Newer noninvasive modalities such as magnetoencephalography are rapidly achieving success in determining the source of seizures.

The success of temporal lobe surgery has led to more aggressive approaches to control epilepsy originating elsewhere in the brain. The pathologic substrates of pediatric extratemporal epilepsies are quite diverse, including cortical dysplasia, developmental abnormalities of neuronal migration, gliosis, tumors, neurocutaneous disorders (e.g., Sturge-Weber syndrome, tuberous sclerosis), and inflammatory lesions. These entities are often intensely epileptogenic from an early age. In such lesions, the MRI abnormality does not strictly correlate with the source of seizures and the epileptogenic focus may, in fact, be relatively diffuse and involve eloquent cortex. Nonetheless, some series show excellent results in more than 50% of patients, particularly if there is complete resection of an epileptogenic focus, including the focal area of interictal abnormality.<sup>22</sup> Intelligence quotient scores tend to be stable or improved in the majority of children selected for surgery.

In some patients, seizures can be lateralized to one hemisphere by preoperative methods but not precisely localized. These patients can be considered for hemispherectomy if there is significant unilateral dysfunction. As radical as such operative resection would appear, the improvement of hemisphere disconnection procedures is in the 70% range for seizure freedom, with likely hemiparesis and hemianopia found postoperatively (although these deficits are often present before surgery). Newer techniques involve a disconnection of the hemisphere without anatomic removal of the affected hemisphere, thereby reducing some of the complications associated with volumetric removal of large portions of the brain.<sup>23</sup>

Corpus callosum sectioning is a palliative surgery in patients who have seizures without focal onset. In patients with drop attacks, division of all or part of the corpus callosum can result in improvement in about 60% of patients by reducing the severity of their seizure and decreasing the likelihood of severe injury from falling.<sup>24</sup>

Vagal nerve stimulation (VNS) is useful for the treatment of partial seizures, providing about a 50% reduction in seizure frequency in patients with intractable seizures who are not candidates for resection. The morbidity of implantation of the vagal nerve

stimulator is extremely small, and the efficacy of the device rivals that of new antiepileptic medications. As opposed to medications, there is no toxicity and no issues of compliance.<sup>25</sup>

## HYDROCEPHALUS

Other than trauma, hydrocephalus is the single most common entity pediatric neurosurgeons are called on to manage. This disorder of CSF circulation and absorption accounts for 0.6% of all pediatric hospital admissions, 1.8% of all pediatric hospital days, and 3.1% of all pediatric hospital charges.<sup>26-29</sup> The care of hydrocephalic patients is a major health care expenditure, hovering near \$1 billion in the United States per year.<sup>30</sup> Although hydrocephalus can afflict individuals at any age, the range of causes and manifestations are larger and often more complex than in the adult population.

CSF is a clear fluid, which is primarily secreted within the ventricles of the brain by the choroid plexus. A considerable volume may be formed by interstitial fluid from the intercellular clefts in the brain and spinal cord.<sup>31-33</sup> The total production of CSF has been calculated at 0.31 mL/kg/hr.<sup>34</sup> The volume in the system turns over nearly four times per day.

The circulation of CSF is complex. CSF exits the brain through the fourth ventricle and has a pulsatile course through the subarachnoid space over the convexities of the brain, the basal cisterns, the spinal subarachnoid space, and ultimately back intracranially to the vertex of the brain. There, the CSF transits through midline arachnoid granulations into the venous system at the superior sagittal sinus. This transfer is passive from a higher-pressure system into a lower-pressure environment.

Escape of the CSF through alternative routes exist, although none is adequate to maintain normal nervous system function. Many mothers have observed that their children look puffy around the eyes when their shunt is malfunctioning. There is perhaps escape of CSF through the craniofacial lymphatics that might account for this observation. This transit of CSF has been confirmed in other mammals, and there is advancing evidence of this in humans.<sup>35-37</sup>

## Congenital Hydrocephalus

Hydrocephalus may be an isolated development or be associated with many syndromes and brain maldevelopment conditions such as holoprosencephaly and schizencephaly.

The most common genetic hydrocephalus is X-linked hydrocephalus. It occurs in 1:30,000 male births and represents 2% to 5% of nonsyndromal cases of hydrocephalus. The aqueduct of Sylvius is narrowed, causing subsequent dilation of the third and lateral ventricles, sparing the fourth ventricle (Figs. 19-3 to 19-5). In its fullest expression, other neurologic abnormalities can occur. Twenty-five percent of males with clear aqueduct stenosis will have X-linked

**Figure 19-3.** A, Sagittal MR image showing aqueduct stenosis and dilated third and lateral ventricles. B, Axial CT after ventriculoperitoneal shunt.

**Figure 19-4.** A, Axial CT scan of Dandy-Walker malformation. B, The axial CT scan shows supratentorial and posterior fossa shunt catheters. The posterior fossa shunt was required after the cyst continued to expand.

**Figure 19-5.** Ultrasound image shows a grade III bilateral intraventricular hemorrhage with ventricular dilation.

hydrocephalus, which is very important in advising couples about future pregnancies.<sup>38</sup> Other causes of aqueduct stenosis can be thickening of the tectum of the midbrain from hamartoma, glioma formation, or from intrauterine infections.<sup>39</sup>

The Chiari II malformation includes alteration in the size and shape of the posterior fossa, descent of the midline cerebellar tonsils through the foramen magnum, and straightening of the brain stem along with a beaking appearance of the tectum or dorsal midbrain. This is the next most common etiology of hydrocephalus and is always present to some degree in children who have the spinal dysraphism of myelomeningocele or meningocele. Chiari II malformation interrupts the egress of CSF from the fourth ventricle as well as disrupts the pulsatile flow of CSF around the confines of the posterior fossa. Children with untreated or undertreated hydrocephalus and Chiari malformation are at risk for the development of hydromyelia or syrinx.

The Dandy-Walker malformation is next in frequency for causing hydrocephalus. In the fullest

expression of this anomaly, one finds a retrocerebellar cyst, which can be quite sizable with a cleft or defect in the vermis of the cerebellum, agenesis of the corpus callosum, and extracranial anomalies such as cardiac septal defects and syndactyly. These children are at higher risk for developmental delays and epilepsy.

In Dandy-Walker malformation, the hydrocephalus is due to an alternation in CSF flow at the exit of the fourth ventricle. Dandy-Walker malformation may be further complicated by a “double compartment” hydrocephalus. The cyst formation may block escape of the CSF at the distal end of the aqueduct of Sylvius with resultant dilation of the third and lateral ventricles. In addition, the choroid plexus within the fourth ventricle will create CSF with no access to the subarachnoid space and subsequent enlargement of the cyst. In infants, this may lead to an unsightly distortion of the cranium and signs and symptoms of hindbrain compression. Not infrequently, additional surgical attention must be directed to the cyst, usually a CSF shunt catheter, either joined with a ventriculoperitoneal shunt or a separate shunt entirely (see Figs. 19-3 and 19-4).<sup>40,41</sup>

## Acquired Hydrocephalus

In the United States there are more than 50,000 very low birth weight infants born each year. Almost 20% of these neonates suffer some degree of intraventricular hemorrhage, most related to bleeding within the germinal matrix adjacent to the ventricles of the brain (see Fig. 19-5). These hemorrhages are graded on a I to IV scale (Table 19-1). Grade I is subependymal only, grade II shows extension into the ventricle, grade III has ventricular dilation, and grade IV includes clot in the parenchyma of the brain. At least 25% of these neonates will develop posthemorrhagic hydrocephalus.<sup>42</sup> Intraventricular blood is a powerful irritant to the ependymal lining of the ventricles as well as to the arachnoid membranes. The resultant inflammatory response and scarring can lead to obstruction of flow of CSF from the ventricle or, more commonly, an intense arachnoiditis with severe restriction of the CSF pathways at the base of the brain. Traumatic intracranial bleeding will manifest the same pathophysiology, leading to “post-traumatic” hydrocephalus. In the worst cases, the resultant inflammation will be both intraventricular

and in the subarachnoid space. It can lead to multiple scar septations within the ventricles and “multiple compartment” hydrocephalus.<sup>43</sup>

By definition, meningitis is inflammation of the arachnoid. In severe cases, especially in the very young, hydrocephalus may be the consequence of compromised subarachnoid spaces. Fetal infection with toxoplasmosis, cytomegalovirus, and *Cryptococcus* are infrequently encountered but are devastating to the developing brain, and the concurrence of hydrocephalus is only more tragic to the infants. Finally, subdural emphysema and brain abscess may lead to altered CSF flow and subsequent hydrocephalus.

It is extremely rare to see a child with congenital hydrocephalus become shunt independent. Thus, such children need to be approached with caution in making such a diagnosis.<sup>44,45</sup>

Brain tumors frequently occur in the midline in children and cause CSF obstruction. In fact, it is often the signs and symptoms of hydrocephalus, not the tumor itself, that brings these children to medical attention. Fortunately, if the tumor can be excised, the hydrocephalus in the majority will resolve without additional surgical management.

There is one entity, congenital or acquired, that creates an overproduction of CSF. This condition is hyperplasia or a tumor of the choroid plexus. Choroid plexus papilloma or carcinomas (<1% of brain tumors) are not infrequently diagnosed in the neonatal period. The choroid plexus tumor is usually obvious on brain imaging studies for investigation of a large head or to delineate the type of hydrocephalus present. Hyperplasia of the plexus might not be as evident and may only become recognized when seeking why hydrocephalus treatment is not effective. CSF ascites, pleural effusion, or failure of an endoscopic third ventriculostomy are examples of treatment failure due to excessive CSF. Choroid plexus hyperplasia may generate hundreds of milliliters of CSF above normal and overwhelm the absorptive capacity of peritoneal, pleural, or other shunt termini.

## Diagnosis

The brain imaging of communicating hydrocephalus typically demonstrates dilation of all the ventricles of the brain and infrequently the subarachnoid space. Patients with postmeningitic hydrocephalus are a typical example. The signs and symptoms of hydrocephalus are age dependent and often relate to the rapidity of the ventricular expansion. In the neonate and young infant, there are typically few symptoms. The child often feeds well and is attentive and happy, and the only clue may be an accelerated rate of head growth.

In older children with a firmer calvaria, hydrocephalus usually creates a more pronounced increase in ICP and the increased pressure will generate more symptoms. Most commonly, there is head pain or excessive irritability in the nonverbal child. Vomiting, detachment, or disinterest in play is common. Other common observations are poor school performance

**Table 19-1** Grading System for Intraventricular Hemorrhage Based on Ultrasound Findings

Grade	Cranial Ultrasound Findings
I	Hemorrhage in germinal matrix only
II	Ventricular hemorrhage without ventricular dilation
III	Ventricular hemorrhage with ventricular dilation
IV	Brain parenchymal hemorrhage

**Figure 19-6.** Axial CT scan shows mildly dilated lateral ventricles and a generous subarachnoid space in the frontal and frontoparietal areas (arrows).

and easy fatigability. Visual changes such as blurriness or change in color perception can be noted by older children. Recumbence increases ICP, and therefore typically the headaches and vomiting are more pronounced in the morning. Seizures may occur, but not usually as a presenting or solitary event.

Physical findings commonly include a large head, a full but not tense anterior fontanelle, and prominent scalp veins. Peculiar to infants is the “sunset” eye appearance. This downward and outward deviation of the eyes is a neuronal mediated response to pressure on the superior colliculi of the midbrain by a dilated third ventricle. After treatment, the extraocular disturbance regresses. Older children may demonstrate a Parinaud sign: the failure of upward gaze, the mature version of the sunset eyes phenomena. Papilledema and altered visual fields often are evident.

Suspicious are to be confirmed by brain imaging studies. Ultrasonography in infants with an open fontanelle is a good screening study, but even if hydrocephalus is diagnosed with that technique, MRI or CT is required to more fully understand the etiology (Fig. 19-6).

## Treatment

The first reproducibly successful treatments for hydrocephalus of all types occurred in the early 1950s. Lumboureteral shunts had been successfully employed in patients with communicating hydrocephalus.<sup>46</sup> Success was then reported with ventricular to jugular vein shunts incorporating a miniaturized spring and ball valve.<sup>47</sup> As silicone replaced the earlier stiffer plastics, the ventriculoperitoneal shunt became and remains the mainstay of hydrocephalus therapy.<sup>48</sup>

Development of shunt hardware has matured. The quality of the silicone has improved, making the tubing more pliable and less hazardous to abdominal organs. Valves can be adjusted to various opening pressures with external magnets. Tubing that incorporates antibiotics within or coating it are available. With these mechanical advances, life expectancy of the shunt itself has improved and the complications have diminished, although only slightly. Realistically, there is little difference in the performance of one brand of shunt over another, despite the claims of the multiple vendors.<sup>49</sup>

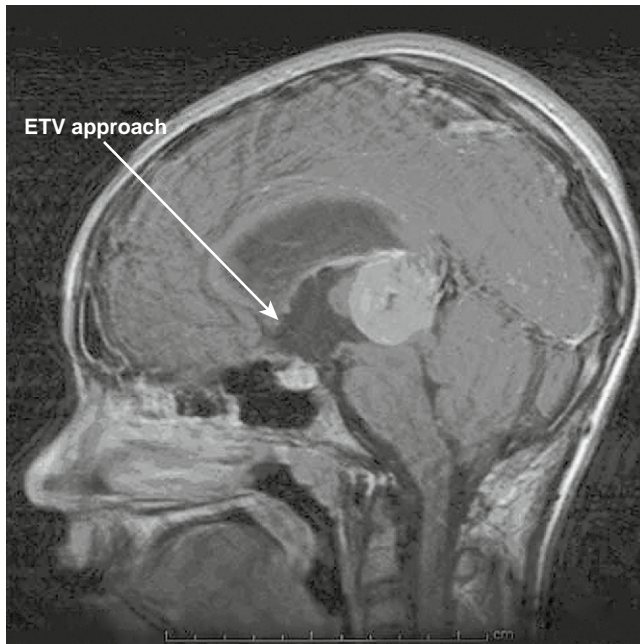

Shunt occlusions and infections are still vexing in our efforts to have these children lead a normal life. Nearly half of all shunt operations are revisions for occlusion or removals for infections. Perioperative antibiotic usage, although not without controversy, has reduced the shunt infection rate to 8% or less in busy pediatric centers.<sup>50</sup> There is no consensus as to which antimicrobial agents or what dose is most efficacious.<sup>51</sup>

Alternatives to ventriculoperitoneal shunts are still useful, if not required in some complex cases. Lumboperitoneal shunts have regained some popularity among pediatric neurosurgeons in selected patients with free communication of CSF from the intracranial compartment to the spinal subarachnoid space. The development of a Chiari I malformation presumably from chronic CSF drainage that draws the cerebellar tonsils downward has given many neurosurgeons pause before considering this shunt in young patients.<sup>52-54</sup> When circumstances make the peritoneum inhospitable to CSF absorption, alternate termini for the tube include the venous system, pleural space, and even the gallbladder.<sup>55</sup>

An alternative to CSF shunting has re-emerged with the miniaturization of endoscopic equipment. Creating an opening in the floor of the third ventricle to look around an obstruction at the aqueduct or the outlet of the fourth ventricle is very appealing. The concept dates from 1922 but was a failure. New technology for minimally invasive surgery has given a rebirth to the idea and, today, most pediatric neurosurgeons are eager to use endoscopic third ventriculostomy (ETV) in lieu of CSF shunts (Fig. 19-7). When successful, the hydrocephalus is managed without the need for foreign body implant and without the inherent risks of infection or valve or catheter failure. This approach has been found to be successful in 60% of properly selected children.<sup>56</sup> The potential complications, such as uncontrollable hemorrhage, neuroendocrine dysfunction, and short-term memory loss, are severe, more so than with shunting. Nevertheless, there is great appeal in having hydrocephalus treated effectively without hardware in the body.

## Shunt Malfunctions

Despite the progress in shunt design and materials, shunts will fail, and at a surprisingly high rate. Forty percent fail within the first year of implant. At 15 years, there is an 80% likelihood of failure. Again, the signs and symptoms will be age dependent. Infants

**Figure 19-7.** Sagittal MRI of patient with a large tumor in the posterior third ventricle causing aqueduct occlusion. The *arrow* depicts the approach for an endoscopic third ventriculostomy (ETV) to bypass the obstruction and relieve the hydrocephalus. At the same operation, the tumor was sampled.

may have minimal symptoms because of the expandable cranium, whereas older children may quickly become dreadfully ill as the ICP increases. Headache, vomiting, and altered mental status predominate as symptoms. The clinical assessment typically includes a brain imaging study, a shunt survey (plain films of the shunt) to look for a fracture of the tube, a shortened end, or a migration. Although a change in the ventricular size noted on imaging is a strong clue to the diagnosis, normal ventricular size can often be a falsely reassuring sign. It is not uncommon for symptomatic children to have no dilation of their ventricles, presumably related to loss of brain compliance.<sup>57,58</sup> Often a percutaneous needle tap of the shunt reservoir or valve will be needed to measure pressure. Some surgeons use radioisotope or contrast flow studies. When in doubt, surgical exploration of the shunt is the best option.<sup>59</sup>

## SPINAL DYSRAPHISM

There are multiple types of spinal dysraphism, or neural tube defects, in children. The most common are myelomeningocele, lipomyelomeningocele, and meningocele.

### Myelomeningocele

Myelomeningocele is the most frequently encountered spinal neural tube defect. In the United States, the incidence is 0.3 per 1000 live births, a decrease of nearly 50% since the widespread use of folic acid in women planning pregnancy or begun in the first trimester.<sup>60</sup> It is rarely a diagnostic problem and is now frequently discovered with fetal ultrasonography. Diagnostic confirmation with ultrasonography and amniocentesis has presented the opportunity for pediatric neurosurgeons to counsel couples as to the ramifications of the disorder and allow them to make an informed decision about continuing the pregnancy.

Essentially, these are defects in the skin, fascia, posterior elements of the spine, and the conus medullaris of the cord, along with a failure in neurulation during the 26th to 28th weeks of gestation. Myelomeningocele is most frequent in the lumbar and lumbosacral area (Fig. 19-8). Often of considerable size, it might be confused with a sacral teratoma. The neonatal assessment may require MRI of the entire spinal canal to exclude concurrent anomalies. Cranial ultrasonography is usually sufficient to evaluate for hydrocephalus. The surgical challenge is not so much in closing the exposed nervous system but in obtaining a tension-free cutaneous closure. The initial surgery is directed at freeing the exposed end of the incompletely fused spinal cord from the cutaneous attachments and closing a pseudo-dural layer to protect it. Not infrequently, the skin closure is the more complex segment of the operation, and plastic surgical techniques (relaxing flank incisions, skin grafts, rotational flaps) may be required to accomplish this closure.

The more rostral the defect, the more severe the neurologic deficit, and the more severe the challenges presented to the patient throughout his or her lifetime. To some degree, all of these children have a concurrent Chiari II malformation, which will lead to hydrocephalus in most patients.

**Figure 19-8.** **A,** A typical myelomeningocele shows a small neural placode at the dome with a large CSF-filled sack and little useful skin. **B,** A meningocele with common surrounding port-wine stains is seen.

## Lipomyelomeningocele

Lipomyelomeningocele is a complex anomaly that consists of a subcutaneous meningocele, fascia and bony defects, and a lipoma interfacing with the spinal cord, which is located dorsally, dorsolateral, or terminally. Externally, these lesions appear in the midline and can range from tiny subtle fatty lumps to large masses often accompanied by skin tags, port-wine stains, and an altered intragluteal fold (Fig. 19-9). Before the availability of CT, the connection with the spinal canal was often missed and cosmetic removal of the subcutaneous fat was performed, often with significant negative sequelae. These lesions often require tedious microdissection with release of any tethering effect on the spinal cord to prevent neurologic (weakness, sensory loss), urologic (neurogenic bladder), or orthopedic (scoliosis, leg-length discrepancies) consequences. These children do not have Chiari malformation, sparing them the burden of hydrocephalus.

Operative correction of the asymptomatic infant with a lipomyelomeningocele is not without controversy. Unfortunately, the natural history of these anomalies is unknown. The rationale for early operation in these patients is to release any tethering on the spinal cord and prevent neurologic, urologic, or orthopedic consequences of spinal cord injury. However, a significant number of patients have suffered the same deficits postoperatively that the surgery was planned to prevent. Some children progress despite surgery, which may be related more to a dysfunctional conus than to tethering effects. The absolute correct approach to this lesion remains elusive.<sup>61,62</sup>

## Meningocele

The least common of the neural tube defects is the simplest one. A meningocele consists of a defect in the skin, fascia, posterior spine, and meninges but not the nervous system. When this anomaly occurs, it has a predilection for the lumbosacral area, although it can develop anywhere along the neural axis. Unlike the myelomeningocele, these lesions are almost always covered by nearly normal skin. Therefore, there is no

**Figure 19-9.** A sizable lipomyelomeningocele is seen with cutaneous port-wine stains.

CSF leak. Because the spinal cord and nerve roots are not involved, the children do not have neurologic, urologic, or orthopedic symptomatology. A Chiari II malformation is prevalent in these patients. Therefore, hydrocephalus and the other maladies discussed earlier are possible.

## Tethered Spinal Cord Syndrome

With any of the spinal dysraphisms, there is a high probability the conus medullaris lies below the L2 disc space and is deemed to be “tethered” by radiographic imaging. The spinal cord moves slightly rostrad and caudad with ambulation. When constricted from free excursion, stretching of the neurons and microvascular ischemia will lead to neurologic dysfunction. This chronic injury leads to a plethora of signs and symptoms, most commonly neurogenic bladder, motor weakness or increasing tone in the lower extremities, sensory loss, and skeletal growth anomalies, including scoliosis. Operative exploration for lysis of adhesions or division of whatever structure is impeding the tethered cord is required. Unfortunately, the process may be recurrent throughout the child’s growing years. All children with spinal dysraphism are at risk for tethered cord syndrome, and long-term follow-up is essential.

# CONGENITAL CHEST WALL DEFORMITIES

Donald Nuss, MB, ChB • Robert E. Kelly, Jr., MD

**C**ongenital chest wall deformities fall into two groups: those with overgrowth of the cartilages causing either a depression or protuberance and those with varying degrees of either aplasia or dysplasia.

Pectus excavatum, also known as an “excavated, sunken, or funnel chest,” is the most common chest wall anomaly, constituting about 88% of deformities (Table 20-1). Pectus carinatum, a chest wall protuberance, comprises approximately 5% of chest wall deformities, whereas combined excavatum/carinatum deformities constitute 6%. Jeune’s syndrome, or asphyxiating chondrodystrophy, is an extreme form of mixed pectus excavatum/carinatum and is very rare. Poland’s syndrome (0.8%) and bifid sternum represent different forms of aplasia of the anterior chest wall. Poland’s syndrome consists of varying degrees of dysplasia of the breast, the pectoralis muscles, and ribs. In bifid sternum, partial or complete failure of the midline fusion of the sternum is seen. This may result in ectopia cordis or varying degrees of sternal dysplasia and deficiencies of associated structures such as the heart, pericardium, diaphragm, and anterior abdominal wall (pentalogy of Cantrell).

Many of these deformities are present at birth. Some cases, such as ectopia cordis, are incompatible with life

and have rarely been successfully repaired. Chest wall deformities are frequently associated with a systemic weakness of the connective tissues and with poor muscular development of the abdominal region, thorax, and spine. Therefore, a markedly increased association with Marfan syndrome, Ehlers-Danlos syndrome, and scoliosis, as well as with omphalocele in the case of bifid sternum, has been identified, all of which complicate the management of these patients (see Table 20-1).

## PECTUS EXCAVATUM

Pectus excavatum is a depression of the anterior chest wall of variable severity and can usually be characterized as mild, moderate, or severe. All variations in depth, symmetry, and breadth of the deformity can be seen. The deformity may be localized and deep (“cup-shaped”; Fig. 20-1A), or diffuse and shallow (“saucer-shaped”; see Fig. 20-1B), or asymmetric (see Fig. 20-1C). The depth and extent of the depression determine the degree of cardiac and pulmonary compression, which, in turn, determines the degree of physiologic effect. Only one third of patients referred from our own region had a deformity severe enough to require surgical correction. Even with referral of patients with a severe deformity from other centers, our ratio of surgical interventions has been only about 50% (Table 20-2).

The deformity may be noted at birth and progresses with growth. During rapid pubertal growth, the progression may become especially pronounced, a fact apparently unknown to many pediatricians, who mistakenly advise families of younger patients that the condition will resolve spontaneously. We have seen many families who were given this advice and missed the opportunity to have the deformity repaired before puberty while the chest was still soft and malleable and before it interfered with physical performance.

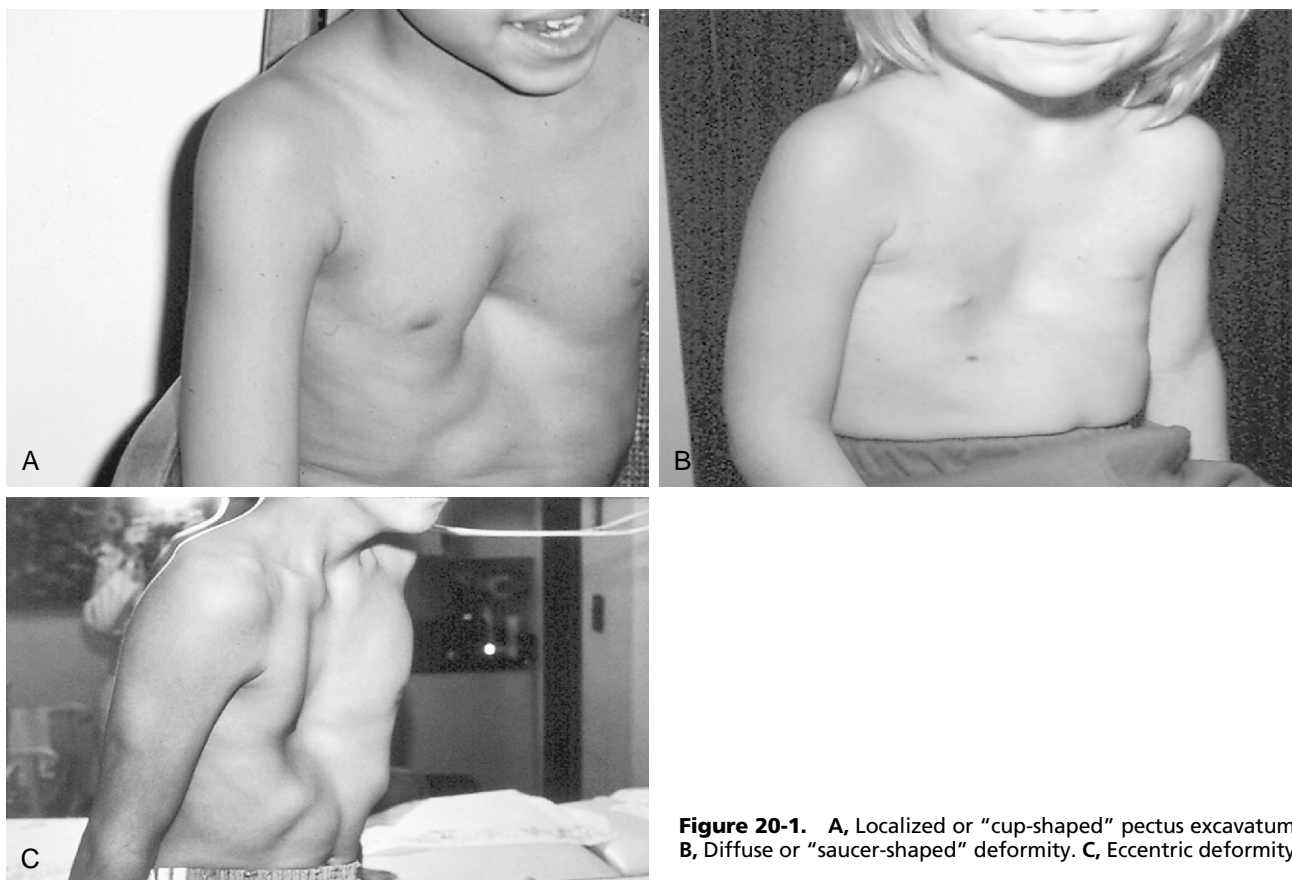

## History

Pectus excavatum was recognized as early as the 16th century. Johan Schenck collected literature on the subject, as cited by Ebstein.<sup>1</sup> A classic article by Bauhinus

**Table 20-1** Incidence and Etiology of Congenital Chest Wall Anomalies Seen at Children’s Hospital of the King’s Daughters

Total children evaluated	2141
Pectus excavatum only	1805
Mixed excavatum/carinatum	116
Carinatum only	208
Poland syndrome	12
Male-female ratio	4:1
Family history of pectus excavatum	36.2%
Incidence of scoliosis	21.7%
Incidence of Marfan syndrome diagnosed	1.7%
Marfanoid—presumed Marfan syndrome	12.0%
Patients with Ehlers-Danlos syndrome	0.7%

Data collected through 12/31/2007.

**Figure 20-1.** A, Localized or “cup-shaped” pectus excavatum. B, Diffuse or “saucer-shaped” deformity. C, Eccentric deformity.

in 1594 described the clinical features of pectus excavatum in a patient who had pulmonary compression with dyspnea and paroxysmal cough, attributed to a severe pectus excavatum.<sup>2</sup> The familial predisposition was first noted by Coulson in 1820,<sup>3</sup> who cited a family

of three brothers with pectus excavatum, and Williams in 1872,<sup>4</sup> who described a 17-year-old patient who was born with a pectus excavatum and whose father and brother also had the condition.

Numerous other case reports appeared in the 19th century, including a five-case report by Ebstein in 1882 that covered the clinical spectrum of this condition.<sup>5</sup> Treatment at that time was limited to “fresh air, breathing exercises, aerobic activities and lateral pressure.”<sup>6,7</sup>

Thoracic surgery remained “forbidden territory” until the early years of the 20th century. The first attempt at surgical correction was a tentative approach in 1911 by Meyer, who removed the second and third costal cartilages on the right side without improvement of the deformity.<sup>8</sup> Sauerbruch, one of the pioneers of thoracic surgery, used a more aggressive approach in 1913 by excising a section of the anterior chest wall, which included the left fifth to ninth costal cartilages as well as a segment of the adjacent sternum.<sup>7</sup> Before his operation, the patient was incapacitated by severe dyspnea and palpitations, even at rest, and was unable to work in his father’s watch factory. After recovery, the heart could be seen to pulsate under the muscle flap, but the patient was able to work without dyspnea and was married 3 years later.

In the 1920s, Sauerbruch performed the first pectus repair that used the bilateral costal cartilage resection and sternal osteotomy technique later popularized by

<b>Table 20-2</b>		<b>Presenting Symptoms in 1015 Patients Who Have Undergone Surgical Correction of Pectus Excavatum at Children’s Hospital of the King’s Daughters</b>
Shortness of breath, lack of endurance, exercise intolerance	89.2%	(906)
Chest pain, with or without exercise	67.0%	(680)
Frequent respiratory infections	23.9%	(243)
Asthma/asthma-like symptoms	27.8%	(282)
<b>Cardiology Indicators</b>

Ravitch.<sup>9</sup> He also advocated external traction to hold the sternum in its corrected position for 6 postoperative weeks. His technique was soon adapted by others in Europe and rapidly gained popularity in the United States. In 1939, Ochsner and DeBakey published their experience with the procedure and reviewed the entire surgical literature on the subject.<sup>10</sup> Also in 1939, Lincoln Brown published his experience in two patients and reviewed the literature with particular reference to the etiology of pectus excavatum.<sup>11</sup> He was impressed with the theory that short diaphragmatic ligaments and the pull of the diaphragm on the posterior sternum were the causative factors.

Ravitch initially subscribed to the short ligament theory as well. As a result, he advocated even more radical mobilization of the sternum, with transection of all sternal attachments, including the intercostal bundles, rectus muscles, diaphragmatic attachments, and excision of the xiphisternum. In 1949, he published his experience with eight patients in which he used this radically extended modification of Sauerbruch's technique of bilateral cartilage resection and sternal osteotomy.<sup>12</sup> However, he did not utilize external traction.

The abolition of external traction may have led to an increased recurrence of the condition. As a result, Wallgren and Sulamaa introduced the concept of internal support in 1956 by using a slightly curved stainless steel bar that was pushed through the caudal end of the sternum from side to side and bridged the newly created gap between the sternum and ribs.<sup>13,14</sup> In 1961, Adkins and Blades modified internal bracing further by passing a straight stainless steel bar behind rather than through the sternum.<sup>15</sup> This technique was rapidly adapted for patients of all ages.

As early as 1958, Welch and Gross advocated a less radical approach than that of Ravitch.<sup>16,17</sup> Welch produced excellent results in 75 cases without dividing all the intercostal bundles or the rectus muscle attachments. However, he still advocated performing the procedure in young patients. Conversely, Pena was very disturbed by the idea of resecting the rib cartilages from very young patients and demonstrated that asphyxiating chondrodystrophy developed in baby rabbits after cartilage resection during their growth phase.<sup>18</sup> Later, Haller also reported the risk of acquired asphyxiating chondrodystrophy as well.<sup>19</sup> As a result, many surgeons stopped performing open pectus repair in young children and waited until they had reached puberty. They also decreased the amount of cartilage resected and spoke about a "modified Ravitch procedure," which effectively was the original Sauerbruch procedure.

In 1997, we published our 10-year experience with a minimally invasive technique that required no cartilage resection and no sternal osteotomy but instead relied on internal bracing made possible by the flexibility and malleability of the costal cartilages.<sup>20</sup>

The rationale for this technique was based on the three following observations:

1. *Malleability of the chest.* Children have a soft and malleable chest. In young children, the chest is so soft that even minor respiratory obstruction can cause severe sternal retraction. Trauma

rarely causes rib fractures, flail chest, and so on, because the chest is so soft and malleable.<sup>21-23</sup> Thus, the American Heart Association recommends "using only two fingers" when performing cardiac resuscitation in young children and "only one hand in older children" for fear of crushing the heart.

2. *Chest reconfiguration.* In middle-aged and older adults, a barrel-shaped chest configuration develops in response to chronic obstructive respiratory diseases such as emphysema. If older adults are able to reconfigure the chest wall, children and teenagers should be able to remodel as well, especially with the increased malleability of their anterior chest wall.
3. *Bracing.* The role of braces and serial casting in successfully correcting skeletal anomalies such as scoliosis, clubfoot, and maxillomandibular malocclusion by orthopedic and orthodontic surgeons is well established. The anterior chest wall, being even more malleable than the previously mentioned skeletal structures, is therefore ideal for this type of correction.

## Incidence and Etiology

Pectus excavatum occurs in approximately 1 in 1000 children and constitutes 88% of all chest wall deformities (see Table 20-1). However, this is not the case in all countries. In Argentina, pectus carinatum is more common than pectus excavatum.<sup>24</sup> Pectus excavatum also is rare in African-Americans. A genetic predisposition, already noted in the 19th century, was found in 36% of our patients. We have seen families with three siblings, as well as cousins and other family members, who had a pectus deformity severe enough to require correction. We also have seen patients whose fathers and grandfathers have the deformity. The male-to-female ratio of 4:1 in our series of pectus excavatum patients is similar to that of other large series.<sup>25</sup> Female patients have an increased risk of associated scoliosis. Inheritance is autosomal dominant, autosomal recessive, X-linked, and multifactorial in different families.<sup>26</sup>

The association with a connective tissue disorder is higher than in the normal population. The vast majority of our patients have an asthenic build and a definitive diagnosis of Marfan syndrome has been found in 1.7% of our patients. An additional 12% have had clinical features suggestive of Marfan syndrome. Ehlers-Danlos syndrome was present in another 0.7%. Mild scoliosis was noted in 21.7% of the patients. In our experience, severely asymmetric pectus excavatum tends to aggravate the postural abnormality of scoliosis. Early correction of the pectus excavatum has improved the mild scoliosis in some patients.

## Clinical Features

Pectus excavatum is noted in infancy in approximately one third of patients<sup>25</sup> and usually progresses slowly as the child grows. Because young children have

**Figure 20-2.** Classic pectus posture with thoracic kyphosis, forward sloping shoulders, and lumbar lordosis.

significant cardiac and pulmonary reserve and their chest wall is still very pliable, the majority of young children are asymptomatic. However, as they become older, the deformity becomes more severe and the chest wall becomes more rigid. Eventually, they find that they have difficulty keeping up with their peers when playing aerobic sports. A vicious cycle may develop as patients stop participating in aerobic activities because of their inability to keep up. Subsequently, their exercise capacity diminishes further. The downward spiral is given added impetus by the fact that these patients, already embarrassed by their deformity, will avoid situations in which they have to remove their shirts in front of other children, further inhibiting participation in school and team activities.

By withdrawing from participation in activities with their peers, they also become depressed, which may affect their schoolwork. Most pectus patients have a typical geriatric or “pectus posture” that includes thoracic kyphosis, forward-sloping shoulders, and a protuberant abdomen (Fig. 20-2). A sedentary “couch potato” lifestyle may aggravate this posture, and the poor posture depresses the sternum even farther. For this reason, we empirically recommend an aggressive pectus posture exercise and breathing program, both preoperatively and postoperatively.

Many patients have a relatively mild deformity during childhood. Because pediatricians are unaware of the potential for marked progression of the deformity with growth, they reassure the parents that it will resolve spontaneously or even improve. Although the deformity may not always deepen, it is unlikely that it will resolve spontaneously. When the patients grow rapidly during puberty, the deformity often suddenly accelerates. A mild deformity may become severe in as little as 6 to 12 months. These patients give a history that “my chest suddenly caved in.” It is the rapid progression that alarms parents and induces them to seek surgical consultation despite their pediatrician’s reassurance.

Patients with a rapid progression of their deformity exhibit the most pronounced symptom-complex.

The earliest complaints are shortness of breath and lack of endurance with exercise. As the deformity progresses, chest pain and palpitations with exercise may occur, giving rise to exercise intolerance. Other symptoms include frequent and prolonged respiratory tract infections, which may lead to the development of asthma (see Table 20-2).

A recent study showed that these patients have a poor body image, which has a major impact on self-worth.<sup>27</sup> Therefore, it is important to correct the deformity before it affects their ability to function normally. One of our patients, a 35-year-old lawyer, confided that he had not married because he was too ashamed of his chest abnormality to have a serious relationship. A 16-year-old patient left a note for his parents, before attempting suicide, detailing the harassment and abuse that he had received from children at school. Just as one would not consider leaving a child with a cleft lip untreated, one should not leave a child with a severe pectus untreated. Both have a physiologic and psychological impact on the patient.

### Cardiac and Pulmonary Effects of Pectus Excavatum

A great deal has been written about cardiopulmonary function in patients with pectus excavatum.<sup>28</sup> Some authors have shown significant compromise of cardiac or pulmonary function, or both.<sup>29,30</sup> Others have been unable to demonstrate significant variation from predicted values.<sup>31</sup> Several factors play a role when testing cardiopulmonary function. These include the severity of the deformity, the inherent physical fitness of the individual patient, the patient’s age, associated conditions, whether the tests are done supine or erect, and whether they are done at rest or during exercise. Recently, a study has shown statistically significant and clinically meaningful improvements in stroke volume, cardiac output, and cardiac index after minimally invasive repair of pectus excavatum.<sup>32</sup> Also, an improvement in exercise cardiopulmonary function has been noted as well.

Cardiac effects fall into three categories: decreased cardiac output, mitral valve prolapse, and arrhythmias (see Table 20-2). Compression of the heart results in incomplete filling and decreased stroke volume, which in turn, results in decreased cardiac output.<sup>29,30,33,34</sup> Second, the cardiac compression interferes with normal valve function. Mitral valve prolapse was present in 17% of our patients and in up to 65% of those in other published series, compared with only 1% in the normal pediatric population.<sup>35-37</sup> Dysrhythmias, including first-degree heart block, right bundle branch block, Wolff-Parkinson-White syndrome, and so on, have been found in 16% of our patients.<sup>38</sup>

Pulmonary effects also fall into three categories: restrictive lung disease, atelectasis due to lung compression, and paradoxical respiration in severe cases. The result is varying degrees of pulmonary compromise, prolonged respiratory infections, and even the

development of asthma (see Table 20-2). Children with a severe deformity from birth tend to compensate by increasing the diaphragmatic component of their respiration. This partly compensates for their deformity and is found in patients who, despite a severe deformity, are able to achieve low-normal pulmonary function studies at rest. However, they demonstrate a lack of endurance during exercise because they have little or no reserve. Stress testing has shown an increase in oxygen consumption for a given exercise when compared with that of normal patients.<sup>39</sup> This shows that the work of breathing is increased and explains why they lack endurance.

## Evaluation and Indications for Operation

A complete history and physical examination is performed in all patients and includes documenting photographs. Patients with a mild to moderate deformity are treated with a posture and exercise program in an attempt to halt the progression and are followed at 6-month intervals (Fig. 20-3).

Patients with a severe deformity or those with a documented progression also are treated with the exercise and posture program. Additionally, they undergo objective studies to evaluate whether their condition is severe enough to warrant surgical correction. These studies include pulmonary function tests (FTP), a thoracic computed tomography (CT) scan, and a cardiac evaluation that includes an electrocardiogram (ECG) and an echocardiogram.

Pulmonary function tests are performed in all patients old enough to cooperate with testing. They are best done while the patient is exercising but also are helpful in the resting state. The cardiology evaluation includes an electrocardiogram, an echocardiogram, and an examination by a pediatric cardiologist to determine the presence of cardiac compression, murmurs,

mitral valve prolapse, conduction abnormalities, or other structural abnormalities. CT scans are very helpful because they clearly show the degree of cardiac compression and displacement, the degree of pulmonary compression and atelectasis, asymmetry of the chest, sternal torsion, compensatory development of a barrel-chest deformity in long-standing deformities, and ossification of the cartilages in patients with previous repairs (Fig. 20-4A, B). They also are used to calculate the CT index, which gives an objective measurement for comparing the severity between different patients. The CT index is calculated by dividing the transverse diameter by the anteroposterior diameter (see Fig. 20-4C).<sup>40</sup>

Determination of a severe pectus excavatum and the need for repair include two or more of the following criteria: (1) a CT index greater than 3.25; (2) pulmonary function studies that indicate restrictive or obstructive airway disease, or both; (3) a cardiology evaluation in which compression is causing murmurs, mitral valve prolapse, cardiac displacement, or conduction abnormalities on the echocardiogram or ECG tracings; (4) documentation of progression of the deformity with associated physical symptoms other than isolated concerns of body image; (5) a failed Ravitch procedure; or (6) a failed minimally invasive procedure. With these criteria, fewer than 50% of patients in our referral practice are found to have a deformity severe enough to warrant surgical correction.<sup>20,41</sup>

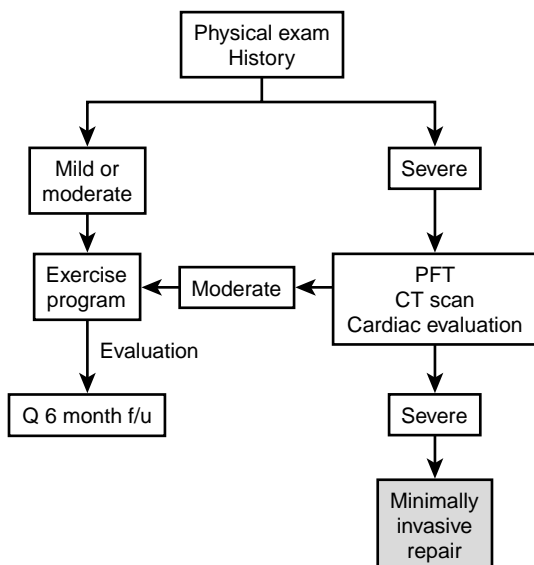

The age parameters for surgical correction depend on the type of procedure selected. Unlike the more invasive procedures (e.g., Ravitch procedure, sternal turnover), no interference with growth plates occurs with the minimally invasive procedure. Therefore, it can be done at any age, as evidenced by the fact that we have successfully operated on patients from ages 17 months to 31 years (Fig. 20-5). However, the concern with patients younger than 11 years is that if the procedure is done at too young an age, many years of subsequent growth remain during which the pectus excavatum may recur.

Our experience has shown that the optimal age for repair is 11 to 14 years. At this age, the patient is pre-pubertal, the chest is still soft and malleable, there is a quick recovery with a rapid return to normal activities, and results are excellent (Fig. 20-6). After puberty, the flexibility of the chest wall is decreased, sometimes requiring the insertion of two bars, which makes the procedure more difficult. It also takes patients longer to recover. However, all of our patients older than age 20 years have been extremely pleased with their results. Several other centers have reported success with patients up to age 44 years.<sup>33,42,43</sup>

## Surgical Technique

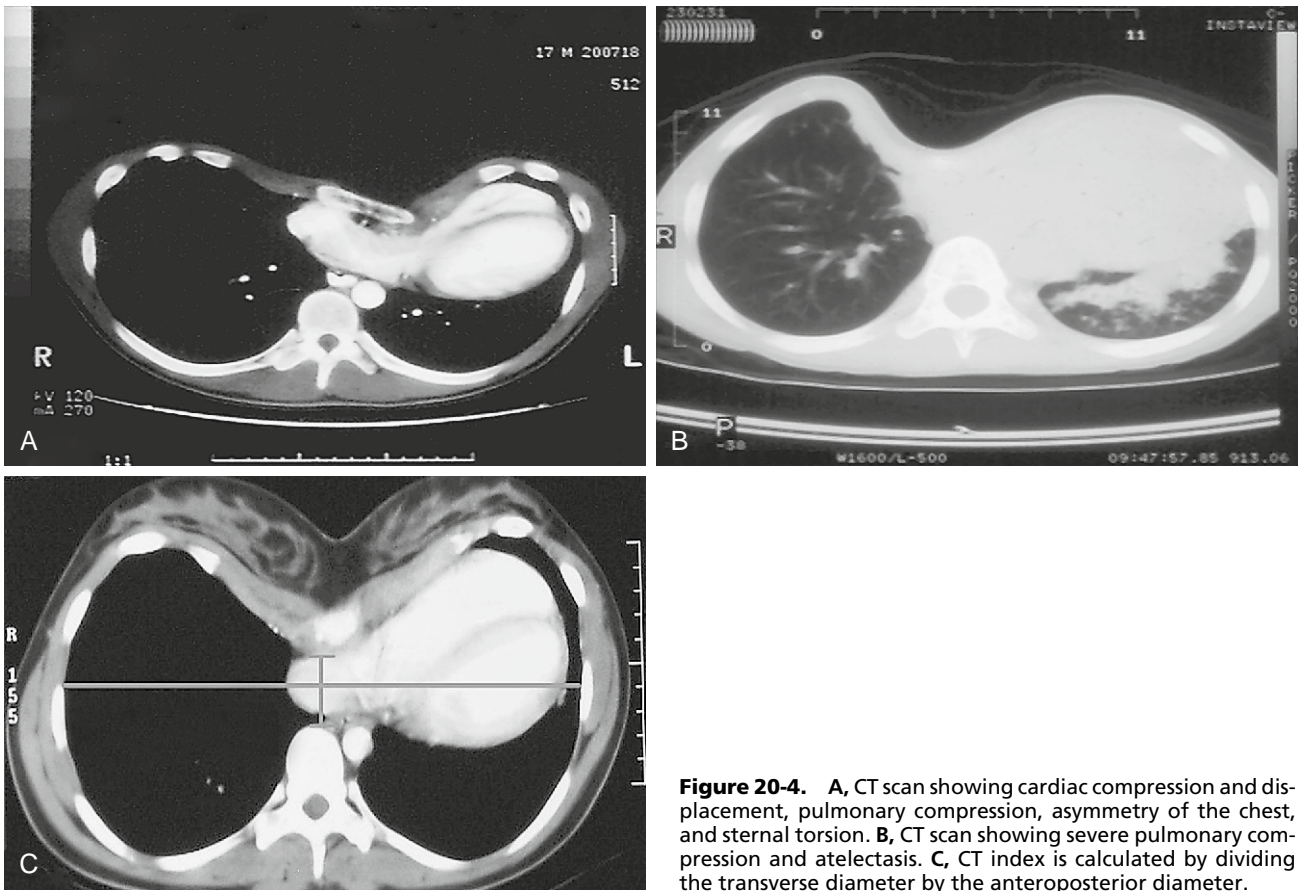

### Minimally Invasive Pectus Repair

The minimally invasive pectus repair (Fig. 20-7) involves making incisions on each side of the chest and creating a subcutaneous tunnel from the lateral thoracic incision to the top of the pectus ridge on each

**Figure 20-3.** Algorithm for evaluation and treatment of patients with pectus deformities.

**Figure 20-4.** A, CT scan showing cardiac compression and displacement, pulmonary compression, asymmetry of the chest, and sternal torsion. B, CT scan showing severe pulmonary compression and atelectasis. C, CT index is calculated by dividing the transverse diameter by the anteroposterior diameter.

**Figure 20-5.** Age distribution of the authors' primary pectus excavatum repairs.

**Figure 20-6.** Long-term results of minimally invasive pectus repair by age groups.

side. At the top of the ridge, bilateral thoracostomy incisions are made and a large introducer is inserted into the chest cavity under thoracoscopic guidance. Very carefully, with the thoracoscope in place and under good vision, the pleura and pericardium are dissected off the undersurface of the sternum and the introducer is slowly advanced across the mediastinum and exteriorized through the thoracostomy incision on the contralateral side. When the introducer is in place, the sternum is lifted out of its depressed position by the introducer. Once the sternal depression has been corrected, an umbilical tape is attached to the introducer, and the introducer is slowly withdrawn from the chest. The pectus support bar is then attached to the umbilical tape and is slowly guided through the substernal tunnel, under thoracoscopic guidance, with its convexity facing posteriorly until it emerges on the contralateral side.

The length of the bar is determined by measuring the distance from midaxillary line to midaxillary line and subtracting 2.5 cm (1 inch). The bar is bent to the desired configuration using a bar bender. Once the bar is in position inside the chest with the convexity facing posteriorly, it is turned over by using specially designed bar flippers, resulting in correction of the pectus excavatum. The bar is secured using a stabilizer on one end of the bar and placing sutures around the bar and underlying ribs. Alternatively, stabilizers can be used on both sides to secure the bar in place. The sutures are usually placed with an autosuture needle under thoracoscopic control. It is essential that the bar be adequately stabilized or it will become displaced. Once the bar has been stabilized, the incisions are closed. The thoracoscope is removed, and the pneumothorax is evacuated by using a water-seal system. The patient is kept on a thoracic epidural analgesia for 3 postoperative days and is then discharged from the hospital, usually on the fourth or fifth day. Patients

need to refrain from sports activities for 6 weeks after surgery. All patients are started on an exercise and posture program to facilitate chest expansion and to maintain a good posture.

Pain management for both the open and closed pectus repairs is the same and is designed to pre-empt the pain cascade. This is accomplished by the use of epidural analgesia and non-steroidal anti-inflammatory agents, which are started immediately before surgery and continued post-operatively for three days. In addition, narcotics and muscle relaxants are added post-operatively. When patients are discharged, they are given prescriptions for non-steroidal, anti-inflammatory medications, muscle relaxants, and narcotic medication. Patients less than 13 years of age are generally able to stop all pain medications after 7 to 10 days while patients 13 and over may require pain medication for 10 to 14 days post-operatively.

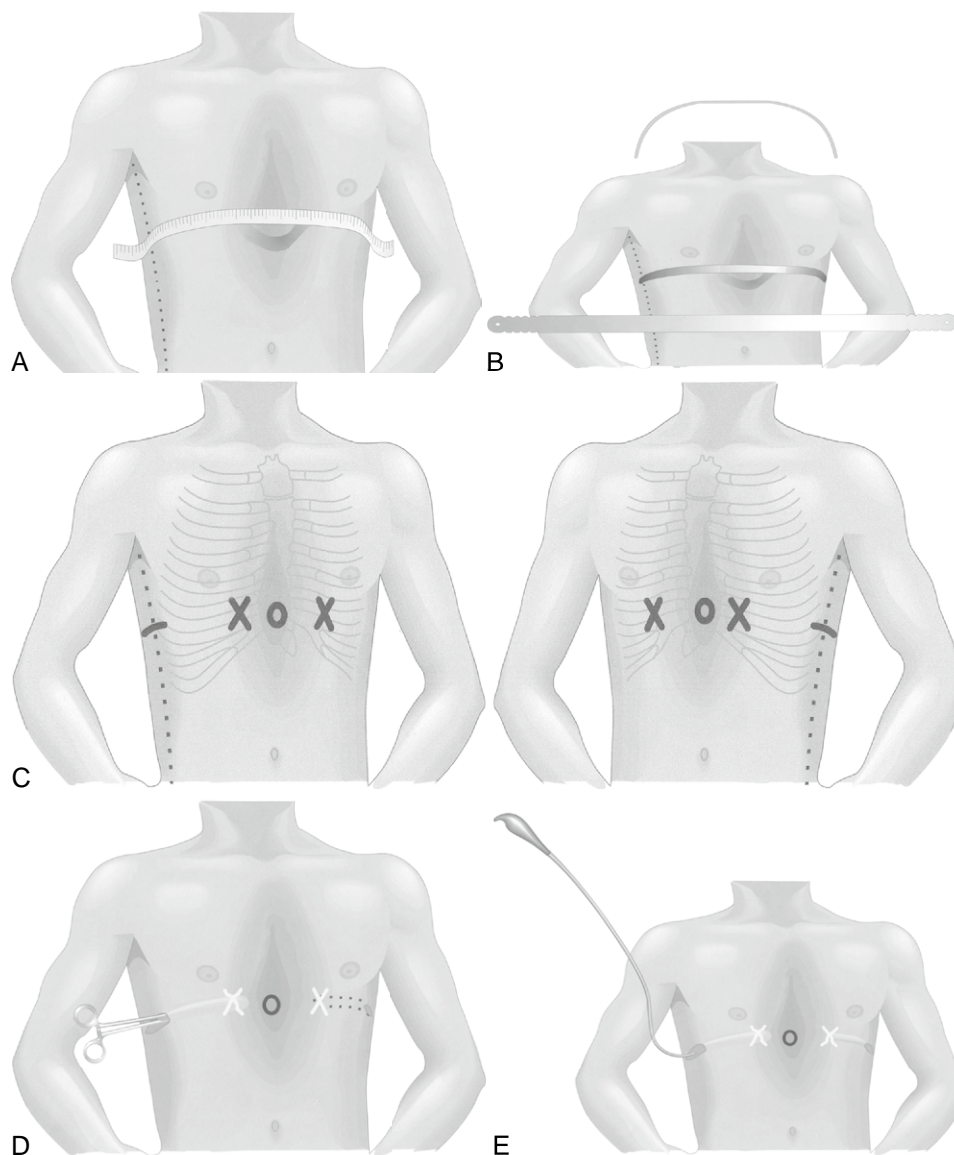

### Open Technique

The preoperative preparation and evaluation are the same for the open approach for repair of pectus excavatum as for minimally invasive technique. However, because of the risk of interference with growth plates in young children and the development of asphyxiating chondrodystrophy, the procedure should be reserved for patients who have completed their growth.<sup>18,19</sup> The open procedure is best suited for the older patients, especially those who have asymmetric or eccentric deformities, and patients with mixed pectus carinatum/excavatum deformities.

The open technique involves making an anterior thoracic incision and elevating skin and muscle flaps until all the costal cartilages from T3 to T6 are exposed. The perichondrium is then incised longitudinally, and the deformed cartilages are either partially or completely removed. Most surgeons now advocate removing only a small section (1 to 2 cm) of the deformed cartilages, as was originally advocated by Sauerbruch and Gross.<sup>9,17</sup> An anterior table, wedge-shaped, sternal osteotomy is performed at the angle of Louis. The sternum is elevated, and the osteotomy is closed with nonabsorbable sutures. Some surgeons utilize a pectus strut that is inserted under the sternum to bridge the gap between the ribs and the sternum and to prevent the sternum from sinking back into the chest. The perichondrial “sleeves” are approximated with absorbable sutures, drains are inserted, the muscle flaps are sutured back into position, and the incisions are closed. Postoperative management is similar to that for the minimally invasive technique except that patients are required to refrain from contact sports for at least 3 months.

### Results

The minimally invasive approach for the repair of pectus excavatum received rapid acceptance by the surgical community because the technique requires neither rib incision nor resection nor sternal osteotomy. The blood loss is minimal, the operating time is short, and the patient rapidly returns to regular activity.<sup>43-50</sup>

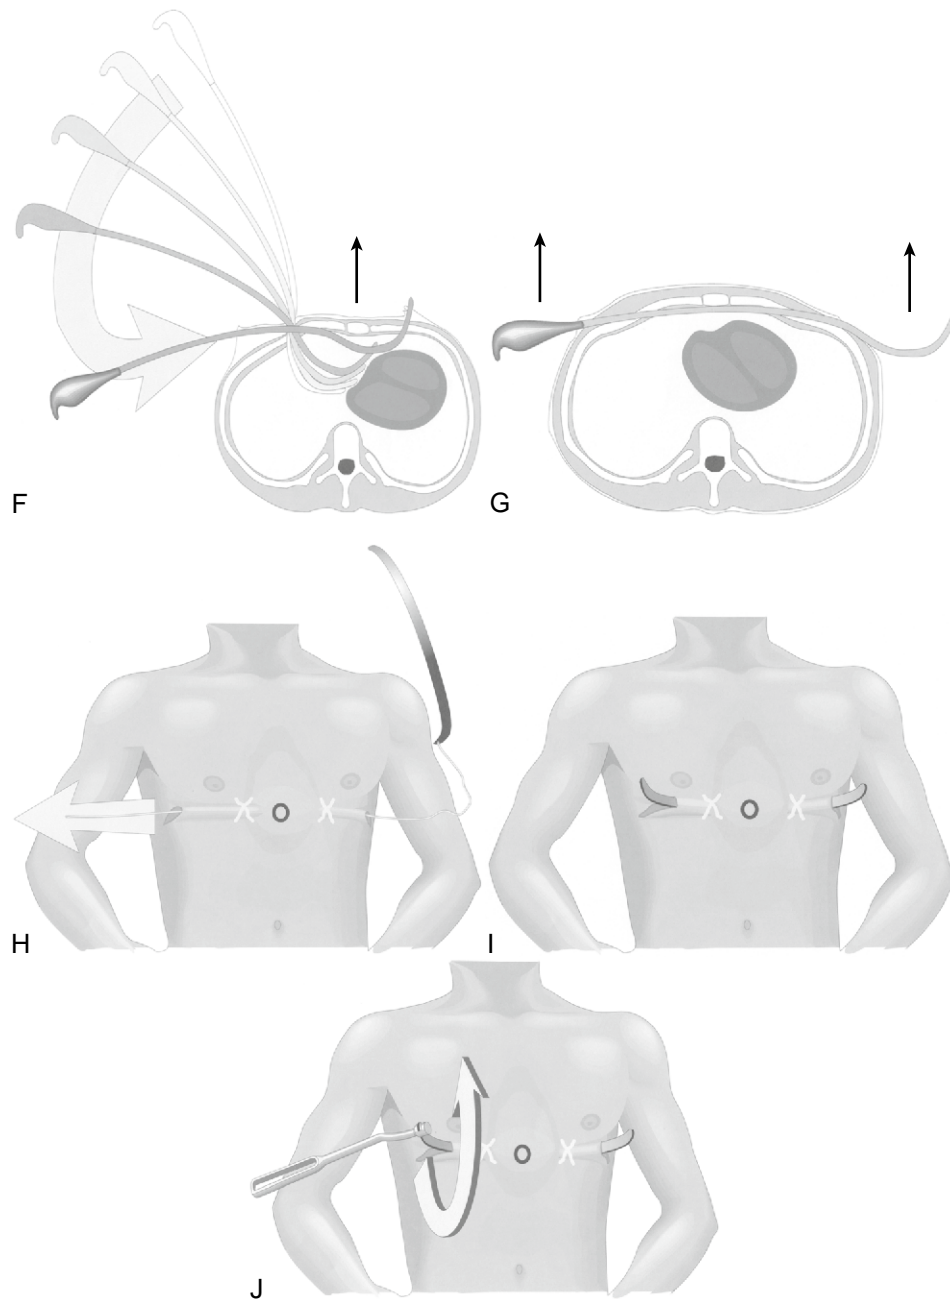

**Figure 20-7.** **A**, To calculate the length of the pectus bar, measure the distance from right to left midaxillary line and subtract 1 to 2 cm (1 inch). **B**, Bend the Lorenz pectus support bar to conform to the desired chest wall curvature. **C**, Mark the deepest point of the pectus excavatum with a circle by using a marking pen. If this point is inferior to the sternum, then move the circle superiorly to the lower end of the sternum just above the xiphoid. This point sets the horizontal plane bar for insertion. **D**, After confirming by thoracoscopy that the internal and external anatomy match up well, make lateral thoracic skin incisions and raise skin flaps anteriorly toward the “X” marked on the external skin at the top of the pectus ridge. **E**, Retract skin incision anteriorly to allow visualization of the intercostal space previously marked with an “X”. Under thoracoscopic control, insert the appropriate-size Lorenz introducer through the right intercostal space at the top of the pectus ridge and at the previously marked “X.”

Although our initial report in 1998 presented a 10-year experience, the numbers were limited (42 patients) and the long-term results were affected by the early learning experience of using a support bar that was too soft. Moreover, in some patients, the bar was removed too soon.<sup>20</sup> From 1988 through December 2007, 1015 patients have had their primary operation at our institution (Table 20-3). Six hundred and ninety patients have had their bars removed. Since the original presentation, numerous important modifications have been made, both to the surgical technique (e.g., routine use of thoracoscopy) and instruments, to minimize the risks of the procedure and facilitate insertion and stabilization of the support bar. These

modifications have markedly reduced the risks and complications and have been previously reported.<sup>41</sup>

In our series of 1015 patients with pectus excavatum, only 7 (0.7%) had a mixed pectus excavatum and carinatum. One (0.1%) patient had associated Poland’s syndrome, and one (0.1%) had an associated complex cardiac anomaly (atrioventricular canal). Marfan syndrome was confirmed or suspected in 13.7% of the patients, and Ehlers-Danlos syndrome was noted in 0.7% of the patients. The male-to-female ratio in patients undergoing repair was more than 4:1. The median age was 14.6 years, with a range from 19 months to 31 years. Preoperative evaluation included CT scan with a median CT index of 4.6 (range, 2.4 to

**Figure 20-7—cont'd.** **F**, When the substernal tunnel has been completed, gently push the tip of the introducer through the contralateral intercostal space at the previously marked "X," medial to the top of the pectus ridge on the left side. **G**, Use the introducer to elevate the sternum. The surgeon lifts on the right side, and the assistant lifts the left side of the introducer. **H**, Attach the previously prepared pectus bar to the umbilical tape and slowly guide the bar through the tunnel by using the umbilical tape for traction. **I**, The bar is inserted with the convexity facing posteriorly. **J**, When the bar is in position, use the specially designed Lorenz bar rotational instrument (bar flipper) to turn the bar over.

21). Cardiac compression was noted on echocardiography or CT scan, or both, in 793 of 889 patients (89%). Mitral valve prolapse was noted in 132 of 889 patients (15%). Resting pulmonary function tests were completed in 454 patients and demonstrated abnormalities in 43%.

In 730 (72%) patients, a single bar was inserted. Two bars were needed in 285 (28%) patients. Blood loss in most patients was minimal ( $\pm 10$  mL), with the exception of 4 patients in whom a hemothorax developed.

Epidural analgesia was used for 3 days in the vast majority of patients. The median length of stay was 5 days.

## Complications

### Early Complications

No deaths or cardiac perforations occurred during the 1015 repairs at our institution. Pneumothorax requiring chest tube drainage occurred in 36 (3.6%) repairs,

**Table 20-3** Results from Patients Undergoing Repair of Pectus Excavatum at Children's Hospital of The King's Daughters

<i>Minimally Invasive Technique</i>		<i>Materials and Methods</i>
2141 patients evaluated for chest wall deformity		
1101 patients had minimally invasive pectus repair		
1015 patients underwent primary operations		
86 patients have had re-do operations:		
41 failed Ravitch procedures		
43 failed Nuss procedures		
2 failed Leonard procedures		
<i>Minimally Invasive Technique</i>	<i>Operation and Length of Stay</i>	
Single pectus bar	71.9%	
Double pectus bar	27.7%	
Triple pectus bar	0.4%	
No stabilizers	12% (124/1015)	
Stabilizers	88% (891/1015)	
PDS sutures	48% (434/891)	
Wired stabilizers	42% (372/891)	
Not wired	10% (85/891)	
Median age	14.64	
Median Haller CT index	4.6	
Median length of stay	5 days	

and hemothorax occurred after 4 (0.4%) repairs. Four (0.4%) pleural effusions required treatment with either a chest tube or aspiration (Table 20-4).

Pericarditis requiring treatment with indomethacin occurred after 5 (0.5%) repairs. One patient required pericardiocentesis. Pneumonia occurred after 6 (0.6%) repairs, and medication reactions have occurred after 36 (3.6%) repairs. Wound infections occurred after 11 (1.1%) repairs. These resulted in bar infections and eventual early bar removal in 2 (0.02%) patients. One hundred seventy-nine patients had a transient Horner syndrome at varying times during the thoracic epidural administration.

### Late Complications

Fifty-eight (5.8%) bars became displaced, and 43 (4.2%) required repositioning. In the 43 cases in which patients required repositioning of the bars, 16 occurred before stabilizers were available, a time period covering our first 105 repairs. After the introduction of stabilizers, the incidence of bar displacement decreased from 15.2% to 6.5%. When the bar and stabilizers were wired together, the incidence of bar displacement decreased to 4.3%. Since we combined placing a stabilizer on the left and polydioxanone (PDS, Ethicon, Inc., Somerville NJ) sutures around the bar and underlying rib on the right, the incidence of bar displacement has dropped to 1%.

In two patients, a late hemothorax developed secondary to trauma. Both underwent thoracoscopy with drainage of the hemothorax. At the time of thoracoscopy, no active bleeding was found. Therefore, an

injury to an intercostal vessel was presumed. Whether hemothoraces would have developed in these patients as a result of their thoracic trauma if they had not had a pectus bar placed in situ is unknown. We do have several patients who were involved in major automobile accidents who sustained head and musculoskeletal trauma but no chest injuries.

Twenty-nine (2.9%) of 1015 patients have had unsuspected allergies to the metal in the bar. These allergies initially presented as rashes in the area of the bar or stabilizer and required revision to custom-made bars of other alloys. Mild overcorrection occurred in 32 (3.2%) patients. In 4 (0.4%), a true carinatum deformity developed. Of the patients in whom a true carinatum deformity developed, 3 had Marfan syndrome and the other had Ehlers-Danlos syndrome. No patient has developed thoracic chondrodystrophy.

### Overall Results and Long-Term Follow-up

Patients are evaluated at 6 months after the operation and then yearly until the bar is removed. Long-term assessment has allowed classification of the results into excellent, good, fair, or failed categories.

An excellent repair indicates that the patient experienced complete repair of the pectus deformity and resolution of associated symptoms. A good repair is distinguished by a markedly improved but not completely normal chest wall appearance and resolution of associated symptoms. A fair result indicates a mild residual pectus excavatum without complete resolution of symptoms. A failed repair is defined as a recurrence of the pectus deformity and associated symptoms or the need for additional surgery (or both) after final removal of the bar.

In addition, patients with ECG conduction abnormalities or mitral valve prolapse had follow-up

**Table 20-4** Early Complications after Initial Pectus Excavatum Repair at Children's Hospital of the King's Daughters

<b>Complication</b>	<b>% (No.)</b>
Pneumothorax w/spontaneous resolution	60.4% (613)
Pneumothorax w/chest tube	3.6% (36)
Horner's syndrome	17.7% (179)
Bar displacement	5.7% (58)
Drug reaction	3.6% (36)
Overcorrection	3.2% (32)
Bar allergy	2.9% (29)
Suture site infection	1.0% (10)
Pneumonia	0.6% (6)
Hemothorax	0.6% (6)
Hemothorax (post-traumatic)	0.2% (2)
Pericarditis	0.5% (5)
Pleural effusion (requiring drainage)	0.3% (3)
Death	0%
Cardiac perforation	0%

Data collected through 12/31/2007.

**Figure 20-8.** The authors' outcomes evaluated over time since bar removal.

assessments. Patients old enough to have pulmonary function studies preoperatively were reassessed with repeated studies.

It has been noted that patients who are sedentary and who do not perform the pectus breathing exercises tend to have mild recurrences over time. Therefore, we strongly emphasize the importance of aerobic activities and deep breathing exercises.

As of December 2007, there were 690 primary repair patients who had undergone bar removal. The cosmetic and functional results of the 587 patients who were more than 1 year post-bar removal were deemed excellent in 84%, good in 12%, fair in 1.5%, and failed in 2.5% (Fig. 20-8). The long-term results are affected by the length of time the bar was left in place (Fig. 20-9).

## Bar Removal

We advise the pectus bar be left in place for 2 to 4 years, with 3 years being an optimal time. We evaluate patients on an annual basis and monitor their growth, activity level, and pulmonary function test results and encourage them to do their pectus exercises and participate in aerobic sports. Patients between the ages of 6 and 10 years often do not grow rapidly. Therefore, they tolerate the bar well for 3 or even 4 years. Conversely, we have had teenagers who have undergone a massive growth spurt, completely outgrowing the bar and requiring bar removal after 2 years. We consider the exercise programs to be as important as the surgical correction. Many children and adults lead sedentary lifestyles and never perform aerobic activities. Therefore, their lungs never expand beyond the resting tidal volume (approximately 10% of total lung capacity). Deep breathing with breath holding for 10 to 15 seconds and aerobic activities, such as running (e.g., soccer, basketball) and swimming, are vigorously

**Figure 20-9.** The authors' outcomes evaluated by the length of time the bar was left in situ.

encouraged. We have seen a mild recurrence over the long term in patients who do not follow our exercise protocol.

Pectus excavatum can be corrected with excellent long-term results without the need for costal cartilage incision, cartilage resection, or sternal osteotomy. A significant number of patients have been safely and effectively managed at long-term follow-up. Pectus excavatum repair without cartilage resection is a simpler operation with tolerable morbidity. As a result, it has received rapid acceptance by the surgical community.

## PECTUS CARINATUM

Pectus carinatum, or protrusion deformity of the chest, occurs less frequently than does pectus excavatum. It comprises about 5% of patients with chest wall deformities.<sup>51</sup> The prominence may be in the upper manubrium of the sternum, which is called a chondromanubrial deformity.<sup>52</sup> The most common protrusion occurs in the lower or body of the sternum (the gladiolus) and is called chondrogladiolar. The protrusion may be unilateral, bilateral, or mixed.<sup>53</sup> About 80% of patients who develop pectus carinatum are boys. Although the etiology is unknown, a genetic component of causation is suggested by the approximately one fourth of patients with a family history of chest wall defect.<sup>51,54</sup> Pectus carinatum has been reported to occur after treatment for pectus excavatum.<sup>55</sup>

The natural history of the condition differs from that of pectus excavatum. Pectus carinatum is usually noted in adolescence and is seen most commonly around the time of a growth spurt, rather than at birth as is often seen with pectus excavatum. Symptoms of dyspnea, reduced endurance, or tachypnea with exertion were noted in all 260 patients in one study.<sup>56</sup>

**Figure 20-10.** This photograph shows a patient who is being treated with bracing for a prominent pectus carinatum.

Associated mitral valve disease has been reported as well.<sup>57,58</sup> Other associations include Marfan syndrome and scoliosis (in 15%).<sup>51</sup>

Orthotic bracing has been applied successfully in some patients with pectus carinatum. Reports have described correction or improvement in this condition by means of a brace analogous to that used for treatment of scoliosis but that exerts pressure in the anteroposterior direction (Fig. 20-10).<sup>24,59</sup>

Our group has had limited success with bracing. Poor compliance contributes to failure of bracing in one third of cases. Surgical treatment consists of costochondral resection with sternotomy. Multiple studies emphasize the importance of performing bilateral cartilage resection, even with unilateral deformity of the cartilages, to prevent recurrence.<sup>25,53,60,61</sup> Recently, minimally invasive correction has been described.<sup>62</sup>

Postoperative complications are uncommon, and recurrence is reported to be rare in centers with a large experience.

## POLAND'S SYNDROME

Poland's syndrome affects 1 in 30,000 live births and is sporadic in occurrence.<sup>63</sup> It is a constellation of anomalies that present in a variety of ways. Clinical manifestations can include any or all of the following: absence of the pectoralis major, pectoralis minor, serratus anterior, rectus abdominis, and latissimus dorsi muscles (Fig. 20-11). Athelia or amastia, nipple deformities, limb deformities (syndactyly, brachydactyly), absent axillary hair, and limited subcutaneous fat can also be found.

In 1841, Alfred Poland, an English medical student, published a partial description of the deformity.<sup>64</sup> However, the syndrome was initially described in the French and German literature in 1826 and 1839.<sup>65,66</sup>

Poland's syndrome does not appear to be genetic, although rare occurrences within families have been reported. The right side is more commonly affected

and is present in boys 70% of the time.<sup>63</sup> Approximately 15% of patients with breast hypoplasia/aplasia have Poland's syndrome. The etiology is unclear, but theories include abnormal migration of the embryonic tissues forming the pectoralis muscles, hypoplasia of the subclavian artery, or in-utero injury.

No correlation has been identified between the extent of hand deformities and the chest wall deformities. Varying degrees of either can occur with mild hypoplasia to total aplasia of muscles, ribs, and cartilage. The latter can lead to major chest wall depression and paradoxical respiratory motion.

Surgical repair is rarely required, except in those patients with aplasia of the ribs or a major depression deformity.<sup>67,68</sup> When necessary, chest wall reconstruction with correction of contralateral carinatum-type protrusions can usually be performed at the same time (Fig. 20-12). Autologous rib grafts, or a variety of bio-prosthetic agents, can be used with or without a latissimus dorsi flap. The use of custom-made chest wall prostheses has been associated with significant problems such as migration, erosion of local tissues, and adverse cosmesis. Chest wall reconstruction should take place before breast reconstruction in a girl with hypoplasia or aplasia of the breast.

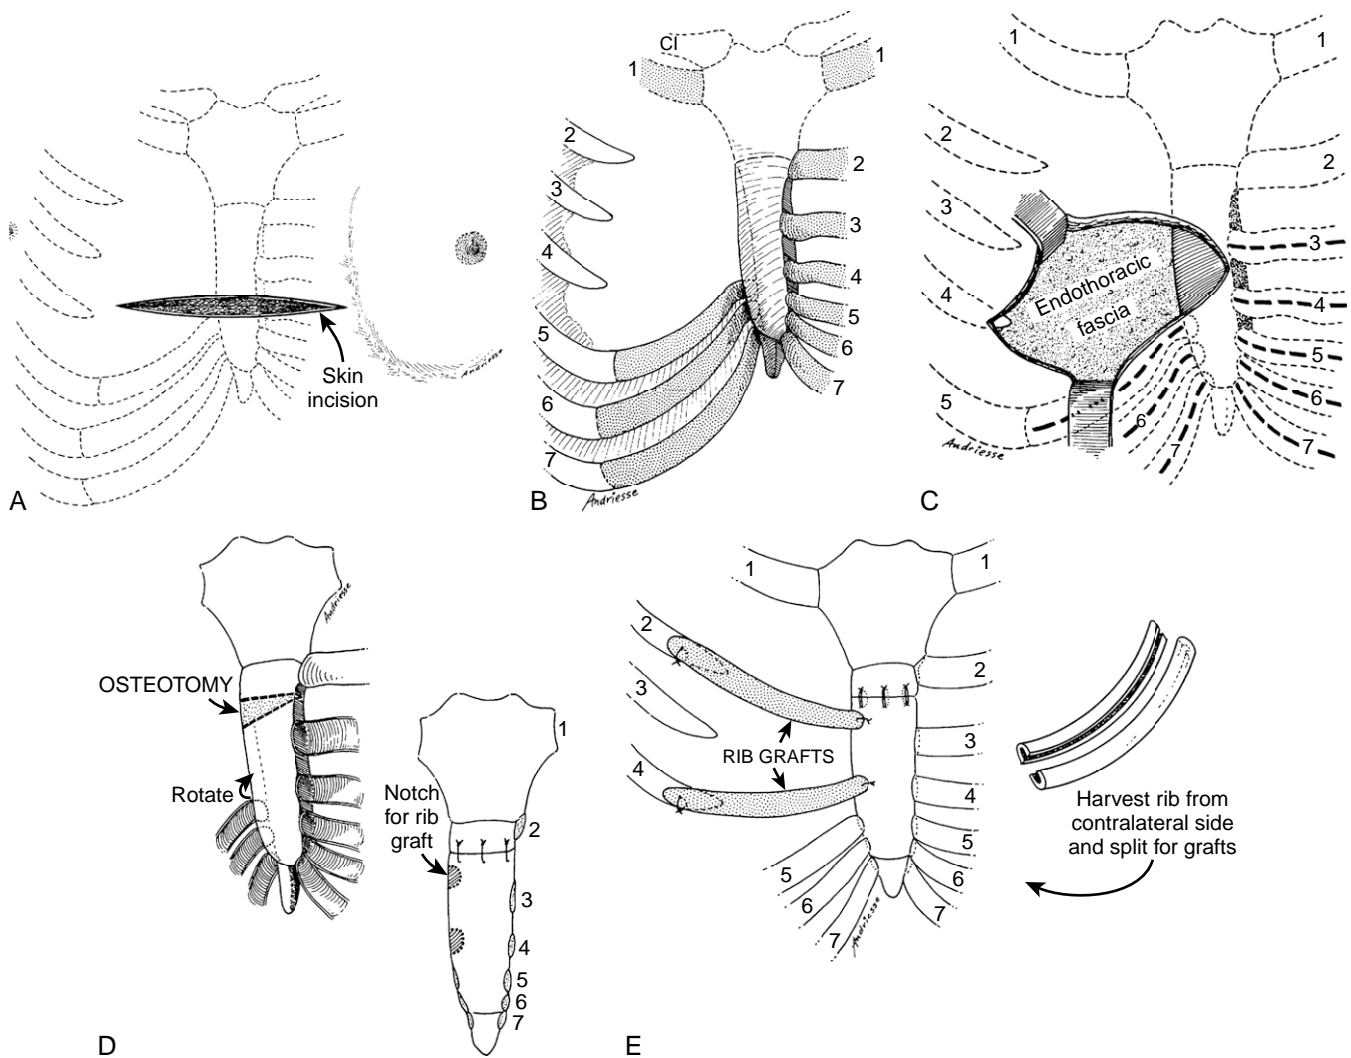

## STERNAL DEFECTS

Sternal defects are midline defects of the upper torso that range from the relatively benign sternal cleft (sternal defect without displacement of the heart) to the very rare and almost uniformly fatal thoracic ectopia cordis (the heart is out of the chest without a skin covering).

Cleft sternum (bifid sternum, partial ectopia cordis) is a rare malformation (0.15% of all chest wall malformations in some series) and is due to partial or total failure of sternal fusion at an early stage of embryonic development. Sternal clefts can be classified as either complete (the rarest form), superior, or inferior.<sup>69</sup>

**Figure 20-11.** A 12-year-old boy with Poland's syndrome and absence of the serratus anterior muscles, leading to a winged scapula on the right.

**Figure 20-12.** A, The transverse incision is placed below and within the nipples. In girls, it is placed in the future inframammary crease. B, A schematic depiction of the deformity with rotation of the sternum, depression of the cartilages of the involved side, and carinate protrusion of the contralateral side. C, In cases with aplasia of the ribs, the endo-thoracic fascia is encountered directly below the attenuated subcutaneous tissue and pectoral fascia. The pectoral muscle flap is elevated on the contralateral side, with the pectoral fascia, if present, on the involved side. Subperichondrial resection of the costal cartilages is carried out as shown (dashed line), preserving the costochondral junction. Rarely this resection must be carried to the level of the second costal cartilage. D, A transverse, offset, wedge-shaped sternal osteotomy is created below the second costal cartilage. Closure of this defect with heavy silk sutures or elevation of the sternum with a strut corrects both the posterior displacement and the rotation of the sternum. E, In cases with rib aplasia, rib grafts are harvested from the contralateral fifth or sixth ribs, split, and secured medially with wire sutures into notches created in the sternum and with wire to the native ribs laterally. Ribs are split as shown, along their short axes, to maintain maximal mechanical strength. (From Shamberger RC, Welch KJ, Upton J III: Surgical treatment of thoracic deformity in Poland's syndrome. *J Pediatr Surg* 24:760-766, 1989.)

Superior clefts are either U shaped (proximal to the fourth cartilage) or V shaped (reaching the xiphoid process). They are most often isolated, with only minor associated lesions. The heart is in a normal position, and cardiac anomalies are rare. Surgical repair, which is very successful, is warranted once the diagnosis is made and can be done electively. Optimally, it is performed in the neonatal age when the sternal bars can be approximated easily because of flexibility and minimal compression of mediastinal structures (Fig. 20-13). After age 1 year, primary repair is difficult and more extensive techniques may be needed, such as the use of autologous structures (costal cartilage, ribs) or prosthetic materials.<sup>70,71</sup>

Thoracic ectopia cordis (true ectopia cordis) is a lesion in which the heart has no overlying somatic structures. It is very rare and usually occurs with some form of an abdominal wall defect, with the heart sitting on the chest and the apex pointed toward the chin (Fig. 20-14). Intrinsic cardiac anomalies are frequent, especially tetralogy of Fallot, pulmonary artery stenosis, transposition of the great arteries, and ventricular septal defects.<sup>72</sup> Survival in patients with thoracic ectopia cordis is rare, with only three survivors being reported. Most patients die because of torsion of the great vessels and compression of the heart while attempting to reduce it back in the chest. The goals of therapy are to cover the heart, preserve cardiac output

**Figure 20-13.** A, Repair of a bifid sternum is best performed through a longitudinal incision extending the length of the defect. These defects are characteristically cleft superiorly, as shown. B, Directly beneath the subcutaneous tissues, the sternal bars are encountered, with the origin of the pectoral muscles on the lateral aspect of the bars. The endothoracic fascia and pericardium are just below these structures. C, The endothoracic fascia is mobilized off the sternal bars posteriorly with blunt dissection to allow safe placement of the sutures. Approximation of the sternal bars may be facilitated by excising a wedge of cartilage inferiorly. Repair is best accomplished in the neonatal period because of the flexibility of the chest wall. D, Closure of the defect is achieved with 2-0 Tevdek or polydioxanone sutures. (From Shamberger RC, Welch KJ: Sternal defects. *Pediatr Surg Int* 5:156-164, 1990.)

**Figure 20-14.** An infant with thoracic ectopia cordis with no significant abdominal wall defect present. Note the characteristic high insertion of the umbilicus and anterior projection of the apex of the heart.

by preventing kinking of the great vessels, repair the associated abdominal wall defect, and stabilize the thoracic cavity so that spontaneous ventilation can be effective.<sup>72-74</sup>

Thoracoabdominal ectopia cordis (Cantrell's pentalogy) involves lesions in which the heart is covered by an omphalocele-like membrane (Fig. 20-15).<sup>74</sup> Intrinsic cardiac anomalies also are common in these patients, with tetralogy of Fallot and ventricular septal defects being the most common. Cantrell's pentalogy consists of an inferior sternal cleft, ectopia cordis, midline abdominal wall defects or omphalocele, pericardial defects, and one or more cardiac defects. Repair in these patients is much more successful than in thoracic ectopia cordis. Initial surgical management addresses the lack of skin overlying the heart and abdominal cavity. After initial stabilization and echocardiogram, the goal of the initial operation is to provide coverage of the midline defects, separate the abdominal and pericardial compartments, and repair the diaphragm. Various techniques to gain closure include flap mobilization, skin closure only, and a variety of bioprosthetic agents. The congenital heart defect is repaired at a later date.

**Figure 20-15.** A newborn with the external features of Cantrell's pentalogy is seen. Flaring of the lower thoracic cavity is present, with a large epigastric omphalocele. The transverse septum of the diaphragm and the inferior portion of the pericardium are absent. The patient also has tetralogy of Fallot.

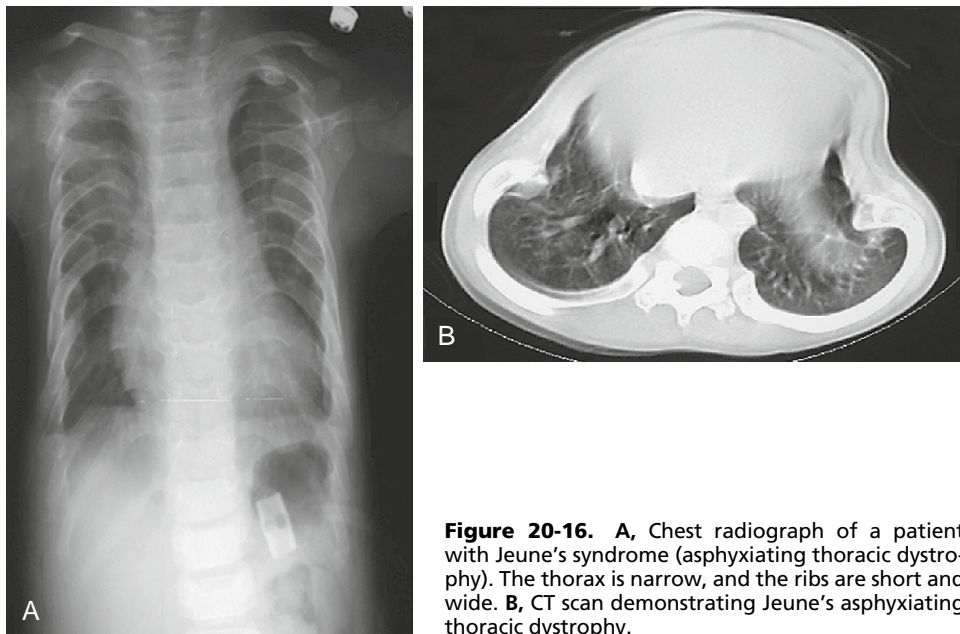

### THORACIC INSUFFICIENCY SYNDROME ASSOCIATED WITH DIFFUSE SKELETAL DISORDERS

Thoracic insufficiency syndrome may be defined as any disorder that produces the inability of the thorax to support normal respiration or lung growth.<sup>75</sup> It includes a spectrum of disorders including asphyxiating thoracic dystrophy (Jeune's syndrome), acquired asphyxiating thoracic dystrophy (after open pectus excavatum repair), spondylothoracic dysplasia (Jarcho-Levin syndrome), congenital scoliosis with multiple vertebral anomalies and fused or absent ribs (jumbled spine), and severe kyphoscoliosis. These

disorders have been viewed and treated as separate entities, with little coordinated effort between specialties. However, they are best addressed with a unified approach integrating pediatric general and orthopedic surgeons as well as pediatric pulmonologists.

Jeune's syndrome is an autosomal recessive inherited osteochondrodystrophy with variable expressions.<sup>76</sup> In mild forms, the chest may support adequate respiration. In more severe cases, the thorax is narrowed both transversely and vertically, with short, wide horizontal ribs and irregular costochondral junctions (Fig. 20-16). This chest wall configuration produces a rigid chest with very little intercostal excursion for normal respiration, leading to ventilatory dependence and death from respiratory failure.<sup>77,78</sup> Pathologic examination of pulmonary structures varies, with some findings of pulmonary hypertension. However, most patients have normal bronchial development with variable alveolar density.<sup>79,80</sup> This suggests that the extrinsic chest wall plays a significant role in the underlying hypoplasia. Other associated skeletal abnormalities in Jeune's syndrome include short stubby extremities, fixed elevated clavicles, hypoplastic iliac wings, and a high incidence of C1 spinal stenosis.<sup>81-83</sup> These patients also have varying degrees of renal dysplasia.<sup>84</sup>

Spondylothoracic dysplasia (Jarcho-Levin) syndrome occurs in two forms with different inheritance patterns. Type I is an autosomal recessive deformity characterized by multiple vertebral hemivertebrae and posterior rib fusions.<sup>85</sup> This produces a marked shortening of the thoracic spine and a crab-like appearance of the chest on a standard radiograph (Fig. 20-17).<sup>86</sup> Associated malformations are noted in 30% of patients and include cardiac and renal anomalies. The type I form is often fatal by age 15 months, and a high incidence is reported in Puerto Rican families.<sup>87</sup> Type II

**Figure 20-16.** A, Chest radiograph of a patient with Jeune's syndrome (asphyxiating thoracic dystrophy). The thorax is narrow, and the ribs are short and wide. B, CT scan demonstrating Jeune's asphyxiating thoracic dystrophy.

**Figure 20-17.** Chest radiograph of a patient with Jarcho-Levin syndrome with a markedly shortened thoracic spine producing a crab-like appearance.

spondylothoracic dysplasia has an autosomal dominant inheritance pattern and is associated with near-normal longevity. It is seen most commonly in white children.<sup>87</sup>

Thoracic insufficiency also may arise secondary to too early or too extensive pectus operations.<sup>19</sup> Complex spine anomalies producing the so-called jumbled spine, unilateral thoracic hypoplasia seen with the VACTERL association, and kyphoscoliosis may be a cause of thoracic insufficiency.<sup>88-92</sup>

Surgical techniques to correct the spectrum of these complex disorders have attempted to address the issue of thoracic volume by various approaches. In both congenital (Jeune's) and acquired (post-pectus) thoracic dystrophy, one approach has been an anterior longitudinal sternal split with widening of the sternum. This has been accomplished with methylmethacrylate, bone grafts or rib, and metal plates.<sup>93-95</sup> A staged approach with a methylmethacrylate plate followed by secondary removal of the plate and latissimus dorsi flaps to cover the created sternal cleft also has been described.<sup>96</sup> Sternal elevation has also been reported in cases of acquired thoracic dystrophy by both the open and the minimally invasive techniques used for standard pectus repair.<sup>19,41</sup> A lateral staged approach with staggered rib osteotomies, staggered division of the chest wall, intercostal muscles, and pleura, with transposition of alternating ribs by using metal plate fixation, also has been described.<sup>97</sup>

These approaches have had variable results because they are not easily revised to allow continued growth of the chest wall to allow lung expansion. The lateral

thoracic expansion may also interfere with intercostal muscle function after division of multiple intercostal muscles and nerves. In regard to patients with Jarcho-Levin syndrome, jumbled spine, and kyphosis, pediatric general surgeons have done little to approach these problems that they considered either lethal or solely in the domain of the orthopedic surgeon.

A promising technique to address patients with the spectrum of causes for thoracic insufficiency syndrome rejoins the disciplines of pediatric general, thoracic, and orthopedic surgery. Expansion thoracoplasty and the use of a vertical expandable prosthetic titanium rib (VEPTR) developed by Campbell and Smith addresses many problems in the spectrum of these disorders. This technique allows serial expansion of the chest wall to allow continued growth of the thorax and spine until skeletal maturity is achieved.<sup>98</sup> More than 300 patients with various disorders have been treated with this approach. In Jeune's asphyxiating thoracic dystrophy, 14 patients have undergone staged bilateral expansions. Anterior rib osteotomies adjacent to the costochondral junction and posterior osteotomies adjacent to the transverse process of the spine in the 3rd to 9th ribs are performed. This creates a mobilized segment of chest wall that is distracted posterolaterally and anchored to a curved VEPTR that is attached to the 2nd and 10th ribs (Fig. 20-18). The segment is anchored to the VEPTR with 2-mm titanium rings, stabilizing the segment and allowing reossification of the multiple osteotomies (Fig. 20-19). The second stage is performed 3 months later, and then the devices are expanded every 6 months.

**Figure 20-18.** Bilateral vertical expandable prosthetic titanium rib (VEPTR) fixed with titanium rings to ribs of the patient with Jeune's asphyxiating thoracic dystrophy seen in Figure 20-16A.

**Figure 20-19.** Postoperative CT scan of the patient from Figure 20-16B after VEPTR placement, demonstrating expansion of the thorax.

In patients with fused or absent ribs and scoliosis, a wedge thoracostomy through the fused segment of ribs not only allows expansion of the chest, but also correction of the scoliosis and the rotational spinal deformity (producing a windswept thorax).<sup>92,99</sup> It also stimulates increased spinal height in both congenital scoliosis and Jarcho-Levin syndrome, in which bilateral devices are placed (Fig. 20-20).

**Figure 20-20.** Bilateral VEPTRs were placed in the patient in Figure 20-17 with Jarcho-Levin syndrome.

# TRACHEAL OBSTRUCTION AND REPAIR

H. Biemann Othersen, Jr., MD • André Hebra, MD

**P**ediatric surgeons are often involved in the management of acute or chronic airway obstruction. Moreover, iatrogenic injury of the pediatric airway occasionally occurs. The large number of operative techniques for the treatment of tracheal stenosis shows that no single procedure or technique is universally applicable and successful. Prevention of, or prompt therapy for, injury is all-important.<sup>1,2</sup>

## PRACTICAL EMBRYOLOGY AND ANATOMY

A working knowledge of the embryonic development of mediastinal structures aids in understanding the etiology and associated anomalies of tracheal obstruction. Malformations of the great vessels (vascular rings) should be suspected and investigated when evaluating a child with complete tracheal rings. The most common vascular malformation associated with complete tracheal rings is a pulmonary vascular sling. This anomaly occurs when the left pulmonary artery arises to the right of the trachea, around which it curves and compresses just above the carina, and then passes between the trachea and esophagus before reaching the left lung (Fig. 21-1).<sup>3</sup> Other vascular ring malformations may produce varying degrees of tracheal, bronchial, and esophageal compression.

## TRACHEAL MALFORMATIONS

### Congenital Subglottic Stenosis

The anatomy of the pediatric airway has been compared to an inverted cone, with the trachea fitting telescopically into the cricoid above it, the cricoid into the thyroid cartilage, and then the thyroid into the hyoid space, as illustrated in Figure 21-2.<sup>4</sup> Congenital subglottic stenosis is the most common morphologic abnormality of the trachea and presents as a narrowing of the airway at the distal end of the larynx, just

at the beginning of the trachea. This subglottic region lies at the junction of the cricoid cartilage and trachea and is the narrowest point of the child's airway. The cricoid cartilage is the only normally complete cartilaginous ring in the airway. Congenital abnormalities of this subglottic area consist of narrowing or malformation of the cricoid cartilage, the etiology of which is not truly known.

When compared with an adult, the anatomy of the trachea and larynx differs in several ways (Fig. 21-3). The child's epiglottis is short and small, and the valleculae are very shallow. Also, the larynx points posteriorly

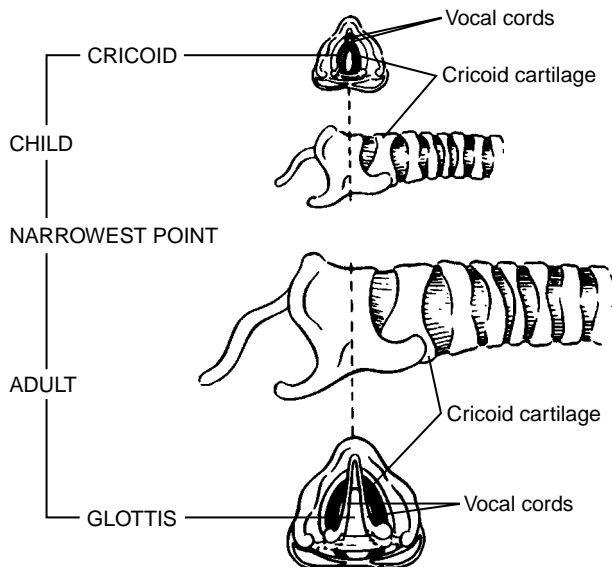

**Figure 21-1.** Complete tracheal rings in distal trachea and pulmonary vascular sling. 1, Left pulmonary artery; 2, trachea; 3, esophagus.

**Figure 21-2.** A, Ventral area of the larynx in the neonate viewed from behind. The ventricle, or “third cavity,” is bounded above by the ventricular folds (Vef) and below by the vocal folds (Vof). Ep, epiglottis. B, Laryngeal cartilages (without arytenoids). Th, thyroid; Cr, cricoid; Tr, trachea; and Hy, hyoid viewed from behind. *Inner dashed lines* show telescopic configuration in the neonate as opposed to the rectangular shape in the adult (*outer dashed lines*). (From Othersen HB Jr [ed]: *The Pediatric Airway*. Philadelphia, WB Saunders, 1991.)

toward the nasopharynx, and the arytenoid apparatus is large in relation to the lumen of the larynx. Finally, the narrowest point of the normal pediatric airway is the cricotracheal junction. In the adult, it is the glottis. Cricoid stenosis is exceeded only by laryngomalacia and vocal cord paralysis in the frequency of congenital airway anomalies.

In the normal trachea, the cartilaginous rings are horseshoe shaped, with the posterior wall composed of connective tissue and muscle. Thus, the lumen may change as the trachea expands or contracts with respiration. Long stenotic segments in the trachea usually consist of tracheal rings that are complete.

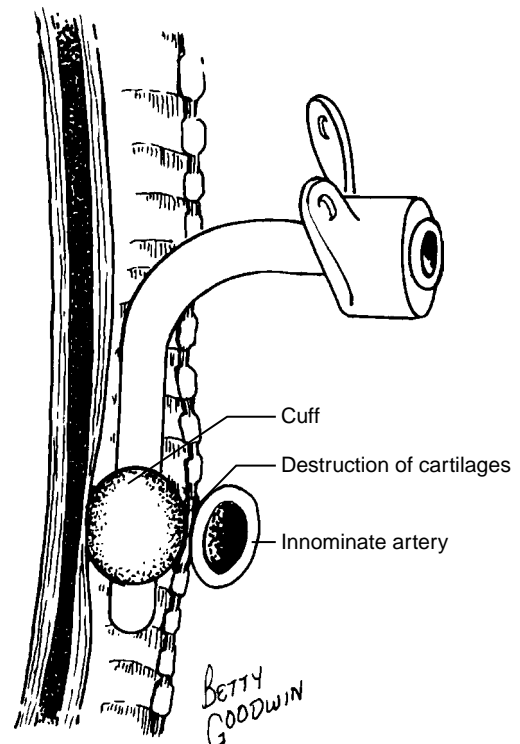

**Figure 21-3.** Difference between adult and pediatric airway. (From Othersen HB Jr: *Intubation injuries of the trachea in children: Management and prevention*. *Ann Surg* 189:601-606, 1979.)

the cartilaginous rings are complete, the lumen is rigid and usually much smaller than the normal trachea. If it does not produce early respiratory distress, complete cartilaginous rings may be detected when an inflammatory process within the trachea produces mucosal edema, which further compromises the rigid lumen and results in acute airway obstruction. Occasionally, tracheal intubation for an elective operative procedure may be impossible and the narrowed segment is discovered.

### Acquired Subglottic and Tracheal Stenosis

Acquired airway malformations usually result from intrinsic injury with subsequent inflammation, ulceration, and scarring, leading to severe subglottic or tracheal scarring and narrowing. Occasionally external trauma is the initiating event,<sup>2</sup> but an iatrogenic event can exacerbate an unstable situation. For example, a child with a congenitally small airway might be asymptomatic until an endotracheal tube is inserted. The tube may be of an appropriate size but, because of the congenital stenosis, it will fit tightly and can lead to ulceration and stricture. Particularly difficult to treat are those injuries that occur well below the subglottic region, usually produced by an endotracheal balloon that has caused compression and ulceration in the trachea. Frequently, these areas of injury are below the usual site for a tracheostomy. The cuff may even erode into overlying vessels (*Fig. 21-4*).

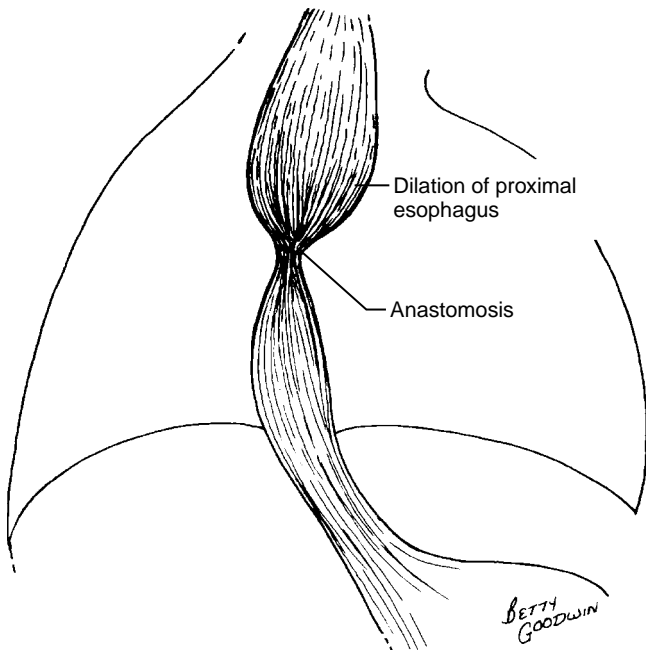

**Figure 21-4.** The inflated cuff of a tracheostomy tube may erode anteriorly into the innominate artery. (From Othersen HB Jr [ed]: *The Pediatric Airway*. Philadelphia, WB Saunders, 1991.)

## VASCULAR COMPRESSIONS

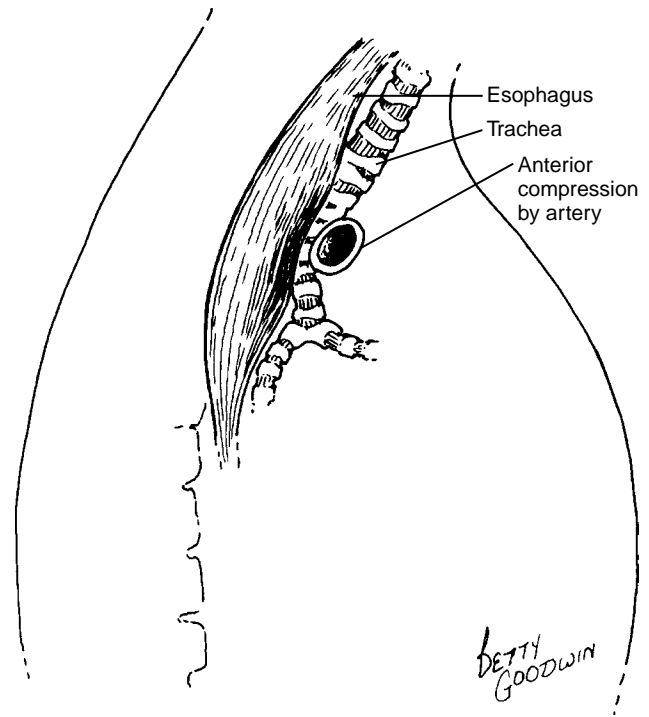

Compression and partial obstruction of the trachea may be caused by abnormalities of the aortic arch that impinge on or encircle the trachea or esophagus or both.<sup>5,6</sup> When both the trachea and esophagus are compressed, swallowing frequently produces acute airway compression and respiratory distress. Vascular rings are often asymptomatic in neonates and infants, yet can lead to significant airway obstruction in a child.<sup>7</sup>

The physiologic impingement on the trachea by a vascular ring is similar to that seen in patients after repair of esophageal atresia. The persistently distended upper esophageal pouch can displace the trachea anteriorly, producing tracheomalacia, or softened tracheal rings (Fig. 21-5). Particularly with swallowing, the distended esophageal pouch may compress the trachea against the innominate artery (Figs. 21-6 and 21-7). This sequence of events is thought responsible for a condition called reflex apnea. Consequently, surgical correction of this problem consists of anterior mobilization and suspension of the innominate artery (Fig. 21-8).<sup>8-12</sup> The treatment of a pulmonary vascular sling usually requires not only relocation and reimplantation of the pulmonary artery but also tracheal repair for the stenotic distal trachea.<sup>7,12,13</sup>

Stridor and dyspnea are symptoms that may be produced by vascular impingement on the trachea. Patients with severe compression from a double aortic arch are usually symptomatic, but their manifestations are variable (Fig. 21-9). Some patients are initially seen with frequent coughing and stridor accompanied by dyspnea and cyanosis, whereas small infants may have

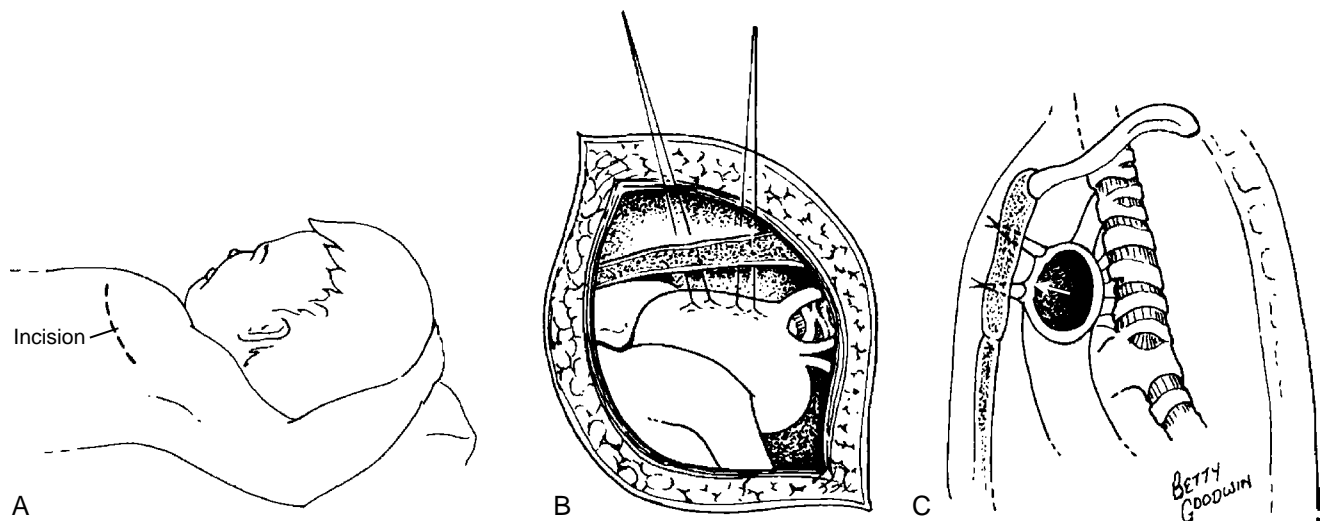

**Figure 21-5.** After repair of esophageal atresia, the proximal esophagus, which is already enlarged, is further dilated by an anastomotic stricture. (From Othersen HB Jr [ed]: *The Pediatric Airway*. Philadelphia, WB Saunders, 1991.)

**Figure 21-6.** A lateral view shows how the dilated proximal esophagus displaces the trachea and compresses it against the overlying innominate artery. (From Othersen HB Jr [ed]: *The Pediatric Airway*. Philadelphia, WB Saunders, 1991.)

**Figure 21-7.** A and B, An enlarged diagram of Figure 21-6 illustrates how the compression is increased by ingestion of food. (From Othersen HB Jr [ed]: *The Pediatric Airway*. Philadelphia, WB Saunders, 1991.)

**Figure 21-8.** The operative technique for aortopexy. **A**, Anterior left thoracotomy in the third interspace. **B**, Sutures placed into the wall of the innominate artery and the aortic arch. **C**, Sutures passed through the sternum and tied to elevate the compressing vessels. Tracheal attachments pull the anterior wall of the trachea forward. (From Othersen HB Jr [ed]: *The Pediatric Airway*. Philadelphia, WB Saunders, 1991.)

reflex apnea. The symptoms of vascular impingement on the trachea are usually more dramatic than those of compression of the esophagus.

The diagnosis of vascular ring anomalies has classically been made or suspected from a barium esophagogram with indentations on the esophageal column of barium and a decrease in the tracheal air column. Offset of the axis of the barium column above and below the indentation is diagnostic of a double aortic arch. Newer imaging techniques with

rapid computed tomographic (CT) scans allow a graphic reconstruction of the trachea and adjacent vessels (Fig. 21-10). Magnetic resonance imaging (MRI) enhanced with intravenous administration of a contrast agent allows excellent visualization of the trachea and vessels.

Occasionally, a child will appear with acute airway obstruction or other medical problems requiring intensive care, during which endotracheal intubation and a concomitant nasogastric tube are inserted. The presence of tubes in both airway and esophagus makes detection of a vascular ring difficult and can generate complications. In a child who is already intubated, performance of contrast radiographic procedures may not be possible. Ultrasonography or CT and contrast-enhanced MRI may delineate the vascular abnormality. When both tracheal and esophageal intubations are necessary in a patient with a double aortic arch, the encircling vessels may sustain pressure necrosis. Erosion into the aortic arch produces an acute aorto-esophageal fistula that may not be manifest until either the endotracheal or the esophageal tube is removed. A sentinel hemorrhage may occur before a massive, and often fatal, hemorrhage into the esophagus. The passage of a Sengstaken-Blakemore tube with inflation of the esophageal balloon can be lifesaving by tamponading the fistula.<sup>14</sup> Because no reliable diagnostic study is available to demonstrate an aorto-esophageal fistula, the observation of a sentinel hemorrhage in such a patient with ultrasound confirmation of a double aortic arch is a clear indication for urgent cardiopulmonary bypass and repair.<sup>14</sup>

Vascular rings cause airway constriction and not vascular problems. Thus, simple division of the vascular ring is often not enough to relieve tracheal compression. Significant numbers of patients are now being treated by the thoracoscopic approach.<sup>15</sup> A vessel that continues to compress the airway must not be dissected away from the trachea but suspended anteriorly,

**Figure 21-9.** Both trachea and esophagus are compressed by a double aortic arch. (From Othersen HB Jr [ed]: *The Pediatric Airway*. Philadelphia, WB Saunders, 1991.)

**Figure 21-10.** This infant presented with stridor. There was a suggestion of tracheal indentation on the chest radiograph. Therefore, a barium esophagogram was performed (A) and shows the double indentations diagnostic of a double aortic arch. On the right (B), a CT scan shows contrast in the double arch that is encircling the trachea and esophagus (collapsed).

often to the back of the sternum, so that the vascular tracheal attachments will lift the anterior tracheal wall and enlarge the lumen (see Fig. 21-8). Regardless of the approach, from the right or from the left,<sup>16</sup> or other technical variations,<sup>17</sup> the recurrent laryngeal and phrenic nerves must be identified and protected. Flexible endoscopic observation of the trachea during these maneuvers can corroborate relief of the compression.<sup>5</sup>

## TRACHEOMALACIA

Often tracheomalacia is produced by the constant pressure of a cardiovascular structure. Thus, it is almost always necessary to suspend the offending vessel and utilize its attachments to the trachea to expand the tracheal lumen. Occasionally, tracheomalacia can be primary in nature and there is no obvious compression. In these cases, suspension of the large mediastinal vessels may enlarge the tracheal lumen.<sup>18-21</sup> Interestingly in the United Kingdom (Scotland), guidelines have been promulgated for the use of thoracoscopic aortopexy to treat severe primary tracheomalacia.<sup>22</sup> The National Health Service believed that these guidelines were necessary because individual surgeons would operate infrequently on infants and children who are good candidates for operative correction.

## INFLAMMATORY OBSTRUCTIONS

Viral laryngotracheitis (croup), bacterial or membranous tracheitis, and epiglottitis are inflammatory conditions that may require surgical intervention. The acute inflammatory airway process may progress rapidly to a life-threatening obstruction and require emergency tracheostomy. However, in all cases of inflammatory obstruction, endotracheal intubation before tracheostomy is advisable, if at all possible. It is important to distinguish croup and bacterial tracheitis from epiglottitis because the treatments are quite different (Table 21-1).

Children with epiglottitis characteristically tolerate endotracheal intubation without airway injury because the inflammation and edema are supraglottic and not circumferential. They do, however, present more risks of intubation failure because of the severe edema of the epiglottis. Some hospitals have strict protocols requiring diagnostic laryngoscopy in the operating room with anesthesia standby for suspected cases of epiglottitis because an emergency tracheostomy is occasionally necessary. Conversely, with viral or bacterial laryngotracheitis, the inflammatory process involves the entire circumference of the airway and prolonged intubation may lead to permanent scarring.<sup>1,23</sup>

**Table 21-1** Characteristics of Laryngotracheobronchitis and Epiglottitis

Characteristic	Laryngotracheobronchitis	Epiglottitis
Incidence	Common	Uncommon
Etiology	Viral	<i>Haemophilus influenzae</i> type b
Age	6 months to 3 years	2-6 years
Clinical picture	Gradual onset, preceding upper respiratory tract infection, barking cough	Rapid onset, fever, drooling, dysphagia
Physical examination	Respiratory distress, inspiratory stridor, low-grade temperature	Anxious, muffled voice, chin forward, drooling, high temperature
Laboratory studies	WBC usually <10,000/mm <sup>3</sup> with lymphocytosis; radiograph shows narrowing of subglottic region	WBC often >10,000/mm <sup>3</sup> with band cells increased; radiograph shows swollen epiglottis

WBC, white blood cell count.

Adapted from McLain LG: Croup syndrome. *Am Fam Physician* 36:213, 1987.

Croup characteristically occurs during viral seasons in children age 3 months to 3 years. Children in whom the classic “croupy” cough develops frequently have a history of an antecedent respiratory infection, usually with a high fever.<sup>24</sup> Bacterial tracheitis, a nonviral infectious disease, is seen with fever and rapid development of upper airway obstruction, characterized by copious mucopurulent secretions. Epiglottitis typically affects children who are age 2 to 6 years and have sore throat and dysphagia. Consequently, speech may be slurred and drooling of saliva is prominent. Lateral radiographs of the neck may show an edematous epiglottitis.<sup>25</sup>

Fortunately, most of these inflammatory processes are now controlled with antibiotics and respiratory care without surgical intervention. Treatment includes oxygen with increased humidification and inhalation of racemic epinephrine. Endotracheal intubation is well tolerated in epiglottitis and usually causes no further injury while antibiotic therapy produces resolution of the epiglottic edema. However, in cases of viral or bacterial tracheitis, even brief (24-48 hours) intubation may cause ulceration in a trachea that is already acutely inflamed and swollen. Therefore, it may be best to use endotracheal intubation to establish a definitive diagnosis. If resolution does not occur within 48 to 72 hours, a temporary tracheostomy may be advisable.

The decreasing incidence of epiglottitis is probably due to the increasing use of immunization against *Haemophilus influenzae* type b, the most common causative organism.<sup>26</sup> Other infectious organisms, however, may produce the typical epiglottic swelling. Intubation is usually not necessary for more than 24 to 48 hours until antibiotics can control the infection. Croup also is now more easily treated without intubation with racemic epinephrine inhalation combined with administration of dexamethasone, 0.6 mg/kg, either orally, intramuscularly, or intravenously.

Regardless of the cause of the inflammatory process, rapid obstruction of the airway can occur in a small child. The surgeon must be prepared to work with the anesthesiologist and pediatrician to establish an airway by endotracheal intubation, bronchoscopy, or tracheostomy.

## INJURIES

### Intrinsic Injuries

Most intrinsic laryngotracheal injuries are iatrogenic and produced by inappropriate introduction of an endotracheal tube or instrumentation of the airway. Benign laryngeal tumors, such as a subglottic hemangioma and lymphangioma, require repeated endoscopic treatments that can be injurious to the larynx. Thus, in such patients, it may be wise to consider a preliminary tracheostomy. Therapy consists of removal of the obstruction with CO<sub>2</sub> or KTP lasers. Laser therapy for these lymphovascular malformations can be painstaking and tedious, requiring multiple treatments.

Other techniques such as sclerotherapy have been applied to these same intrinsic airway lesions. Intraleisional corticosteroid injection has been reported to promote rapid involution of a subglottic hemangioma.<sup>27</sup> OK-432 has shown promise when injected into lymphovascular lesions around the head and neck.<sup>28,29</sup> OK-432, derived from group A *Streptococcus pyogenes*, stimulates a local inflammatory reaction that leads to involution of the lymphovascular mass. This compound has been used extensively in Japan and Europe.<sup>30</sup> One such series of children with lymphangioma described a case of partial airway obstruction resulting from OK-432 injection and cautioned against use of this agent around the airway.<sup>31</sup> Controlling the depth of injection of this agent and others is difficult and may result in damage to the airway in an area where treatment is difficult.

Another intrinsic injury is a thermal burn of the trachea. The inhalation of hot gases, steam, and toxic smoke produces acute injury that can lead to inflammation and edema in addition to actual burn necrosis. These individuals require special considerations in their management.<sup>32,33</sup> Whenever an endotracheal tube is passed through an inflamed glottis and upper trachea, early tracheostomy should be considered. With more extensive involvement, prolonged stenting with a T-shaped tracheostomy or T-tube with open proximal and distal limbs may be required.<sup>33</sup> Also, the overaggressive use of lasers or cautery may produce direct tissue thermal injury or may lead to an airway fire.

### Extrinsic Injuries

Extrinsic injury to the larynx and trachea may occur when an unrestrained child in an automobile strikes his or her neck on the dashboard or the back of the front seat (Fig. 21-11). A blow directly to the neck from

**Figure 21-11.** Mechanism of head injury. With a padded dashboard, external evidence of injury is minimal. (From Othersen HB Jr: Cardiothoracic injuries. In Touloukian RJ [ed]: *Pediatric Trauma*. New York, John Wiley & Sons, 1978.)

**Figure 21-12.** This neck injury may produce fracture or transection of the airway with little evidence of skin injury. (From Othersen HB Jr: Cardiothoracic injuries. In Touloukian RJ [ed]: Pediatric Trauma. New York, John Wiley & Sons, 1978.)

a wire when falling or when riding a bicycle (“clothesline injury”) (Fig. 21-12) may damage the larynx or trachea. Transection of both the trachea and esophagus can occur without visible external neck injuries beyond slight erythema. Crepitus may be present. A good history is essential in determining the mechanism of injury.<sup>34</sup> In these instances, and particularly in conjunction with severe craniofacial injuries, a tracheostomy performed under general anesthesia but without endotracheal intubation is usually advisable, because attempts at intubation may further compromise the tenuous airway. Penetrating injuries in children are infrequent, but the same general principles used for management in adults should be followed.<sup>35</sup>

## ENDOTRACHEAL INTUBATION

Endotracheal intubation may be difficult in small children. The best laryngoscopic blade for children is a straight blade, such as the Miller or the Wis-Hipple. The latter is a straight blade with a design that allows passage of a bronchoscope or endotracheal tube through the blade. The child’s head should be in the neutral position and not extended. Because the larynx is anterior in small infants, extension of the head draws the airway even farther anteriorly and makes visualization of the larynx difficult. With the infant’s head in the neutral, or “sniffing,” position and not extended, the laryngoscope blade is introduced and the tongue and floor of the mouth lifted to expose the epiglottis. Once the epiglottis is seen, extension or flexion of the head and neck may be required to improve visualization. Although many elect to stiffen the endotracheal tube with a curved stylet for all intubations, the use of a stylet may make introduction of the tube somewhat more difficult in a child because the stylet is usually curved slightly at the tip. When the tube is inserted through the glottis, the tip may impinge on the narrow anterior subglottic region. A tube without a stylet tends to follow the lumen more easily.

**Figure 21-13.** An endotracheal tube should fit through the external nares without deforming it. (From Othersen HB Jr [ed]: The Pediatric Airway. Philadelphia, WB Saunders, 1991.)

Usually an endotracheal tube that approximates the size of the child’s external nares will be appropriate (Fig. 21-13). For pediatric patients, a commonly applied formula to determine the correct endotracheal tube size is  $(\text{age} + 16)/4$  or  $\text{age}/4 + 4$ . If a child must be rapidly intubated with a tube that fits snugly and allows no air leak, this fact should be noted and documented. At the earliest possible opportunity, the snugly fitting tube should be changed to a smaller size. If intubation is required for a long period (usually > 2-3 weeks), tracheostomy should be considered. An air leak is generally an indication that the tube is not too snug.

Usually a cuffed endotracheal tube is not necessary in children because compensation for air leaks can be accomplished by increasing the volume of air delivered by a ventilator. However, with massive craniofacial injuries and bleeding or with severe gastroesophageal reflux, a cuff may be necessary to prevent aspiration of blood or gastric contents. Otherwise, it is best not to use a cuff for fear of damage to the trachea below the cricoid region. The mechanism for production of a tracheal injury by endotracheal tubes has been known for some time,<sup>36</sup> and steps for prevention have been suggested.<sup>1,37</sup> Although many surgeons elect to intubate the patient initially via the mouth, it is easier to overestimate the endotracheal tube size and produce a subglottic injury when compared with a nasally passed tube. Additionally, the conscious or unconscious movement of the tongue will produce a shearing injury to the glottis and subglottis with prolonged orotracheal intubation. The considerations for determining whether endotracheal intubation should be continued or tracheostomy performed are summarized in Table 21-2.

## TRACHEOSTOMY

Our experience has been that tracheostomy with a linear tracheal incision through the second, third, and, possibly, fourth rings without excising any of the anterior wall of the trachea is the preferred technique in children (Fig. 21-14). Cruciate incisions should not be used because the flaps created may be inverted and narrow the lumen. However, some surgeons continue to espouse a technique called Starplasty.<sup>38,39</sup> Cruciate incisions in the skin and the anterior tracheal wall are sutured together to produce a permanent ostomy. This

Table 21-2 Indications for Endotracheal Intubation and Tracheostomy		
Clinical Situation	Endotracheal Intubation	Tracheostomy
Emergencies	Always, except →	Severe craniofacial or head and neck injuries
Neonates and infants <6 months	Oral intubation unless no hope of extubation →	When long-term intubation is required or when there is difficulty in maintaining intubation because of activity
Infants >6 months and children	Maintain for 7-14 days and then →	When long-term intubation or ventilatory support is required for conditions such as severe head injuries
Epiglottitis	Until infection has cleared	Usually not necessary
Croup or other severe glottic inflammatory diseases	If does not respond to inhalations of racemic epinephrine or with airway obstruction as a temporary measure before →	When glottic edema and inflammation are severe

technique should be reserved for permanent tracheostomy because operative closure is necessary when a tracheostomy tube is no longer needed.

Tracheostomy is best performed with an endotracheal tube in place so that the airway is controlled. A transverse incision made in the lower neck is deepened to allow lateral retraction of the strap muscles after the midline is opened. This dissection is then carried down to the trachea. In small children, palpation of the ridges of the tracheal cartilages is frequently more valuable than visualization for determining the appropriate level of tracheostomy. The incision in the trachea is made below the thyroid isthmus, no higher than the second ring. The tracheostomy tube specifications are illustrated in Table 21-3. Traction sutures of polypropylene, left long and labeled "Left" and "Right," allow easier reintubation in the event of accidental dislodgement within the first week. If the tracheostomy has been in place for longer than 2 weeks, bronchoscopy can be helpful during decannulation.

A large granuloma frequently develops at the superior rim of the tracheostomy stoma and may need endoscopic excision.

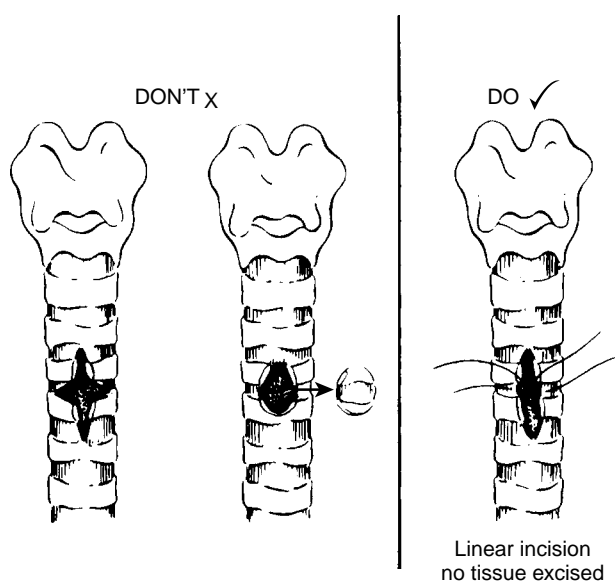

## TRACHEAL REPAIR

### Congenital Stenosis

Most congenital obstructions have a cartilaginous base but also have a fibrous tissue component. As mentioned earlier, many congenital stenotic lesions in the airway are asymptomatic until an acute event such as an injury, acute tracheal inflammation, or endotracheal intubation. At that point, the constriction of the airway becomes symptomatic. Complete tracheal rings may first be suspected when the child requires an anesthetic and an endotracheal tube meets a tracheal obstruction.<sup>40</sup>

For treatment of long-segment obstruction from complete tracheal rings, we have devised a procedure in which either the KTP or CO<sub>2</sub> laser is used to divide each complete cartilaginous ring in the posterior midline.<sup>41</sup> With an endoscopic balloon, the trachea is gradually dilated as the rigid bronchoscope is advanced. When all complete rings have been divided, a tube is inserted to serve as a stent. If long-term stenting is required, a T-tube is used (see later). If this procedure is done carefully without forceful dilation, no air leak should occur because the esophagus posteriorly fills the gap in the posterior tracheal wall. With a short segment of complete rings, resection and anastomosis has been accepted as effective therapy, but few surgeons have a large experience with this technique.<sup>42</sup> Other groups have used resection for long and short lesions but are now considering slide tracheoplasty.<sup>43</sup>

An improvement on standard resection procedures, slide tracheoplasty allows reconstruction without tension.<sup>44</sup> The narrowed segment is transected in its midportion, and the remaining stenotic segments are incised. One end of the trachea is opened in the posterior midline, and the other is incised in the anterior midline. Long-term evaluation has been satisfactory.<sup>45</sup> The diameter of the resulting anastomosis is broad enough to avoid airway narrowing.

**Figure 21-14.** Two techniques of tracheostomy to be avoided in children and the preferred linear incision. (From Othersen HB Jr: Intubation injuries of the trachea in children: Management and prevention. *Ann Surg* 189:601-606, 1979.)

	6	7.0	10.0	46

ID, inside diameter; OD, outside diameter.

Some surgeons have compared laryngotracheal reconstruction with cricotracheal resection and attempted to categorize the indications for each procedure.<sup>46</sup> The surgical therapy for these patients continues to evolve, as evidenced by a recent review of 50 patients treated for congenital tracheal stenosis at a single institution over an 18-year span (1982 - 2000).<sup>47</sup> Although the operation originally preferred was pericardial tracheoplasty,<sup>48</sup> four procedures were compared: pericardial-patch tracheoplasty (28 patients), tracheal autograft (12 patients), tracheal resection (8 patients), and slide tracheoplasty (2 patients). These authors concluded that their operation of choice for short segments would be resection. Resection with tracheal autograft was preferred for long-segment stenoses (more than eight rings).<sup>49</sup> In this latter procedure, the stenotic trachea is incised anteriorly and the midportion is excised. A primary anastomosis is made posteriorly, and the anterior defect is closed with a free autograft fashioned from the excised trachea. Others have used human cadaver tracheal allografts for reconstruction.<sup>50,51</sup> The ideal surgical treatment for congenital tracheal stenosis has not yet been devised.

Anterior cricoid split is a procedure that is useful in treating moderate subglottic stenosis in neonates and young infants.<sup>52,53</sup> Infants selected for the anterior cricoid split procedure should weigh more than 1500 g and require assisted ventilation or inspired oxygen of more than 35%. They should also not be in cardiac failure. This technique is illustrated in [Figure 21-15](#).<sup>54</sup> Proper selection of patients for anterior cricoid split is crucial. After anterior cricoid split, those infants who can be successfully extubated have excellent

long-term outcomes, whereas those who continue to need intubation will require tracheostomy.

## Acquired Stenosis

When an endotracheal tube is removed, tracheal injury may be manifested by stridor or dyspnea. Prompt therapy may allow the trachea to heal without cicatricial stenosis. We treat the patients by introducing an endotracheal tube of a size that allows a slight air leak to serve as a temporary stent. A polyvinyl (Portex, Smiths Medical, St. Paul, MN) tube is pliable, softens at body temperature, and is preferred. This soft tube can be left in place while the patient is treated with high doses of systemic corticosteroids (0.8 to 1 mg dexamethasone/kg/day) in an attempt to soften the dense scar. Before insertion of the stent, the trachea may require gentle dilation by using balloon dilators. Rigid dilators may produce more injury, because even though they dilate they also impart a shearing force to the tracheal mucosa. Balloons dilate with only radial forces. Dexamethasone is continued in the dose of 0.8 to 1 mg/kg/day divided into four doses (0.2 to 0.25 mg/kg/dose) for at least 72 hours. Longer treatment may be necessary for more severe injuries. The corticosteroids are then rapidly tapered, and the endotracheal tube is removed once the patient is stable and spontaneously breathing without ventilatory assistance.

If a dense stenosis has already occurred, the previously described technique will not be effective. Acquired tracheal obstruction can be classified as granulomatous, inflammatory, fibrous, or calcific. Congenital obstructions are usually cartilaginous. With dense fibrous and calcific strictures, open resection and reconstruction is usually necessary. However, endoscopic laser incision with gradual and gentle balloon expansion of the lumen combined with insertion of an endotracheal stent may allow a functional airway to remodel over a period of time. Some authors advocate treatment of tracheal granulation tissue with mitomycin C.<sup>55</sup> Topical application of mitomycin C during endoscopic surgery helps reduce recurrence of granulation tissue. If stenosis recurs when the stent is removed, the stent can be reinserted and a balloon tracheoplasty performed with the stent in situ.

T-tubes have been used effectively as stents in the past for both children and adults.<sup>33</sup> Newer expandable metal stents are frequently used in adults. Some of these nickel-titanium (nitinol)-coated stents have been used in children in selected cases.<sup>56</sup> However, these stents may not be appropriate for children because the child will grow and the metal stent does not. Removal of the stent is then necessary and may be hazardous. Moreover, the ingrowth of granulation tissue through the interstices of the metal stent may produce obstruction in itself and lead to severe hemorrhage when removal is attempted. Finally, the medical conditions for which the stents are placed in children are different from those in adults. Stent use in adults is often due to neoplastic conditions that are associated with a short life expectancy. However, in children, a stent may be required for years.

**Figure 21-15.** The anterior cricoid split procedure. **A**, Make a horizontal incision over the cricoid cartilage. **B**, Use a combination of sharp and blunt dissection to expose the larynx and upper trachea. **C**, Split the lower portion of the thyroid cartilage, the cricoid cartilage, and upper tracheal rings. **D**, Close the wound loosely over a drain with the airway stented by a nasotracheal tube. (From Othersen HB Jr [ed]: *The Pediatric Airway*. Philadelphia, WB Saunders, 1991.)

Straight tracheal stents of silicone rubber have been successfully used in adults, but fixation by projections from the circumference of the tube is necessary to prevent migration when it is not used as a T-tube.<sup>57,58</sup> The small diameter of a child's trachea makes these stents impractical. A T-shaped tube inserted through a tracheotomy with proximal and distal tracheal extensions can be readily inserted into a child's airway and will not migrate.

We prefer a modification of the Montgomery T-tubes for tracheal stents in children. These tubes are made of silicone rubber and are pliable yet rigid enough to serve as a stent. The tubes can be constructed to the exact dimensions necessary to fit the individual child's trachea. The proximal limb can be placed below the vocal cords, and the distal limb can be made as long as necessary for bridging the obstruction. Also, the cervical tube can be used for suctioning or for insufflation in an emergency. If these measures do not improve the airway obstruction, the T-tube can be removed by the parents and replaced with an endotracheal tube inserted through the cervical stoma. Finally, the modified T-tube allows normal laryngeal breathing

and phonation when the side arm is plugged. Our technique for insertion of a T-tube is shown in Figure 21-16.

### Open Laryngotracheoplasty

Many variations exist in the operative techniques of procedures available for tracheal reconstruction for a scarred and stenotic trachea.<sup>59,60</sup> First, an open procedure can be done with or without cardiopulmonary bypass.<sup>61</sup> Recently, there has been a tendency to avoid bypass and use only endotracheal anesthesia. Second, the repair can be performed with or without an augmentation graft. The grafts may include tracheal autografts, costal cartilage, cartilage from other sites such as thyroid or alar cartilage, autologous or allogeneic pericardium, skin, and tracheal allografts. Third, a stent may be used to maintain the lumen and can remain in place for hours, days, months, or years.

When open laryngotracheoplasty is performed without a cartilage graft, it is essentially a cricoid split or the expansion of the lumen with the use of a castellated

**Figure 21-16.** A to I, T-tube stent insertion with the aid of a dilating balloon to stiffen the T-tube during insertion.

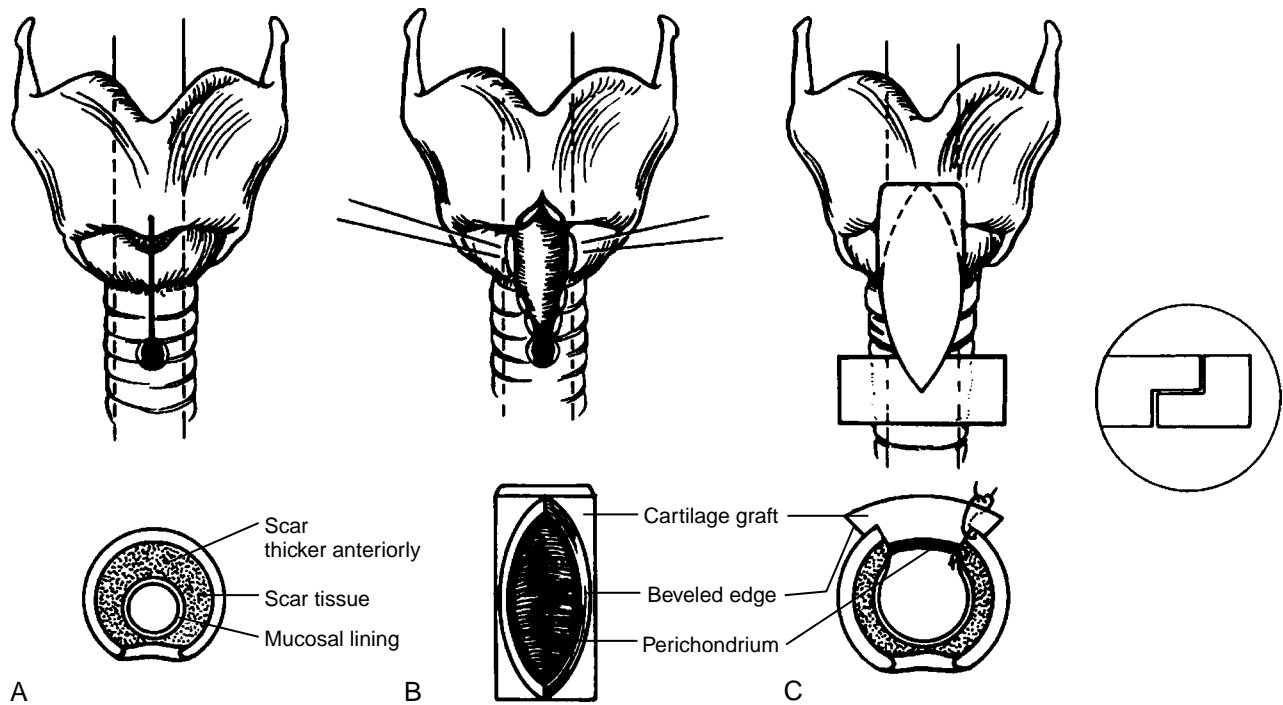

incision.<sup>62</sup> These procedures are often performed with an internal stent.

The classic cartilage laryngotracheoplasty utilizes a cartilage graft (Fig. 21-17).<sup>63,64</sup> An omental flap may help a long cartilaginous graft survive.<sup>65</sup> The cartilage is inserted anteriorly after incising the stenotic segment.<sup>46,66</sup> Cartilage inserts also can be placed posteriorly and laterally in sites where the stenotic cricoid is incised. Ciliated mucosa has been found on the surface of a mature costal cartilage graft if the perichondrium faces the airway lumen.<sup>67</sup> Another option is resection and primary anastomosis. The stenotic portion of the trachea is excised, and an end-to-end anastomosis is performed.<sup>68</sup>

A slide tracheoplasty uses autologous trachea by dividing the trachea in the midportion of the stenotic

segment. The upper and lower portions of the stenosis are incised in the midline, one anteriorly and the other posteriorly, and the anastomosis is then performed.<sup>69,70</sup>

Another option for repair of tracheal stenosis is by anterior incision and closure of the defect with pericardium. All pericardial patch operations are done on cardiopulmonary bypass.<sup>47</sup> However, experience at some centers has not been as good because of complications secondary to patch collapse.<sup>71</sup> The original proponents of pericardial patching have now reported improved results with a free tracheal autograft in which the excised stenotic segment is flattened and used as a free anterior autograft to expand the lumen at the anastomosis.<sup>49</sup>

**Figure 21-17.** An autogenous costal cartilage graft reconstruction. **A**, Expose the larynx and upper trachea. **B**, Incise the aforementioned region, remaining superior to the tracheostomy stoma if the stenosis does not involve this site. **C**, Sew the costal cartilage to the incised edges of the larynx and trachea, placing the perichondrium internally. (From Othersen HB Jr [ed]: *The Pediatric Airway*. Philadelphia, WB Saunders, 1991.)

**Figure 21-18.** Diagram of a custom bifurcated T-tube with extension into the left main-stem bronchus and a hole for the right main-stem bronchus. A guide wire is placed with visualization by a flexible scope and a balloon catheter passed over it. With the balloon inflated, introduction of the stent is facilitated.

Silicone T-tubes are often used as internal stents to maintain the tracheal lumen and allow tracheal remodeling.<sup>72</sup> These tubes can be placed temporarily to allow for growth of the airway or to maintain the lumen while the airway heals after tracheoplasty. Alternatively, T-tubes can be effective as a permanent stent for the difficult pediatric airway or in cases of failed tracheoplasty. In very complicated and difficult cases, we have utilized custom-made T-tubes. One such custom T-tube is shown in Figure 21-18. This tube was necessary for treatment of tracheomalacia at the carina. A bifurcated Y-tube is difficult to insert. Thus, a bronchial arm extended into one bronchus and a hole allowed aeration of the other bronchus.<sup>73</sup>

## CONCLUSION

One group has attempted to set up a foundation to develop a “disease-based and operation-specific model” to predict the outcome of airway reconstruction.<sup>74</sup> The operations for pediatric laryngotracheal reconstruction are challenging, and multiple procedures may be required. Therefore, prevention of tracheal stenosis or injury is extremely important.

Minimally invasive approaches by thoracoscopy will improve the techniques available for operative repair. However, the principles of surgical correction must be the same for the thoroscopic or for the open approach.<sup>15</sup>

To summarize, the following principles are essential in treating the pediatric airway:

1. Be gentle. Endotracheal tube insertion should be atraumatic and of a size that allows an air leak.
2. If injury occurs and dilation is necessary, use balloon, not rigid, dilators.
3. Stents may aid in the healing process by maintaining the lumen.
4. Immediate high-dose and short-term corticosteroid therapy may be helpful in acute injuries, and their use may prevent dense cicatrix.
5. In all children with an endotracheal tube in place, document the size of the tube, presence or absence of an air leak, cuff inflation, and considerations regarding possible tracheostomy.

# CONGENITAL BRONCHOPULMONARY MALFORMATIONS

Karl G. Sylvester, MD • Saif Ghole, MD • Craig T. Albanese, MD

A variety of developmental abnormalities of the tracheobronchial tree and pulmonary parenchyma are found in the newborn. Some of these have a genetic basis and produce widespread physiologic abnormalities. Many of these, such as surfactant protein deficiency, alveolar capillary dysplasia, and generalized pulmonary hypoplasia, are newly described and are not in the traditional scope of care of the pediatric surgeon. Thus, they are not addressed in this chapter. In this chapter, the more focal anatomic abnormalities of the foregut and its anlagen, traditionally termed *bronchopulmonary malformations* (BPMs), are covered. Although these lesions have been recognized for years and grouped as related for discussion purposes, no uniform pathologic or embryologic reason exists for this clustering. Rather, this grouping remains appropriate to facilitate an understanding of the common clinical presentation and management of BPMs.

With the advent of near-routine prenatal ultrasonography, a great deal has been learned about the natural history and pathophysiology of BPMs. Currently, ultrasound findings are altering many of the conventional beliefs and understanding of these lesions. Moreover, prenatal identification and a more accurate depiction of their natural history have given rise to advanced fetal interventions. The lessons learned from prenatal ultrasonography have also affected the postnatal management of cystic lung lesions, because previously unrecognized and likely clinically silent malformations are being detected with ever greater frequency. Still, despite these advances, BPMs defy a common embryologic classification and, as a whole, their pathophysiology remains varied.

## EMBRYOLOGY AND CLASSIFICATION

The traditional understanding is that the tracheobronchial tree and proximal gastrointestinal tract arise from a common foregut anlagen.<sup>1-3</sup> At the end of the third week of gestation, the laryngotracheal groove or diverticulum can be seen in the caudal end of the

embryonic foregut. This groove arises as a ventral enlargement of the foregut and then grows caudad to form the primordium of the trachea and lung bud. This outgrowth of endoderm is ventral and in parallel with the more dorsal portion of the foregut or future esophagus. Next, the lateral walls of the foregut, now called longitudinal ridges, begin to approximate in the midline, forming the tracheoesophageal septum. The separation of the dorsal esophagus and the more ventral tracheobronchial tree is thought to be caused by this tracheoesophageal septum and is complete by the sixth week of gestation. If this process fails or is incomplete, congenital defects affecting the trachea, conducting airways, or esophagus may result.

Some now question this traditional embryologic description.<sup>4</sup> Several lines of evidence tend to refute these long-held beliefs. With the use of scanning electronic microscopy at various stages of development, findings in chick embryos have described a paired caudal “lung bud” diverticulum with no identifiable tracheal primordium.<sup>4</sup> Even more elusive is the developmental program of the lung primordia after separation from the foregut anlagen, which occurs between 6 and 16 weeks’ gestation. Current advances in molecular biologic techniques, including conditional mutants and transgenic mice, have allowed a more in-depth investigation and understanding of the molecular regulators of airway and pulmonary parenchymal development. In more generalized terms, the epithelium of the trachea, bronchi, and alveoli originate from endoderm, whereas muscle and cartilage originate from mesoderm.<sup>2</sup> Subsequent epithelial mesenchymal interactions result in the changes of branching morphogenesis and yield site-specific specialized epithelia for air conduction and gas exchange.<sup>5,6</sup> Studies in mice have established non-overlapping cell lineages of conducting airways (trachea and bronchi) as being distinct from those of peripheral airways (bronchioles, acini, and alveoli), well before formation of the definitive lung buds.<sup>7,8</sup> Similarly, studies in knockout mice and conditional mutants have revealed the involvement of many of the secreted protein morphogens involved in

Table 22-1 Bronchopulmonary Malformations: Classification by Site of Origin		
Trachea and Bronchi	Pulmonary Parenchyma	Vascular
Agenesis	Congenital pulmonary airway malformations	Hemangioma
Atresia, stenosis	Bronchopulmonary sequestration	Arteriovenous malformation
Tracheal bronchus	Congenital lobar emphysema	Scimitar syndrome
Esophageal bronchus/lung (communicating bronchopulmonary malformation)	Agenesis	Congenital pulmonary lymphangiectasia
Bronchogenic cyst	Aplasia	Lymphangioma
Enteric duplication cyst	Hypoplasia	Congenital chylothorax
Neuroenteric cyst	Bronchiolar cysts (cystic bronchiectasis— multiple)	
Bronchial cysts (peripheral)	Lobulation anomalies	

organogenesis throughout mammalian development, such as members of the BMP, FGF, Hhh, and Wnt families.<sup>8-11</sup>

Knowledge of this embryology serves to elucidate the reasons for the frequent consideration of the close relation between anomalies of the proximal gastrointestinal tract and pulmonary system. Congenital BPMs comprise a broad spectrum of clinical lesions from both systems, including esophageal duplications, cystic lung lesions, and anomalies of solid pulmonary parenchyma with abnormal vascular supply. Classification of congenital BPMs therefore is not easy from either a morphologic or an embryologic standpoint. A simplified listing of BPMs by anatomic location becomes the most useful classification system for the clinician charged with managing the myriad presentations and diagnoses (Table 22-1).

## PRENATAL DIAGNOSIS AND THERAPY

The widespread use of prenatal ultrasonography has expanded our understanding of the natural history and pathophysiology of some of the more common BPMs.<sup>12</sup> With ever-increasing sophistication in prenatal imaging, a wide range of lesions including bronchogenic and enteric cysts, mediastinal cystic teratomas, congenital lobar emphysema, bronchial atresia, and the cystic lung masses of congenital pulmonary airway malformations (CPAMs) and bronchopulmonary sequestrations (BPSs) are now identified with regularity.<sup>13</sup> Confusion still can occur, particularly in the fetus with a basilar cystic lung lesion in which the diagnosis of congenital diaphragmatic hernia (CDH) also is possible. More recently, ultrafast magnetic resonance imaging (MRI) of many of these same lesions has allowed an even more detailed distinction based on an assessment of their anatomic variability.<sup>14</sup> Overall, prenatal imaging of BPMs also has demonstrated the rarity of

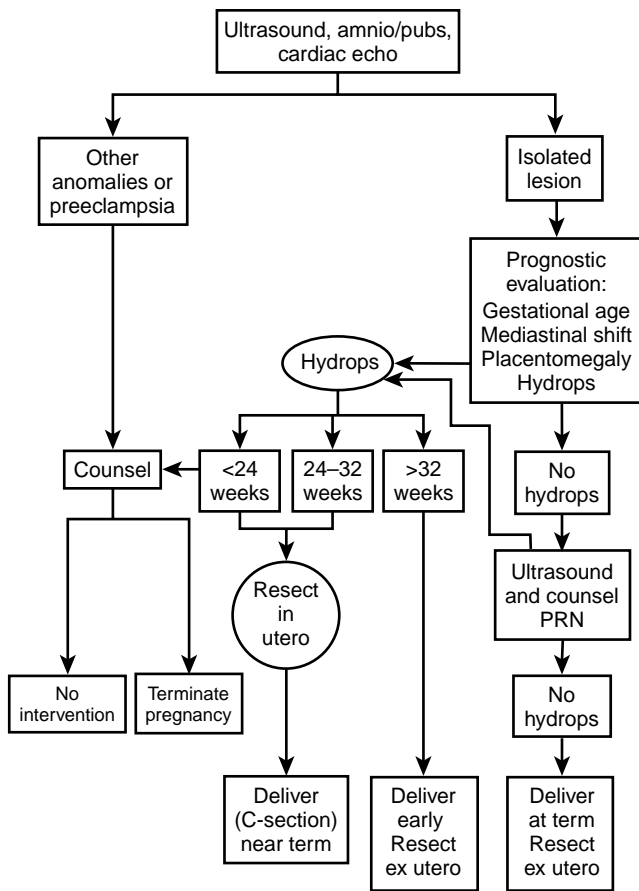

other associated anomalies, a fact of importance when therapeutic options are considered.<sup>15</sup>

The most commonly identified prenatal pulmonary anomaly remains the cystic lung lesion (Fig. 22-1).<sup>12,16</sup> An irregularity in the ultrasound echogenicity of lung parenchyma has become the initial diagnostic hallmark of the congenital cystic lung masses.<sup>17</sup> CPAMs, which are manifest histologically by an adenomatoid increase in terminal respiratory bronchioles, can be classified according to their prenatal ultrasound findings.<sup>13,17,18</sup> Microcystic lesions appear as a solid echodense mass.<sup>17</sup> Macrocytic lesions, which are composed of either a single dominant cyst or several daughter cysts measuring more than 5 mm in diameter, appear more echolucent and less dense.<sup>15</sup> In contrast to a CPAM, a BPS is defined by its morphologic characteristics of nonfunctioning lung parenchyma without communication to the tracheobronchial tree and with an anomalous systemic blood supply.<sup>18</sup> These characteristics are the clinically relevant diagnostic findings both grossly and by prenatal ultrasonography. A BPS appears, like some CPAMs, as an echodense homogeneous mass.<sup>13,17</sup> The finding on color Doppler imaging of a systemically derived feeding arterial vessel, as opposed to bronchial circulation, is pathognomonic of BPS.<sup>12,17</sup> Microcystic CPAMs and BPSs can have an otherwise identical sonographic appearance if the anomalous blood supply is not identified. Ultrafast fetal MRI can aid in the distinction between these two lesions.<sup>13,14,19</sup> However, in the majority of cases without definitive in-utero pathologic manifestations, the distinction is perhaps irrelevant.

Cystic fetal lung lesions may manifest several alternative outcomes. The overall prognosis of cystic lung masses relates to size, although with great

**Figure 22-1.** This fetal ultrasound image shows a large unilocular cystic lesion above the fetal liver in the chest. C, cystic lesion; I, inferior vena cava.

**Figure 22-2.** Proposed algorithm for the management of a fetus found by prenatal ultrasonography to have a thoracic mass. Pubs, percutaneous umbilical blood sampling.

variability.<sup>13,20</sup> Small pulmonary masses as an incidental finding may be entirely asymptomatic both in utero and after birth. Very large masses can have reproducible physiologic effects on the developing fetus. Compression of the fetal esophagus may impede the normal swallowing of amniotic fluid and can result in polyhydramnios. Simple mass effect can displace normal or unaffected lung, producing pulmonary hypoplasia. Through a similar mechanism of extreme vena caval obstruction and cardiac compression, low-output cardiac failure and fetal hydrops can develop. Either polyhydramnios or hydrops can occur in isolation because they do not represent a continuum of pathophysiology. Hydrops is manifested by fetal ascites, pleural and pericardial effusions, and skin or scalp edema, or both. These findings have historically been viewed as a harbinger of fetal or neonatal death.<sup>13,15</sup> The ability to identify a lesion and witness its pathophysiologic evolution has produced a management scheme based on prognosis that now includes fetal intervention. This algorithm is outlined in Figure 22-2.

In 2003, an extensive 7-year experience with 350 prenatally diagnosed cystic fetal lung lesions was reported.<sup>15</sup> In this experience, 15% of CPAMs and 68% of BPS lesions were observed to decrease in size during gestation. Other groups have reported similar findings of involution of fetal cystic lung masses.<sup>21-23</sup>

The mechanism by which these lesions involute remains unknown. Despite the strong association of hydrops due to a cystic lung mass and fetal death, a recent series of three cases of hydrops resolution with fetal survival was reported after the administration of prenatal corticosteroids.<sup>21</sup> Although the occasional case of fetal hydrops has been documented to resolve with spontaneous tumor shrinkage, it remains the collective experience that hydrops portends a poor either prenatal or postnatal outcome.<sup>12,13,15,17,21-23</sup> Overall, caution should be exercised when discussing the prognosis of the fetus because an understanding of which lesions will shrink remains unclear.

In an effort to derive a more objective prognostic tool, measurements of overall cyst size relative to the remainder of the fetus have been compared. The index of CPAM volume ratio (CVR) is obtained by dividing the CPAM volume by the fetal head circumference.<sup>20</sup> This index was found to be predictive of fetal hydrops when the ratio is greater than 1.6. Through these and similar serial ultrasound observations, it has been shown that most CPAMs do not increase in size relative to overall fetal size after 28 weeks' gestation. Based on these data, the authors' recommendations for fetuses less than 28 weeks' gestation are twice-weekly ultrasound examinations, given a CVR greater than 1.6, and weekly scans for those with smaller indices.<sup>15,20</sup>

The reproducible finding on prenatal ultrasonography that fetuses with very large cystic lung lesions and hydrops remain at risk has led to the development of fetal therapeutic options. Fetal thoracentesis and thoracoamniotic shunting have been performed with some success in fetuses with large, space-occupying pleural effusions, usually associated with BPS, or for the dominant cyst in a principally macrocystic CPAM.<sup>15,24,25</sup> Thoracentesis alone has proven ineffective because of the rapid reaccumulation of fluid and should therefore be considered as only a temporizing measure. Shunt placement for the continuous decompression of large single-cyst-predominant masses has resulted in the consistent resolution of hydrops in several centers.<sup>24,25</sup> In one report, nine fetuses were successfully treated for macrocystic CPAM with thoracoamniotic shunting, all with complete hydrops resolution, and with eight survivors.<sup>15,26</sup> Given an average time to delivery of 13 weeks, it seems that percutaneously placed shunts are well tolerated by the gravid uterus with respect to preterm labor after therapeutic fetal intervention. Of course, microcystic CPAMs associated with hydrops would not be amenable to shunting, based on knowledge of their microscopic anatomy and subsequent behavior. Somewhat paradoxically, the rare BPS with hydrops also has been treated successfully with shunting.<sup>13</sup> In BPS with hydrops, fluid accumulates in the pleural and peritoneal spaces and is believed to produce a tension hydrothorax from the obstructed flow of either fluid or lymph. All surviving fetuses should undergo more definitive postnatal resection after delivery and stabilization.

Numerous studies in the fetal lamb model that simulate a large thoracic mass with the mechanisms

of compression, hydrops, and subsequent resolution, have been studied.<sup>12,27-29</sup> The techniques of fetal surgical resection, anesthetic, and tocolytic management were extensively investigated in nonhuman primates before the first clinical application of open fetal therapy.<sup>12</sup> Drawing on these collective experiences, guidelines based on the gestational age of the fetus, size of the lesion, maternal health and well-being, and the presence of hydrops have allowed selected fetuses with life-threatening lesions to be surgically approached (see Fig. 22-2). Open fetal surgery is offered at a few selected centers after a comprehensive multidisciplinary screening process.<sup>16</sup> Extensive prenatal ultrasonography and echocardiography is done to exclude associated anomalies.<sup>12,16</sup> In addition, amniocentesis or percutaneous umbilical blood sampling is performed to confirm a normal karyotype. With the knowledge that prenatal hydrops from mass effect is highly predictive of fetal death, massive multicystic or predominantly solid CPAMs associated with hydrops can be resected in utero before 32 weeks' gestation. The largest reported series to date described 22 cases, with 11 healthy survivors of procedures performed between 21 and 31 weeks' gestation.<sup>15</sup> Findings at operation in the original 22 cases necessitated 16 single lobectomies, 4 double lobectomies, and 2 pneumonectomies. In the 11 survivors, histologic confirmation of CPAM was acquired and all survivors had postresection resolution of hydrops within 1 to 2 weeks. In addition, compensatory fetal lung growth was noted as the mediastinum returned to a more anatomic configuration. In this same series, 11 failures were noted from a variety of causes. The same lessons of advanced fetal hydrops or maternal preeclampsia, also known as the maternal mirror syndrome, were causative in several cases. Mirror syndrome is a maternal hyperdynamic state that remains poorly understood.<sup>30</sup> It seems that there is a rationale for the belief that close ultrasound follow-up is warranted to identify fetuses before the complications of hydrops render the fetus unsalvageable. Preterm labor precipitated fetal delivery and death in several others. Thus, it seems that the lessons learned about the indications and limitations of the open operative fetal cases are reproducible.

For fetuses that have reached 32 weeks' gestation or more at the time of presentation, early elective delivery is recommended to effect ex-utero resection (see Fig. 22-2).<sup>15,16</sup> However, the outcome remains dismal for hydropic fetuses, even with advanced postnatal support, including extracorporeal membrane oxygenation (ECMO). The combined results and experience cited earlier have demonstrated that fetal CPAM resection is a viable option for selected fetuses with otherwise fatal BPMs and hydrops.

## POSTNATAL MANAGEMENT

Several fetal anomalies can be confused with CPAMs and BPSs.<sup>3</sup> Chief among these are CDHs, bronchogenic and enteric cysts, mediastinal cystic teratomas, congenital lobar emphysema (CLE), and bronchial

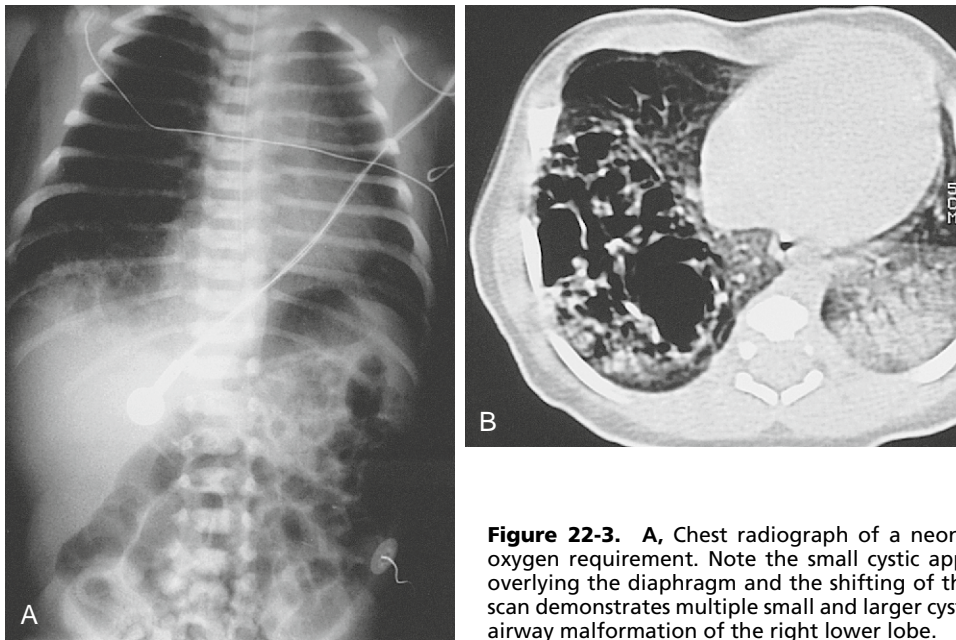

Table 22-2 Comparison of CPAM Classification Schemes		
	Stocker (Classic)	Anatomic (Current)
<b>Cyst Size</b>	I (>2 cm)	Macrocytic (>5 mm)
	II (<2 cm)	Microcytic (<5 mm)
	III (solid)	Microcytic
	II	
<b>Associated Anomalies</b>		
<b>Prognosis</b>		
Favorable	I	Macrocytic
Unfavorable	III	Microcytic

Solid (echogenic)	III	Microcytic
Cystic (echolucent)	I, II	Macrocytic

atresia.<sup>31-34</sup> Smaller lesions may be asymptomatic at birth. Before the increased use of prenatal ultrasonography, many of these lesions went unnoticed, even on perinatal chest radiography. Current practice is to obtain computed tomography (CT) of the chest either before discharge or in the first several weeks of life. Planned elective resection of asymptomatic CPAMs and BPSs is recommended, given the accumulating evidence for the risks of either infection or occult malignant transformation.<sup>3,35-38</sup> However, this remains debatable and practice patterns are still evolving for the small asymptomatic lesions. Moderate-sized lesions may cause some respiratory embarrassment at birth, either from hyperinflation or from the secondary mass effects on normal lung. The traditional postnatal management of planned delivery with multidisciplinary neonatal evaluation, stabilization, and eventual excision has produced an excellent overall prognosis. On rare occasions when severe perinatal respiratory distress is anticipated, a strategy using ECMO has been described.<sup>13,15</sup>

## CONGENITAL PULMONARY AIRWAY MALFORMATION

CPAM is traditionally described as a multicystic lung mass resulting from a proliferation of terminal bronchiolar structures with an associated suppression of alveolar growth. On histologic examination, these cysts are lined by cuboidal or columnar epithelium.<sup>18</sup> A pathologic classification system adopted by Stocker and colleagues<sup>39</sup> is important to note for historic purposes but does not currently represent a clinically helpful designation to predict the natural history.

The Stocker classification system subdivides cysts based on size into three major subtypes (Table 22-2).<sup>39</sup> Type I lesions have large multiple cysts of varying size, each measuring at least 2 cm and lined by a ciliated pseudostratified columnar epithelium. Type II cysts are also multilocular, yet they tend to be smaller, are

**Figure 22-3.** **A,** Chest radiograph of a neonate with mild respiratory distress and oxygen requirement. Note the small cystic appearance of the right lower lung field overlying the diaphragm and the shifting of the mediastinum to the left. **B,** Chest CT scan demonstrates multiple small and larger cysts suggestive of a congenital pulmonary airway malformation of the right lower lobe.

more uniform in size (daughter cysts are  $< 2$  cm), and are lined by ciliated cuboidal to columnar epithelium. Type III lesions are macroscopically and microscopically solid, without cystic components. Many problems of overlap with hybrid lesions and atypical cysts that do not fit this classification system have subsequently been identified.<sup>40,41</sup> One published report documented a complex lesion with elements of a CPAM, BPS, and bronchogenic cyst, prompting speculation about a previously unidentified common ontogeny.<sup>41</sup>

Currently, a more generalized classification of cysts into macrocystic ( $>5$  mm diameter) and microcystic ( $<5$  mm diameter) subtypes is more commonly used and seems more clinically relevant (see [Table 22-2](#)).<sup>42</sup> The macrocystic lesions are not true cysts because they do communicate with the more proximal conducting airways. Therefore, these lesions typically are first seen in early infancy with progressive respiratory distress because air trapping leads to cystic expansion and compression of normal lung. These lesions are being identified prenatally with increasing frequency and are only infrequently associated with hydrops or pulmonary hypoplasia. Therefore, macrocystic lesions have a generally favorable prognosis and are frequently asymptomatic at birth.

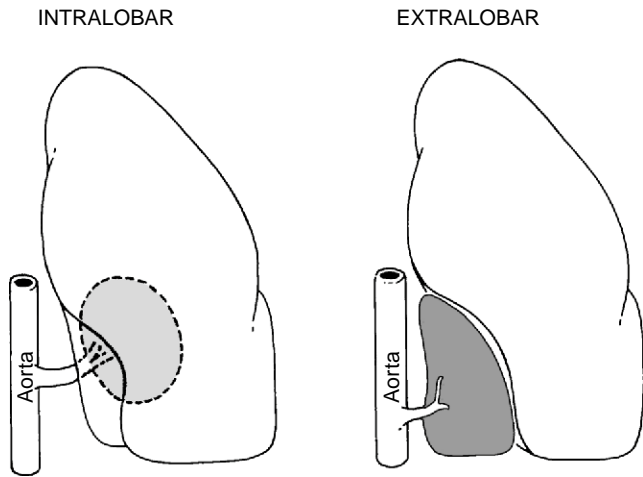

Microcystic CPAM lesions can be distinguished from the macrocystic type radiographically, pathologically, and clinically.<sup>16,42</sup> These lesions appear more homogeneous and solid on imaging. Similar to the macrocystic lesions, they are not true cysts. The microcystic lesions, however, are currently believed to be more frequently associated with other developmental abnormalities. Therefore, these patients have a worse prognosis.<sup>16,42</sup> The small-cyst CPAMs may be seen in association with developmental airway obstruction due to bronchial atresia or stenosis. The pathologic features are consistent and demonstrate focal areas of

increased bronchiolar proliferation, variable alveolar development, and regional displacement of unaffected lung parenchyma.

Macrocystic CPAMs most typically affect only one lobe and may have one or more dominant cyst-like structures with multiple smaller daughter cysts. While all cysts have some respiratory epithelial lining, some also contain mucigenic epithelium resembling stomach. In some series, at least 25% of these lesions have an associated systemic, nonpulmonary, arterial supply. Confusion between macrocystic and microcystic lesions may exist shortly after birth, with both appearing as solid on early imaging. The cystic nature of the macrocystic lesions becomes apparent within a few postnatal days as amniotic fluid is replaced by air ([Fig. 22-3](#)). When very large cystic changes occur on imaging, other diagnoses such as pulmonary interstitial emphysema, pneumatocele, pleuropulmonary blastoma, and intraparenchymal lymphangioma need to be considered.

## BRONCHOPULMONARY SEQUESTRATION

Sequestrations should be distinguishable from CPAMs by their pathologic, radiologic, and clinical characteristics.<sup>16</sup> A pulmonary sequestration is classically described as a cystic mass of nonfunctioning lung parenchyma that lacks a demonstrable connection to the tracheobronchial tree. In addition, this sequestered mass of lung tissue receives its blood supply anomalously from the systemic circulation. However, as with many of these lesions, exceptions are common, with a wide variety of arterial supply and venous drainage combinations being described. Because of the anomalous blood supply, many believe the true embryologic

**Figure 22-4.** Locations for a pulmonary sequestration. These lesions occur either within the lung or outside the visceral pleura.

derivation of these lesions should classify them as vascular anomalies. However, because the majority of the clinical symptoms are respiratory, we continue to classify these as lung lesions. Sequestrations are largely solid lesions. Pathologically, these lesions demonstrate parenchymal maldevelopment, reflected as microcystic abnormalities similar to type II microcystic CPAMs.

Sequestrations are typically classified as either intralobar or extralobar (Fig. 22-4). If the lesion is contained within the same investing pleura as normal lung, it is intralobar. Extralobar lesions are found outside the investing parietal pleura of adjacent normal lung. Intralobar sequestrations are usually found in the lower lobe basilar segments and are more common in the patient's left hemithorax. Extralobar lesions have a more variable occurrence pattern. However, their typical location is also basilar, below the more normally formed lung (Fig. 22-5A). Extralobar lesions also have been found in the upper thorax, below the diaphragm in the upper abdomen (see Fig. 22-5B), throughout the mediastinum, and within the pericardium.<sup>16,32,43-47</sup>

Many sequestrations are asymptomatic. Given the lack of communication to the tracheobronchial tree,

infectious complications most likely develop from hematogenous seeding. Extralobar sequestrations are frequently identified as an incidental finding, with approximately 15% occurring below the diaphragm and, not infrequently, in association with a left-sided CDH.<sup>45</sup> The radiographic findings for either intralobar or extralobar sequestrations are usually that of an opacified solid lung mass or a cystic parenchymal lesion with an air-fluid level secondary to infection. Intralobar BPS accounts for the majority of lesions overall, yet extralobar lesions are more likely to have other associated anomalies in as many as 50% to 65% of cases.<sup>47,48</sup> The most commonly recognized anomalies associated with BPS, in addition to CDH, include diaphragmatic eventration and other foregut malformations such as tracheoesophageal fistula and esophageal duplication.<sup>43,44,48</sup>

Historically, angiography was performed to confirm the anomalous systemic blood supply and to help in planning surgical management. Currently, the hallmark anomalous vascular supply can be identified by Doppler ultrasonography, CT, or MR angiography or a combination of these modalities. Typically, a single large feeding vessel arising from the abdominal aorta is found (Fig. 22-6). This vessel can be typically found within a pedicle or stalk. However, not infrequently, more than one major vessel is found to supply the sequestration. The venous anatomy may be even more variable, with systemic, bronchial, and azygous system involvement. If a bronchus is found within the pedicle, communication with the gastrointestinal tract should be sought.

## SURGICAL MANAGEMENT OF CONGENITAL PULMONARY AIRWAY MALFORMATION AND BRONCHOPULMONARY SEQUESTRATION

Although somewhat debatable, the finding of a CPAM or BPS, regardless of symptoms, is an indication for resection, given the risk of either infection or malignant transformation. In an asymptomatic newborn,

**Figure 22-5.** A, The CT scan demonstrates an extralobar sequestration in the typical basilar location of the left chest (arrow). B, In a different patient, the chest radiograph shows a large transdiaphragmatic extralobar sequestration (arrow).

**Figure 22-6.** Systemic arterial feeding vessel from the infradiaphragmatic aorta to an intralobar sequestration. **A**, Chest radiograph. **B**, CT scan. **C**, Three-dimensional reconstruction of the CT scan.

the resection can be electively performed at 3 to 6 months of age. Both pleuropulmonary blastoma and bronchoalveolar carcinoma have been reported in infants, children, and adults with known CPAMs.<sup>35-38</sup> The preoperative chest CT can help in planning the operative approach. Traditionally, a lateral thoracotomy has been performed, depending on the location of the target lesion. Either a lobectomy, or less frequently, a segmentectomy allows complete removal of the majority of these lesions. For extralobar sequestrations, the preoperative imaging and localizing studies are even more important, given the possibility that some lesions are located below the diaphragm. Obviously, for extralobar lesions, a nonanatomic resection is possible and is facilitated by the stalk or pedicle-like nature of the feeding vessel.

Over the past decade, the thoracoscopic approach for resection of CPAMs and BPSs has been well described.<sup>49-55</sup> The advantages of this approach include a reduction in postoperative pain, decrease in hospital stay, improvement in cosmesis, and, importantly, the avoidance of morbidities (namely, musculoskeletal complications) associated with a thoracotomy.<sup>54</sup> The first large series of thoracoscopic pulmonary procedures in infants and children was reported in 2000.<sup>51</sup> The vast majority of the 113 cases reported were pulmonary biopsies and wedge resections. Lobectomies were performed with a hybrid technique of directed thoracoscopy and mini-thoracotomy. This report predated many of the instruments that are currently used for hemostasis and tissue sealing. The Ligasure (Tyco, Inc., Norwalk, CT), for example, also can be used to seal neonatal lung parenchyma when an incomplete fissure is encountered. Since this initial review, numerous reports attesting to the safety and efficacy of the thoracoscopic technique in the management of BPS and CPAM have been published.<sup>49,50,52,53,55</sup> In a recent report, 65 of the 97 patients underwent thoracoscopic resection for either CPAM or BPS.<sup>53</sup> All but 4 of the 97 lobectomies performed were completed thoracoscopically. Three postoperative complications were described (pneumothorax, pneumonia, and persistent air leak). Postoperative hospitalization averaged 2.4 days in patients who underwent successful thoracoscopic surgery. In 2007, a two-surgeon experience was published detailing a series of 144 consecutive

pediatric lobectomies, 112 of which were performed for CPAM/sequestrations.<sup>49</sup> Lung abnormalities were diagnosed prenatally (by ultrasonography and/or MRI) and postnatally (by CT). The majority of these resections were lower lobectomies, which are technically less difficult than upper lobe resections. The median operating time was 125 minutes, and the median postoperative hospitalization was 2.8 days. Long-term follow-up (1-10 years) has not revealed any problems with musculoskeletal deformity or weakness.

In a 2008 study, thoracoscopic resection was compared with open resection in the treatment of 36 consecutive postnatally treated CPAMs over a 10-year period at UCSF Children's Hospital.<sup>55</sup> The 12 patients undergoing thoracoscopic resection were noted to have significantly shorter postoperative hospitalization (2 days vs. 5 days,  $P = .0003$ ), a shorter time required for the chest tube (2 days vs. 3 days,  $P = .047$ ), and a lower incidence of postoperative complications (16.7% vs. 58.3%,  $P = .03$ ) than the 24 patients who underwent an open operation. However, the thoracoscopic resection group did experience a longer average operative time (164 minutes vs. 104 minutes,  $P = .02$ ). The average hospital costs were noted to be similar in both groups, further validating the use of thoracoscopic techniques in the management of bronchopulmonary malformations. (See Chapter 28 for further information about the thoracoscopic approach.)

With further evolution in the thoracoscopic technique, a broader range of lesions, such as bilateral disease and very large lesions, can be approached. On the other hand, it may be best to stage bilateral cases to give the remaining normal lung a period of accommodation between elective resections. Currently, the main limiting factor for the thoracoscopic approach is the child whose condition is unstable because of the mass effect, because the large size may eliminate the effective working space needed for thoracoscopic resection. On occasion, intraoperative cyst rupture has provided the necessary working space for resection by minimal-access techniques. An exceedingly large lesion requiring pneumonectomy also will require additional plans for managing potential pulmonary hypertension or the temporary respiratory insufficiency that can result from pulmonary hypoplasia. ECMO may be useful as a temporizing measure in such cases.

**Figure 22-7.** A, Chest radiograph demonstrates the characteristic changes in an infant with congenital lobar emphysema (CLE). Marked overdistention of the left upper lobe caused the mediastinal shift, flattening of the diaphragm, and likely subsequent respiratory distress. B, Bronchogram shows the absence or occlusion of the left upper lobe bronchus, producing the typical findings in CLE. C, Operative photograph demonstrates the dramatic herniation of an emphysematous lobe through the thoracotomy incision.

## EMPHYSEMATOUS LESIONS

On occasion, CLE can be confused with a macrocystic CPAM.<sup>31,34</sup> Radiographically, CLE appears as overdistention involving one or more lobes (Fig. 22-7A). This is believed to be caused by a variant of bronchomalacia with a focal cartilaginous deficiency of the tracheobronchial tree, leading to regional airway collapse with expiration.<sup>2,3</sup> With postnatal air exchange, air trapping behind a structurally inadequate conducting airway leads to these emphysematous changes. Other rare causes include extrinsic compression from anomalous pulmonary vessels or by a very large ductus arteriosus (see Fig. 22-7B).<sup>3,56</sup> In the premature infant with significant respiratory distress syndrome, pulmonary interstitial emphysema, in its more chronic form, can evolve into a variant of CLE. One third of cases remain classified as idiopathic.<sup>2,3,57</sup>

The clinical presentation of CLE can be as varied as its numerous causes. With massive lobar overdistention (see Fig. 22-7C), compression of the normal lung and the mediastinum can cause respiratory and cardiovascular collapse. In these cases, emergency thoracotomy is necessary as a lifesaving maneuver. In less dramatic presentations, progressive tachypnea and expansion lead to assisted ventilation and radiographic identification of the offending lesion. Plain chest radiographs and CT scans have been used both for diagnosis and for determining the appropriateness of surgical resection and the boundaries of normal lung. In most cases, resection of the abnormal lung allows re-expansion and compensatory growth of the normal lung. Expectant management is acceptable for the largely asymptomatic lesion.<sup>57</sup> However, complete resolution of the radiographic findings is rare, and, for this reason, surgical resection is indicated.<sup>57-59</sup> The aforementioned concerns of retained secretions as a nidus for infection exist with CLE as for CPAMs.

The acquired forms of emphysematous pulmonary lesions generally are first seen in a more time-dependent fashion than are the lesions caused purely by congenital structural defects.<sup>57-59</sup> A history of chronic ventilation of a poorly compliant premature

lung precedes the development of pulmonary interstitial emphysema and its sequelae of lobar emphysema or parenchymal cysts. Many of these lesions will resolve spontaneously. However, if the mass effect produces some of the same clinical symptoms of compression of the normal lung and mediastinum, then surgical intervention is indicated. In the most chronic forms of CLE, operative therapy for cystic pulmonary lesions from prolonged ventilator barotrauma can be quite difficult because little residual normal lung will be available for continued gas exchange.

## LOBULATION ANOMALIES AND ISOMERISM

Significant variations of lung anatomy occur with respect to the pattern of lung lobulation. The most common variability is an absent or incomplete fissure separating the anatomic lobes. Absent fissures occur in 30% of individuals, whereas incomplete fissures can be seen in more than half of the general population.<sup>2,3</sup> However, these variations do not indicate disordered lobulation and, as such, have no clinical significance, other than to the operating surgeon. True lobulation and segmentation abnormalities can result in extra lobes such as a cardiac lobe (division of the left lower lobe into two separate lobes) or supersegmentation of the lower lobes.<sup>2,3</sup> The majority of these anomalies are without clinical relevance. Lobulation anomalies can occur with abnormal bronchial patterns as seen with accessory tracheal lobes with direct airway connection to the trachea.

The azygos lobe is a malformation usually of the right upper lobe that is caused by an aberrant azygos vein that is suspended by pleura and acts as a mesentery that produces the defect.<sup>2</sup> These lesions also most likely are clinically silent. Reports have mentioned esophageal lung, also termed *communicating bronchopulmonary foregut malformation*, in which a tract is preserved between the respiratory and alimentary systems.<sup>60</sup> These anomalies are almost always seen in association with esophageal atresia and tracheal stenosis or fistula.

Pulmonary isomerism is the mirror-image reversal of pulmonary lobar sidedness, in which the left lung has three lobes and the right has two.<sup>2</sup> This abnormality may or may not be associated with situs inversus but nearly always involves other organ system abnormalities, most notably congenital cardiac lesions. In addition, asplenia and polysplenia have been described with relative frequency. The associated cardiac lesions are usually responsible for the majority of the clinically relevant morbidity.

### PULMONARY AGENESIS, APLASIA, AND HYPOPLASIA

Pulmonary agenesis is the complete failure of both airway and parenchymal development. Pulmonary aplasia is used to describe the incomplete development of lung parenchyma supplied by a rudimentary bronchus. Pulmonary hypoplasia is distinguished by a normal tracheobronchial tree and underdeveloped pulmonary parenchyma. Agenesis can occur either unilaterally or bilaterally. In the latter case this would be incompatible with life. In cases of unilateral agenesis, frequently other associated severe developmental abnormalities are also found.<sup>2</sup> Most commonly, these include the elements of the VACTERL syndrome. The etiology and embryonic pathophysiology of aplasia and agenesis remain largely unknown.

Pulmonary hypoplasia is the most commonly encountered anomaly of underdeveloped lung parenchyma. There are a variety of known causes. The compressive effects of lung, mediastinal, or cardiac masses or herniated abdominal viscera, as seen with CDH, can result in arrested pulmonary parenchymal development. Other causes include the abnormal mechanical effects of fetal diaphragmatic excursion or fetal lung and amniotic fluid volume. Specifically, abnormal or absent fetal breathing or oligohydramnios, with or without renal dysgenesis or obstructive uropathy, can be causative of pulmonary hypoplasia.<sup>61</sup>

The diagnosis and treatment of pulmonary hypoplasia is dependent on the underlying etiology.<sup>61</sup> For example, severe respiratory impairment can be seen with pulmonary hypoplasia from a CDH. In these cases, stabilization of the underlying physiologic impairment is the priority. In cases of aplasia or agenesis, the chest radiographs may demonstrate opacification of the ipsilateral hemithorax and an ipsilateral mediastinal shift with volume loss. In addition, asymmetry of the chest with obviously impaired respiratory movement of the affected side is seen. Treatment is initially directed at any associated anomalies, with particular focus on congenital cardiac lesions. If an operation is needed to remove a nonfunctioning lobe or lung, every effort is made to preserve functional parenchyma. In cases that render an empty hemithorax, consideration should be given to the intrathoracic placement of a tissue expander to prevent significant musculoskeletal disfigurement from the eventual mediastinal and skeletal shift toward the volume loss side (Fig. 22-8).

**Figure 22-8.** This chest radiograph was taken of a 3-year-old who underwent right pulmonary plumbage with insertion of three Ping-Pong balls 1 year earlier.

### MEDIASTINAL CYSTS

As has been discussed, many of the commonly recognized congenital bronchial malformations, such as bronchial agenesis, atresia, or stenosis, produce parenchymal abnormalities that distinguish these lesions clinically. However, a subset of congenital malformations is unique to the bronchial tree and has been traditionally grouped under the nomenclature of bronchogenic cysts or foregut duplication cysts. As discussed earlier, the embryologic derivation of these from a common foregut anlagen, their occurrence in the chest, and their most frequent clinical symptoms make their inclusion appropriate in a discussion of BPMs. The nomenclature in common usage remains confusing. In general, the term *foregut duplication cyst* appropriately links these lesions embryologically as arising from a common developmental structure. When one considers their histologic architecture, these lesions can be divided into three subdivisions: (1) bronchogenic cysts, (2) enteric duplication cysts, and (3) neuroenteric cysts, all of which reveal their common endodermal origins.<sup>62</sup>

Bronchogenic cysts are lined by respiratory bronchial epithelium, are mucus filled, and may contain cartilage in their walls.<sup>2,62</sup> Enteric duplication cysts are lined by intestinal epithelium (either esophageal or gastric) and may contain smooth muscle. Most commonly, enteric cysts occur within the muscular wall of an otherwise intact esophagus without communication with the lumen. Neuroenteric cysts are the embryologic exception, arising from a failure of separation of notochord and foregut. These lesions contain gastrointestinal mucosa with well-developed smooth muscle walls and communicate with the central nervous

**Figure 22-9.** A, Chest radiograph in this 10-year-old child shows a right upper lobe infiltrate. B, Chest CT scan demonstrates a large bronchogenic cyst with an air-fluid level indicating bronchial communication.

system (CNS), spinal cord, and perhaps dura. This association explains their frequent coexistence with congenital vertebral defects, most commonly hemivertebrae.<sup>63</sup> Neuroenteric cysts are, however, much rarer than either bronchogenic or enteric cysts.

Foregut duplications must be considered in the differential diagnosis of a cystic mediastinal lesion (Fig. 22-9). Bronchogenic cysts can be diagnosed prenatally, perinatally, or in an older child. The lesion may be seen in the newborn with acute respiratory distress because a large lesion can compress adjacent normal lung tissue. They may be totally asymptomatic in an older child or may occur with infection in an occult lesion. Occasionally, the lesion is discovered incidentally on chest radiography performed for unrelated reasons. Further studies should include CT of the chest to identify the lesion and its relation to surrounding structures. Mediastinal cysts also have been identified on prenatal ultrasonography and are followed up perinatally with these same imaging modalities. Close scrutiny of the mediastinal structures is indicated because all bronchogenic cysts, whether symptomatic or not, should be excised, given their propensity for expansion, infection, and hemorrhage.<sup>64</sup> Because bronchogenic cysts are most commonly discrete lesions, they can be successfully approached thoroscopically. Care must be taken to avoid injury to either the bronchial or esophageal wall, particularly when they share a common wall. The development of intracorporeal suturing techniques has enhanced our ability to excise these lesions endoscopically. Previous infection makes their removal more difficult by either the open or thoracoscopic approach, given the fibrovascular reaction that occurs surrounding infected lesions.

Bronchogenic cysts also may occur within the pulmonary parenchyma separate from the hilar structures. Peripheral bronchogenic cysts may be multiple, in which case they are more appropriately termed *bronchiolar cysts* or *cystic bronchiectasis*.<sup>2</sup> The more peripheral bronchogenic or pulmonary cysts are lined by ciliated respiratory epithelium and likely result from abnormalities during the latter portion of the pseudoglandular stage of lung development, as contrasted to the

more central lesions that are true foregut abnormalities.<sup>2</sup> These lesions invariably communicate with the airway and often create obstruction of accompanying bronchi. Peripheral lesions may initially be seen early from the accumulation of mucus that leads to obstruction, or they may be seen later as infected peripheral lesions. They may be confused with necrotizing pneumonia. Diagnostic evaluation almost always includes CT. The treatment is surgical resection, given the natural history of persistence with recurring symptoms. (See Chapters 25, 28, and 40 for further information about bronchogenic cysts and esophageal duplications.)

## VASCULAR ANOMALIES

Although the majority of pulmonary vascular anomalies are more appropriately discussed with congenital cardiac defects, several vascular malformations of the peripheral pulmonary parenchyma are within the scope of treatment for most pediatric surgeons. Pulmonary arteriovenous malformations (AVMs) typically are seen initially with a triad of symptoms, including dyspnea on exertion, cyanosis, and clubbing of the digits. The symptoms are produced because of the significant right-to-left shunting produced by these lesions. Radiographically, pulmonary AVMs appear as solid, frequently peripheral, lobulated masses of varying size. A CT scan reveals the tortuous nature of the involved vessels. Angiography may be needed to delineate the exact nature of the lesion. Complications of pulmonary AVMs include cardiac failure and, less commonly, rupture and hemorrhage, either into a neighboring bronchus or into the pleura. Treatment options include segmental surgical resection or catheter-directed embolization (which may be the preferred approach for the emergent bleeding AVM).

A rare entity known commonly as scimitar syndrome is a distinct variation of both BPS and the AVM anomalies. Also known as congenital venolobar syndrome, scimitar syndrome consists of a hypoplastic and malformed right lung with anomalous venous return directly to the vena cava.<sup>2</sup> Similarly, the arterial supply

is variable and normally includes a hypoplastic right pulmonary artery and a systemic arterial branch from the aorta to the right lower lobe. Occasionally confused with BPS, this lesion always involves the right lung and maintains its bronchial connection to the airway. The syndrome takes its name from the scimitar appearance on a plain radiograph, arising as the lateral outline of the abnormal pulmonary venous connection with the vena cava (Fig. 22-10). This constellation of anatomic abnormalities produces a left-to-right shunt. Associated intracardiac anomalies frequently occur. Treatment options include redirecting the venous drainage to the left atrium or a right lower lobectomy.

Lymphatic malformations in the thorax are rare but, when present, can take one of two different forms. Congenital pulmonary lymphangiectasia is an anomaly with diffuse dysplasia and dilation of the pulmonary lymphatics. This can be seen in association with generalized lymphangiectasia. It may be secondary to pulmonary venous hypertension, or it can be seen as an isolated finding. With generalized lymphangiectasia, the treatment is supportive, whereas the less frequent focal abnormalities may be amenable to surgical excision.

Congenital chylothorax is the accumulation of chyle in the pleural space. In the newborn, this results either from a congenital abnormality of the thoracic duct or from birth trauma. Frequently, the exact etiology cannot be identified, rendering the label “idiopathic.” For the majority of congenital chylothoraces, treatment is supportive with enteral diet modification or total parenteral nutrition. Serial thoracenteses or tube thoracostomy (or both) are the mainstays of therapeutic

**Figure 22-10.** Chest radiograph shows the classic appearance of a patient with scimitar syndrome. The right lung is hypoplastic, and the anomalous pulmonary venous drainage to the inferior vena cava (IVC) is marked with the *arrow*. The outline of this vein gives the appearance of a scimitar. This vein probably drains into the supradiaphragmatic IVC. The vein is usually larger if it is partially obstructed or is draining into the IVC below the diaphragm. (Photo courtesy of Dr. Jim Brown, Children’s Mercy Hospital.)

interventions that are largely temporizing and not curative. Recalcitrant cases may necessitate interventional radiology–guided attempts at embolization, thoracoscopic thoracic duct ligation, or placement of a thoracoabdominal shunt. These lesions can be fatal.

# ACQUIRED LESIONS OF THE LUNG AND PLEURA

Bradley M. Rodgers, MD • Marc P. Michalsky, MD

Acquired pulmonary and pleural lesions in the pediatric age group continue to pose a significant challenge for the surgical community. Despite dramatic advances in antibiotic therapy and the implementation of widespread immunization protocols, the emergence of opportunistic infections and changes in disease patterns have led to increasing complexity with regard to the choice of treatment modalities. Furthermore, the widespread and often inappropriate use of antibiotics, along with increased numbers of immunocompromised children (as a result of better chemotherapeutic regimens and emergence of human immunodeficiency virus [HIV] infections) has led to increases in the prevalence of several acquired pulmonary and pleural processes previously regarded as uncommon. The treatment of these diseases poses a significant challenge and requires that the surgeon caring for such children is well versed in the varied and often complex therapeutic options.

## EMPHYEMA

Empyema is the accumulation of infected fluid within the thoracic cavity. In the pediatric population, this pathophysiologic process is typically associated with severe pneumonia and an associated parapneumonic effusion. Although pneumonia remains the leading cause of thoracic empyema in both the pediatric and adult populations, other potential sources of pleural

infection include the extension of mediastinal, retropharyngeal, and/or paravertebral infectious processes. In addition, empyema may also develop as a complication of thoracic surgery or as a consequence of direct trauma to the thoracic cavity.<sup>1</sup> Although the incidence of this disease process is reported to be as low as 0.6% in hospitalized pediatric patients,<sup>1</sup> the associated mortality may be as high as 8%.<sup>2-7</sup>

## Pathogenesis

In the early 1960s, the American Thoracic Society characterized three pathologic stages of empyema that remain pertinent today (Table 23-1).<sup>8</sup> Stage I, commonly referred to as the “exudative stage,” generally consists of thin pleural fluid (with minimal cells) that moves freely within the thoracic cavity and is associated with mobile lung parenchyma. This phase, often referred to as a “parapneumonic effusion,” occurs within the initial 24 to 72 hours and is typically amenable to a combination of simple drainage (thoracocentesis or chest-tube placement) and broad-spectrum antibiotics. Stage II, or the “fibrinopurulent stage,” lasts for 7 to 10 days and is marked by the presence of fibrinous debris and fluid laden with large numbers of polymorphonuclear cells. At this phase, the fluid is often acidic, in comparison with fluid collected during the exudative stage. A notable difference, compared with the earlier stage, is the fact that the fluid is often compartmentalized as a result of the formation of

**Table 23-1** Characteristics of the Three Stages of Empyema

Stage	Time after Onset of Empyema	Fluid Characteristics	Treatment
I. Exudative	24-72 hours	Thin fluid, few cells	Drainage (needle or chest tube)
II. Fibrinopurulent	5-10 days	Fibrinous debris, many PMNs, loculated septations	Fibrinolysis (thoracoscopic debridement for failures)
III. Organizing	2-4 weeks	Thickened visceral and parietal pleura	Pleurectomy—open usually

PMNs, polymorphonuclear leukocytes.

multiple septations (Fig. 23-1). The presence of organized loculations makes effective tube drainage more difficult. With this limitation in mind, the use of computed tomography (CT) becomes an invaluable tool when planning the placement of chest tubes in the hopes of establishing adequate drainage of the thoracic cavity. Stage III, or the “organizing stage,” typically occurs 2 to 4 weeks after the initial process has begun and is marked by thickening of the visceral and parietal pleura as a consequence of significant fibroblast ingrowth. The result is the establishment of an organized peel or rind (Fig. 23-2), which is intimately associated with the visceral pleura and which serves to entrap the underlying lung parenchyma.

The bacteriologic characteristics associated with thoracic empyemas have changed significantly over the past half-century. Although pneumococcal species were the predominant organisms associated with the development of thoracic empyemas in the mid-20th century, the introduction of penicillin and pneumococcal vaccine has resulted in *Staphylococcus aureus* now being the leading bacterial pathogen.<sup>7,9</sup> *S. aureus* has been reported to be cultured in the majority of pediatric patients and in approximately 50% of adult patients with documented empyema.<sup>9</sup>

Additional organisms include *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Pseudomonas aeruginosa*, and several *Bacteroides* species. However, the effective treatment of *S. aureus* has resulted in the emergence of a variety of other species with a greater proportion of gram-negative organisms.<sup>1</sup> Recent series have shown the emergence of antibiotic-resistant organisms, including penicillin-resistant *S. pneumoniae* and methicillin-resistant *S. aureus*. Several contemporary series have demonstrated resistant organisms to comprise the majority of gram-positive cultures from pediatric empyemas.<sup>7,9-11</sup> Interestingly, some relatively recent series cite a re-emergence of *H. influenzae* and streptococcal species among pediatric patients,<sup>12</sup> although it has been speculated that the increasing use

**Figure 23-1.** This thoracoscopic view shows the inflammatory septations that can develop after the development of an empyema. These septations often result in loculations of the fluid, which makes chest tube drainage alone ineffective. Note the collapsed lung (asterisk) as a result of this inflammatory material.

**Figure 23-2.** This gross specimen demonstrates significant pleural thickening encountered in the latter stages of thoracic empyema.

of vaccination against *H. influenzae* may further affect the current trends.

### Clinical Presentation and Diagnosis

Because the usual cause of empyema in children is infection related to an underlying pneumonia, the typical clinical presentation consists of a recent history of upper respiratory tract symptoms with fever and cough. This clinical scenario often progresses to a state of respiratory distress, accompanied by malaise, persistent fever, and pleuritic chest pain.<sup>4,7,12-14</sup> The patient's typical appearance often includes lethargy with pronounced tachycardia, shallow and rapid breathing, and diminished breath sounds with dullness to percussion on the affected side. Dehydration requires aggressive resuscitation with intravenous fluids. A paralytic ileus is commonly encountered at the initial presentation.

A chest radiograph obtained at the time of presentation often reveals the presence of a moderate to large pleural effusion in conjunction with pleural thickening and underlying pneumonia (Fig. 23-3). The ability to differentiate between a simple parapneumonic effusion and a complicated effusion or empyema requires an analysis of the pleural fluid. Thoracentesis may reveal thick pleural fluid, with a purulent appearance, clearly indicating an empyema. Standard criteria for differentiating between a complicated effusion and an uncomplicated parapneumonic effusion include analysis of pleural fluid pH, glucose, and lactate dehydrogenase. A pH value less than 7.20, a glucose level less than 60 mg/dL, or a lactate dehydrogenase value greater than 1000 units/L suggests a complicated pleural effusion. Recently, one study has suggested the use of pleural tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) for differentiating a complicated effusion.<sup>15</sup> These investigators have suggested that a TNF- $\alpha$  level greater than 80 pg/mL suggests a complicated effusion.

CT and/or ultrasonography of the chest are helpful during the initial evaluation of children with a pleural effusion (Fig. 23-4). These studies may help assess the condition of the underlying lung parenchyma during advanced stages of the disease process and allow identification of loculated fluid collections that have not been adequately drained. The identification of complex and undrained loculations suggests the need for more aggressive surgical management.

**Figure 23-3.** Anteroposterior (A) and lateral (B) chest radiographs show a large right thoracic empyema. The decubitus radiograph did not show any layering of the pleural fluid.

## Therapy

The optimal course of therapy for children with empyema has been the topic of much debate over the past several decades. The treatment is dictated by the stage at which the individual patient is first seen (Fig. 23-5). Several authors have proposed treatment pathways encompassing several clinical and radiologic factors in an effort to help define optimal therapeutic management of this patient population.<sup>6,11</sup>

For patients initially seen during stage I disease, the fluid is usually thin and communicates freely throughout the thoracic cavity. The optimal treatment for empyema diagnosed in this stage consists of drainage of the infected fluid. This can be accomplished through the use of paracentesis or chest tube drainage.

The combination of drainage and antibiotics often results in rapid improvement in the clinical picture. The early clinical effects (24-48 hours) of closed chest tube drainage and antibiotic therapy are often quite dramatic with defervescence, decrease in the serum leukocyte count, and improved respiratory status. Failure to demonstrate rapid clinical improvement often indicates the presence of residual pleural fluid.

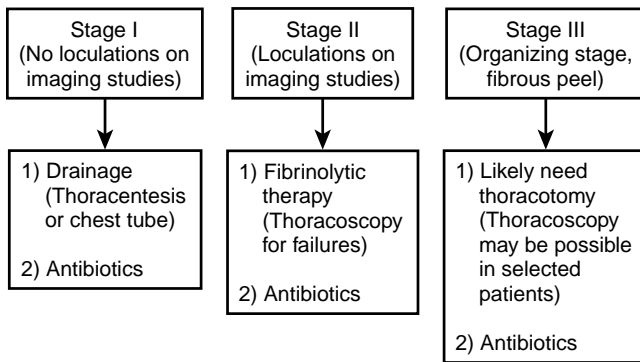

A typical uncomplicated course involves removal of the chest tube(s) within 1 to 2 weeks' time and discharge from the hospital soon thereafter.

Although serial chest radiographs are often used to guide the effectiveness of therapy in patients with early disease, complete resolution of the radiologic findings may take weeks to months. The persistence of such radiographic abnormalities during the convalescent phase must be carefully followed. Specifically, when presented with a patient whose overall clinical picture continues to improve, one must consider the potential "lag time" encountered for resolution of the radiographic abnormalities and thereby avoid the mistake of misinterpreting such radiologic findings as being consistent with a diagnosis of chronic empyema.

Tube thoracostomy is rarely capable of completely evacuating the pleural space in a child who has progressed to an advanced disease stage (i.e., stages II and III). Most often, these patients require more invasive surgical techniques to ensure complete evacuation of the affected pleura. Advancement of the disease process to stage II is marked by a change in the consistency of the pleural fluid. During this stage, the fluid is often thick

**Figure 23-4.** Ultrasonography and/or CT of the chest are helpful during the initial evaluation of children with a pleural effusion and possible empyema. **A**, In the ultrasound study, note the loculations identified in the pleural fluid. **B**, On the CT scan, a large pleural effusion (asterisk) is noted. Also there is collapse of the underlying lung parenchyma as well as septations (arrow).

**Figure 23-5.** This schematic shows management of empyema depends on the stage. Simple drainage is usually possible for stage I disease. However, most patients present to the surgical service with stage II disease. Fortunately, stage III disease is not frequent today but was quite prevalent 30 years ago.

and turbid. In addition, free communication of the fluid, typically noted in the earlier disease process, is hindered by the presence of fibrinous strands within the fluid itself and frankly organized loculations (see Figs. 23-1 and 23-4). This results in the formation of multiple, non-communicating fluid compartments within the pleural space. When patients are encountered in the later stages of the disease process, or in those for whom initial therapy with chest tube drainage and intravenous antibiotics fails, more complicated therapy is needed.<sup>7,9,16-32</sup>

Historically, surgeons utilized formal thoracotomy for decortication as the treatment for children in these more advanced stages of the disease process. Over the past decade, most pediatric surgeons have employed thoracoscopy for this purpose (Fig. 23-6).<sup>18-20</sup> This minimally invasive technique allows complete evacuation, irrigation, and debridement of the involved pleural space during the fibropurulent stage (stage II) but is less effective during the more advanced, or organized, stage III. Nonetheless, thoracoscopy has replaced open thoracotomy for the surgical treatment of empyema in the vast majority of children who require operative intervention.

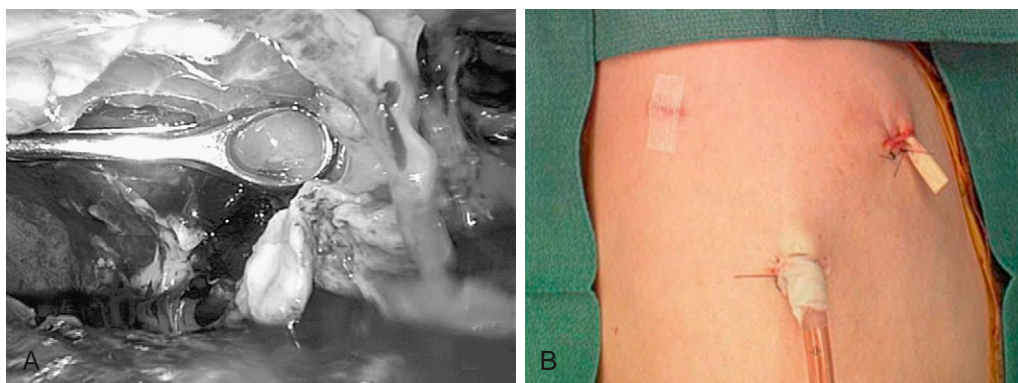

In the past several years, there have been a number of reports describing the effective use of fibrinolytic therapy to facilitate evacuation of the pleural space

in children with empyema.<sup>21-32</sup> Initially, streptokinase and urokinase were used for this purpose. More recently, tissue plasminogen activator (tPA) has been the principal agent utilized. Recently, two prospective randomized trials comparing fibrinolytic therapy to thoracoscopic debridement and decortication have been completed.<sup>31,32</sup> The study designs for each of these two trials were very similar. The primary difference was that tPA was used for fibrinolysis in the Kansas City trial<sup>31</sup> and urokinase was used in the London trial.<sup>32</sup> In comparing the two treatment groups, there was no significant difference in length of hospitalization after initial intervention (fibrinolysis or thoracoscopy), days until the patient was afebrile, days of oxygen therapy, or the number of doses of analgesics. The primary difference was in the statistically significant higher cost involved with the thoracoscopy group. Interestingly, the excess cost was almost identical for each study. Failure of fibrinolysis occurred in 16% in both randomized trials. These patients then required thoracoscopic debridement.

Based on this level 1 evidence showing fibrinolytic therapy to be as effective and less costly than thoracoscopy, we have changed our treatment algorithm and have begun initially treating these patients with fibrinolytic therapy. In our own clinical experience, children in whom residual pleural fluid loculations are confirmed radiographically after placing a chest tube receive 3 days of intrapleural fibrinolytic therapy. Alteplase (Genentech Inc, San Francisco, CA) (0.1-0.2 mg/kg), a tPA produced by recombinant DNA technology, is mixed with 60 mL of saline and injected into the chest cavity through the chest tube. The tube is not clamped and is left open to underwater seal. If residual fluid remains at the completion of this 3-day trial of fibrinolytic therapy, these patients proceed to thoracoscopic debridement and decortication.

## Outcomes

Despite the complex nature of this disease process, and the need to individualize patient care, the overall morbidity and mortality is relatively low. Patients

**Figure 23-6.** Over the past decade, most surgeons have utilized thoracoscopy for surgical management of empyema. **A**, Often, sponge forceps can be placed directly through the incisions to extract the inflammatory debris. **B**, In the postoperative photograph, three 8- to 10-mm incisions have been used for the thoracoscopic debridement. The chest tube is exteriorized through the most inferior incision. A small Penrose drain has been placed in one of the incisions because this was the site of a catheter that had been placed by the pediatric service for drainage of the empyema.

rarely have significant sequelae if treated successfully, although some reports indicate chronic pleural scarring and restrictive pulmonary pathophysiology as the result of a prior history of empyema.<sup>2</sup> The outcomes appear similar for initial fibrinolytic therapy as with thoracoscopy, but fibrinolytic therapy is more cost effective. However, 10% to 20% of patients initially treated with fibrinolysis will require thoracoscopic debridement.<sup>31,32</sup>

## BRONCHIECTASIS

First described by Laënnec in 1819,<sup>33</sup> bronchiectasis is defined as a permanent dilatation of segmental airways and continues to be cited as the cause for a significant number of deaths due to respiratory insufficiency. In 1950, Reid described three pathologic forms of bronchiectasis: saccular, cylindrical, and fusiform (or varicose).<sup>34</sup> Saccular bronchiectasis tends to occur in third- and fourth-order bronchioles, whereas cylindrical bronchiectasis occurs in sixth- to seventh-order bronchioles. The fusiform variety has an intermediate type of pathology and involvement. Many forms of cylindrical bronchiectasis are largely reversible with control of the underlying infection and probably should best be referred to as “pseudobronchiectasis.” As better treatment paradigms have been established, the frequency of bronchiectasis has decreased significantly in the industrialized world, although it continues to be a major problem in developing nations.

### Pathogenesis

Bronchiectasis should not be thought of as a diagnostic entity in itself. Rather, the term refers to the morphologic abnormalities that represent the final common pathway of a variety of conditions causing long-standing pulmonary inflammation. The etiology of bronchiectasis can be divided into congenital or acquired, depending on the source and cause of the inflammation (Table 23-2). Most patients with congenital causes are found to have bilateral disease, whereas most patients with acquired bronchiectasis present with only unilateral disease. Although the disease process may involve any pulmonary segment, it is most commonly encountered in the left lower lobe or lingula or in the right middle lobe. A specific cause for the development of bronchiectasis is found in less than 40% of patients. Recent series indicate that about 50% of those patients in whom a specific cause is determined developed their first pulmonary insult before age 14 years.<sup>35,36</sup>

The bronchial dilatation develops after destruction of the elastic lamina and muscularis of the bronchial walls, secondary to recurrent infection. The pathologic process usually begins with impaired pulmonary clearance of mucus and bacteria and results in an increased endoluminal pressure. Migration of leukocytes into the bronchial lumen leads to degranulation and release of tissue-damaging oxidants, neutrophil elastase, and myeloperoxidases, in addition to the inflammatory cytokines TNF- $\alpha$ , Interleukin (IL)-8, and IL-6.<sup>37</sup> The ciliated epithelium is destroyed, leading to an increased

**Table 23-2** Congenital and Acquired Conditions Associated with the Development of Bronchiectasis

#### *Congenital*

#### *Acquired*

Pneumonia  
Repeated aspiration (gastroesophageal reflux disease)  
Sequestration  
Tuberculosis  
Airway foreign body  
Endobronchial tumor  
Smoking  
Human immunodeficiency virus infection

propensity for recurrent infection. Repeated localized infection leads to replacement of the ciliated epithelium by squamous epithelium and loss of the supporting cartilage, allowing further bronchial inflammation and dilatation.

The overall incidence of bronchiectasis in the United States has declined progressively since the 1950s. This has been attributed to the widespread use of bacterial and viral immunizations in childhood and aggressive antibiotic treatment of pulmonary infection. The near elimination of tuberculosis in this country is also considered a factor in this decline. Conversely, there is a suggestion that the incidence of bronchiectasis is beginning to increase in children as fewer are uniformly vaccinated and resistant strains of tuberculosis are being encountered more frequently. An accelerated form of bronchiectasis has been described in patients with HIV infections.<sup>38</sup>

### Clinical Presentation and Diagnosis

Children with active bronchiectasis initially appear with systemic signs of infection such as fever, fatigue, and anorexia. This presentation is often accompanied by a productive cough, pleuritic chest pain, and hemoptysis. Physical examination usually reveals coarse inspiratory crackles and expiratory wheezes. Because few specific signs of bronchiectasis exist, the diagnosis often is delayed. The initial diagnostic workup should include a chest radiograph. Although this is sensitive for the diagnosis of bronchiectasis in only 50% of patients, it may show focal increase and “crowding” of interstitial markings. In diffuse, long-standing disease, a coarse honeycomb appearance may be seen (Fig. 23-7). For many years, the specific diagnosis of bronchiectasis depended on the performance of bronchography, a relatively invasive test in children. In the past decade, high-resolution CT scans have replaced bronchography for this purpose. Modern thin-section CT scans have more than a 90% correlation with bronchographic findings.<sup>39</sup> The characteristic changes

**Figure 23-7.** A, Chest radiograph demonstrating the classic appearance of bronchiectasis in a pediatric patient with cystic fibrosis. B, Magnified view of patient in A demonstrating honeycombed appearance.

on thin-section CT include focal regions of volume loss and vascular crowding, “ring shadows” of dilated bronchi sectioned on end, bronchoarteriolar ratios less than 1, loss of bronchial tapering, and visualization of bronchi within 1 cm of the pleural surface. Of these findings, the presence of bronchi within 1 cm of the pleural surface appears to correlate best with bronchographic findings.<sup>40</sup> Additional types of CT studies that may be useful in evaluating patients with bronchiectasis include inspiratory-expiratory CT, which can give insights into the pathophysiologic processes involved; spiral CT and virtual bronchoscopy, which may allow better visualization of peripheral bronchi; and CT angiography, which may demonstrate neovascularization of the chronically inflamed bronchi.

## Therapy

The best therapy for bronchiectasis involves prevention of the disease by aggressively treating recurrent pulmonary infections. The development of bronchiectasis may be inevitable in children with congenial causes such as cystic fibrosis or ciliary dyskinesia, but the disease in those patients with acquired causes should, for the most part, be preventable. Aggressive treatment of children with recurrent pulmonary infections should be accomplished with targeted antibiotic therapy and pulmonary physical therapy. A high index of suspicion must be maintained for bronchial obstruction, either by foreign body or endobronchial tumors, and bronchoscopy plays an important role in the early management of these children.

Pulmonary resection is reserved for those children who have repeated localized involvement despite adequate medical therapy. The absence of vascular perfusion, as determined by either angiography or perfusion nuclear scans, is an indication for operation for end-stage disease.<sup>40</sup> Those patients will generally experience a good operative result. Patients with perfused segments may have reversible, cylindrical bronchiectases and should probably continue to receive medical management. Occasionally, massive hemoptysis will be the indication for surgical resection, although embolization of bronchial vessels using interventional radiology may eliminate resection as an emergency procedure.

The principles of surgical therapy should be to preserve uninvolved pulmonary tissue by the liberal use

of segmental pulmonary resection.<sup>41</sup> On the other hand, resection of all diseased segments is critical for a successful operative result, including staged bilateral thoracotomy, if necessary. Care must be taken to avoid contamination of the dependent lung while the patient is in the lateral decubitus position. The use of bifurcated endotracheal tubes or cuffed tubes with main-stem bronchial blockers is recommended.<sup>42</sup> Hacıbrahimoglu and colleagues described the operative results of pulmonary resection in 35 children with bronchiectases treated at their institution between 1985 and 2001.<sup>43</sup> Eleven percent of these children had pulmonary tuberculosis. The average age at thoracotomy was 10.6 years, and 68.5% of the patients had cylindrical bronchiectases. There was a single death in this series. Follow-up studies revealed that 64.7% of the children were asymptomatic and 23.5% were significantly improved clinically. About 12% had no clinical improvement. The authors stress the importance of careful selection of patients and complete resection of the disease. It is generally conceded that surgical outcomes are better in younger patients. Finally, thoracoscopic lobectomy for acquired disease is becoming more frequently utilized.

## Outcomes

While resolution of bronchiectasis may be anticipated with effective treatment of the underlying infectious process, patients with chronic underlying pulmonary diseases, such as cystic fibrosis, are likely to experience less favorable outcomes. In addition, outcomes may also be influenced as a result of the specific infectious organisms and treatment regimens.<sup>44</sup> Most of these patients are found to have significant airway obstruction that progresses over time. Pulmonary function studies indicate intrathoracic airway obstruction of the medium to small airways associated with hyperinflation. Sophisticated studies indicate an increased residual volume and a reduced FEV<sub>1</sub> in these patients.<sup>44</sup>

## LUNG ABSCESS

Lung abscess in the pediatric population is considered to be relatively rare and typically results from an infection with mixed aerobic and anaerobic flora.

The treatment of a lung abscess in an infant or child follows the same basic principles of postural drainage and pulmonary toilet used in adults, but it is more often ineffective, secondary to the small airway size.<sup>45,46</sup>

## Pathogenesis

The etiologic conditions associated with formation of a primary pulmonary abscess are not clearly identified in many cases. Associated events include aspiration of gastric contents, operations involving the upper respiratory tract, foreign body aspiration, or prolonged unconsciousness.<sup>47,48</sup> In addition, formation of a lung abscess may be associated with a preceding necrotizing pneumonia characterized by a significant degree of necrosis.<sup>46</sup> The resulting inflammation leads to the formation of a cavity surrounded by a thick fibrous wall.

As in adults, the development of a lung abscess in a child is the result of contamination with a mixed spectrum of both aerobic and anaerobic organisms. Specifically, one or more species of anaerobic oral bacteria, along with *Staphylococcus*, *Streptococcus*, or gram-negative enteric organisms, are recovered from culture of the airway and/or abscess fluid. The most commonly recovered organisms include *S. aureus*, *Streptococcus viridans*, group A hemolytic *Streptococcus*, *S. pneumoniae*, and *H. influenzae*. Less commonly encountered species include *Escherichia coli*, *Pseudomonas*, *Klebsiella*, *Peptococcus*, and *Peptostreptococcus*.

## Clinical Presentation and Diagnosis

The presentation of a pediatric patient with a lung abscess is characterized by tachycardia, fever, malaise, pleuritic chest pain, and a productive, often foul-smelling cough. Underlying disorders may include an immunocompromised state, severe neurologic impairment, chronic lung disease, or poor oral hygiene. When a lung abscess is encountered in infants, underlying conditions such as congenital cystic adenomatoid malformation, bronchogenic cysts, or airway foreign bodies should be suspected. In older children, an intralobar pulmonary sequestration should be evaluated as a potential etiologic factor.

Most primary lung abscesses are located in the posterior segment of the right upper lobe and the superior segments of the right and left lower lobes. In contrast, secondary and/or recurrent collections may be found in multiple locations with no specific anatomic predilection. Chest radiographs are often nondiagnostic during the early phase of development but can go on to reveal striking abnormalities, including cavitory lesions with or without associated air-fluid levels. In a recent study, the etiologic organisms were identified in most cases of lung abscess (82%) despite prior use of antibiotics.<sup>49</sup> Immunocompromised children developing lung abscesses often grow fungal organisms and require more aggressive therapy.<sup>46</sup>

## Therapy

As with any abscess, the therapeutic goal is centered on establishing adequate drainage. Unlike in the adult patient, however, the use of postural drainage in the treatment of lung abscesses in infants and children, along with coughing and chest physiotherapy, is less effective. This observation is thought to be due to smaller airways and less effective patient-driven pulmonary toilet (i.e., purposeful coughing and incentive spirometry). In addition, bronchoscopy, with direct catheter suction and irrigation of the cavity, has been recommended as a diagnostic and therapeutic modality, often producing excellent results.<sup>42</sup> In concert with these maneuvers, a prolonged course (2 to 3 weeks) of broad-spectrum antibiotics is also needed.

Bacterial organisms recovered from most cases of lung abscesses have been susceptible to penicillin, although antibiotic-resistant organisms are being found more frequently. Improved results can usually be achieved by a combination of ampicillin and metronidazole or clindamycin. Although the typical antibiotic regimen is administered intravenously throughout the hospital stay, completion of the prescribed course in an outpatient setting with oral antibiotics is often successful and has not been shown to result in an increased incidence of recurrent disease.

In patients who fail medical therapy, more invasive surgical intervention may be required. The procedure of choice for a solitary abscess located directly beneath the parietal pleura is pneumonostomy. Alternatively, thoracotomy and pulmonary resection may be required for abscesses that are more centrally located.<sup>46,47</sup> Patients with fungal isolates and immunocompromised patients generally require early and aggressive pulmonary resection.

## Outcomes

As described previously, successful management of a lung abscess is based on adequate drainage in combination with long-term antibiotic therapy. Resolution of the infectious and inflammatory processes can be seen over a period of several weeks. Although unusual, recurrence of a lung abscess at the site of the primary lesion can occur if the underlying cause persists (e.g., poorly treated gastroesophageal reflux in a nonambulatory patient). The mortality associated with primary lung abscess in immunocompetent children is very low. Increased complications and less favorable outcomes are seen, however, in immunocompromised individuals and in the neonatal population.

## CHYLOTHORAX

Chylothorax, defined as an abnormal collection of lymphatic fluid within the pleural space, is rare and may be encountered at any age. First described as a clinical entity by Asellius in the 17th century,<sup>50</sup> chylothorax typically occurs during infancy and childhood and is seen less often in adults.

## Pathogenesis

Although the exact course of events responsible for the development of many chylous effusions remains uncertain, related pathophysiologic factors are often subcategorized as being traumatic or nontraumatic in origin. Potential traumatic events include a multitude of potential iatrogenic causes secondary to thoracic surgical procedures, penetrating thoracic injuries or crush wounds, and injuries related to the birth process (presumably secondary to hyperextension of the spine). Nontraumatic causes associated with chylous effusions include various congenital abnormalities (i.e., lymphangiomatosis), venous thrombosis (which also may be associated with traumatic causes), and mediastinal and thoracic infections or malignancies.

During the neonatal period, the development of a chylous effusion has been commonly referred to as spontaneous and/or congenital. Although presentation during this early period has been associated with various dysmorphic syndromes, most cases have no identifiable etiology. In these patients, it is presumed that the formation of a chylous effusion is the result of a structural defect involving the lymphatic vessels.<sup>51,52</sup> Although reports of nontraumatic chylous effusions in the postneonatal period have been reported, traumatic causes, as described earlier, are far more common. Injury to the main thoracic duct as well as to major tributaries has been reported as a result of both blunt and penetrating thoracic trauma, with an incidence of as high as 0.9% after cardiac surgery in children.<sup>53</sup>

## Clinical Presentation and Diagnosis

Chylothorax typically presents as significant respiratory distress. However, it may be encountered as an incidental finding during routine prenatal ultrasonography or while obtaining a thoracic imaging study for other indications. In the case of postoperative chylothorax, a seemingly unremarkable postoperative effusion may rapidly increase once enteral nutrition is resumed, raising the suspicion of an injury to the thoracic duct and/or the network of intrathoracic lymphatic vessels. In addition to the obvious respiratory embarrassment that can occur as a result of the accumulation of significant volumes of fluid within the thoracic cavity, prolonged loss of chyle results in severe nutritional deficiencies, immunologic disturbances, and electrolyte derangement.

The diagnosis of chylothorax is established by using fluid analysis. The gross appearance is typically described as “milky,” although straw-colored fluid is often encountered in patients who are not being fed. Chylothorax should be considered if the pleural fluid is noted to contain a total fat content greater than 400 mg/dL, triglycerides greater than 200 mg/dL, or a specific gravity greater than 1.012. In addition, Gram stain analysis demonstrates the presence of more than 90% lymphocytes and Sudan red staining may reveal the presence of chylomicrons.<sup>54</sup>

The term *pseudochylothorax* refers to the circumstance of a prolonged (i.e., several weeks) pleural effusion,

which may have a milky appearance, and elevated triglyceride levels. In the patient with no obvious risk factors for true chylothorax, this entity may be differentiated by using lipoprotein electrophoresis.<sup>55</sup>

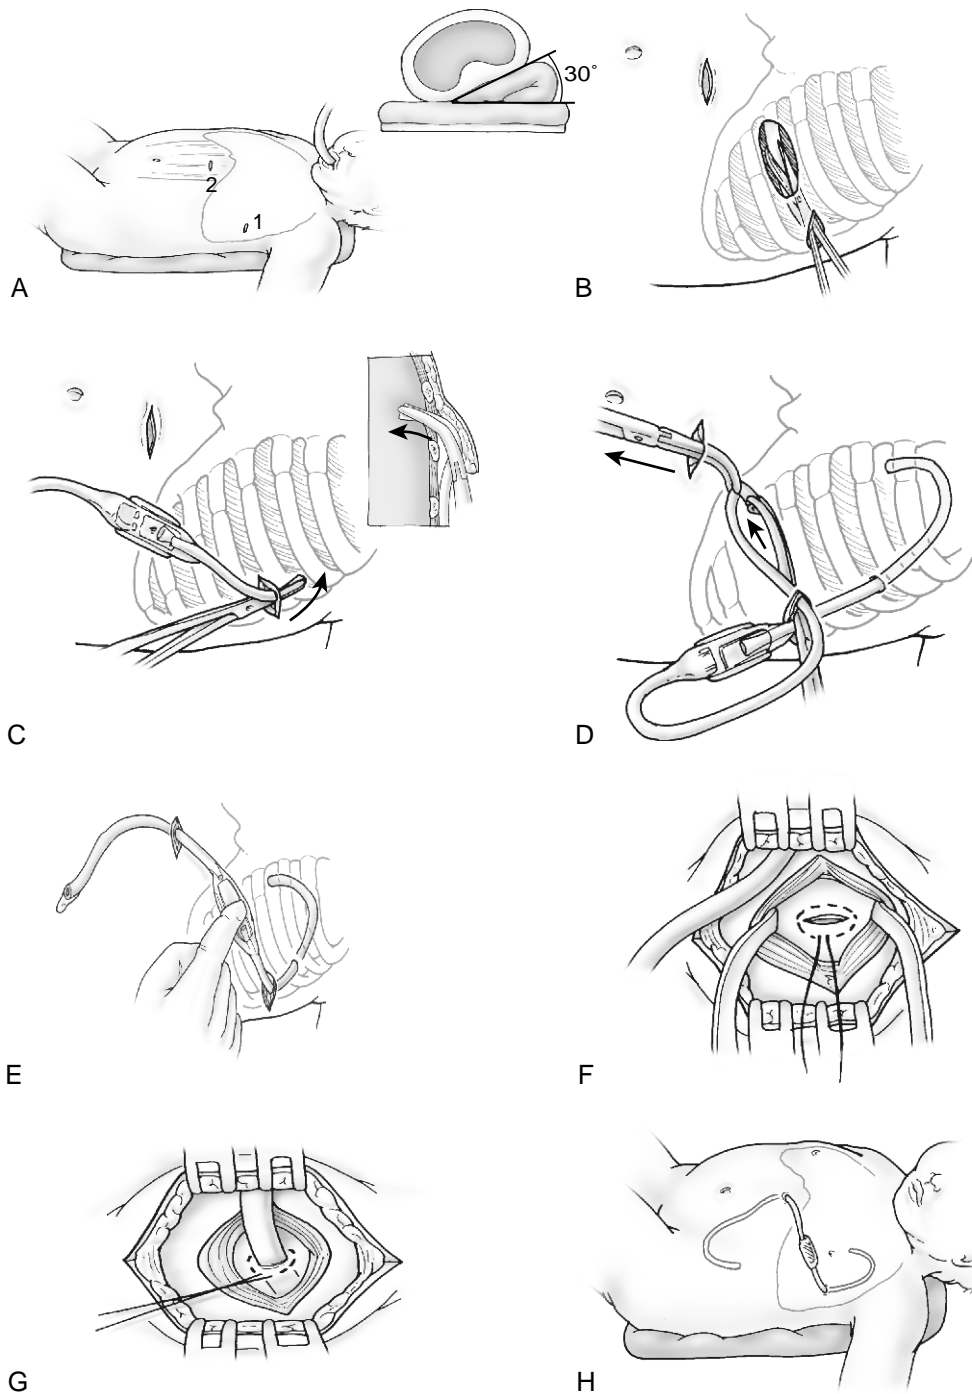

## Therapy

Treatment of chylothorax has traditionally been nonoperative. As many as 80% of patients respond to conservative management.<sup>54</sup> Most treatment algorithms are based on adequate drainage of the pleural fluid in combination with attempted trials of dietary modifications. Although no strict guidelines exist, many authors recommend several attempts at draining chylous fluid using thoracentesis. With persistent reaccumulation, however, formal chest tube drainage is needed.

The use of medium-chain triglyceride (MCT)-based formulas, with a high protein content, leads to spontaneous resolution in some patients. The success of this management is thought to be the result of effectively reducing the amount of chyle produced while still providing adequate nutrition. This is the result of preferential absorption of MCT into the portal venous system rather than into the intestinal lymphatic network. The resultant reduction in chyle formation is thought to improve the likelihood of achieving spontaneous resolution. In cases in which this therapeutic approach fails, many physicians use complete cessation of enteral feeds along with the concurrent administration of total parenteral nutrition (TPN).

Because considerable volumes of pleural fluid can be lost daily (representing large amounts of protein and lymphocytes), vigorous efforts to replenish these losses, typically with albumin, are needed to avoid the development of severe nutritional and hemodynamic derangements. In addition to drainage of the pleural space in combination with dietary interventions and/or TPN, recent literature supports the use of somatostatin in the treatment of ongoing chylous effusions.<sup>56,57</sup> Although the exact mechanism of action is not understood, these reports cite the reduced need for surgical intervention, the potential for early return to enteral feeding, and shorter overall hospitalization with minimal side effects. Although the majority of such reports cite the use of somatostatin analogs in the treatment of postsurgical chylous effusions, recent experience, including that of the authors, suggests a potential role for its use in the case of spontaneous chylothorax as well.<sup>57-59</sup>

If nonoperative therapy fails to stop the lymphatic drainage, several surgical options are available. The ideal timing of such operative interventions remains unclear. Most authors advocate a trial of nonoperative therapy for only 5 to 14 days before considering surgical intervention.<sup>54</sup> The principles of operative intervention focus on attempts to ligate the thoracic duct or obliterate areas of leakage either directly (if visualized) or by pleurodesis.<sup>60</sup> Moreover, they are dictated by the nature of the chylothorax (i.e., traumatic or nontraumatic). Many of these patients are now managed with thoracoscopy. Right thoracoscopy with occlusion of the thoracic duct as it crosses the

**Figure 23-8.** Insertion of pleuroperitoneal shunt. **A**, The affected hemithorax is elevated 30 degrees. The two incisions are planned to allow the pump chamber to rest on the costal margin. **B**, A small incision is made over the rib in the anterior axillary line, and a deep subcutaneous pocket is created inferiorly. **C**, Insertion of pleuroperitoneal shunt into the pleural space is done with a large curved clamp. The pleural catheter is tunneled 2 to 3 cm and bluntly passed through the intercostal space. The catheter must be carefully passed through the intercostal muscle at an angle to avoid kinking. **D**, A second small incision is made overlying the rectus muscle, and the peritoneal catheter is tunneled through this incision. The distal end of the shunt device is delivered to the second incision, as shown. The pumping chamber is drawn into the subcutaneous pocket by traction on the peritoneal catheter. **E**, The flow of chyle is confirmed before the distal catheter is inserted into the peritoneum. **F** and **G**, A purse-string suture is used to secure the peritoneal catheter at the level of the posterior rectus fascia. **H**, Both incisions should be closed with an absorbable suture, leaving a totally implanted system. (From Murphy M, Newman B, Rodgers B: Pleuroperitoneal shunts in the management of persistent chylothorax. *Ann Thorac Surg* 48:195-200, 1989.)

diaphragm has been shown to be a useful technique in patients with traumatic disruption of the thoracic duct after an operation.<sup>61,62</sup> Others have described direct suture of the area of chylous leak with the concurrent application of fibrin glue.<sup>63</sup> The use of a pleural-peritoneal shunt has been advocated as a less invasive technique to manage refractory chylothorax (Fig. 23-8). In these patients, pleural chyle is manually pumped into the peritoneal cavity where it is absorbed, presumably into the venous system.<sup>64</sup> These shunts are left for 3 to 4 months until the chylous leak seals. Recently, a technique of percutaneous injection of the cisterna chyli with platinum coil embolization of the thoracic duct has been utilized for adults with refractory chylous effusions. This technique has proven to be remarkably successful and probably would be applicable for use in adolescents but not infants. Cope has described a greater than 70% success rate with this technique in patients with high-output chylothorax in whom conservative therapy has not been successful.<sup>65</sup>

### Outcomes

Because of the relatively small number of cases in the current literature, the natural course of childhood chylothorax and the exact success rate of non-surgical therapy in the pediatric age group remain unclear. Despite this, however, most patients appear to be successfully treated with pleural drainage and a combination of dietary intervention and/or TPN and somatostatin. Most authors agree that a relatively short period of nonoperative therapy should be tried before an operation is considered.

## TUBERCULOSIS

Tuberculosis (TB) is a virulent pulmonary infection caused by *Mycobacterium tuberculosis*. Primary pulmonary infection with atypical mycobacterial organisms is rare in children. After several decades of dramatic reduction in the frequency of pulmonary TB, particularly in the United States, a worldwide increase is now being seen. In 1993, the World Health Organization declared pulmonary tuberculosis “a global emergency.”<sup>66</sup> In 1995, pulmonary TB caused more fatalities worldwide than any other infectious disease. It is currently estimated that about one third of the world’s population is inoculated with TB.

The incidence of pulmonary TB in the United States has shown a progressive increase over the past 2 decades for a number of reasons, including immigration of individuals from countries with a high incidence of infection, increasing incidence of HIV infection, increasing intravenous drug abuse, and a general worsening of social conditions in many of the larger cities.<sup>66</sup> Children, particularly in the younger age groups, are at high risk, often living in close contact with infected adults. Pulmonary TB in young children is usually the primary form of the disease, whereas adolescents tend to have reinfection TB and lung cavitation.

## Clinical Presentation and Diagnosis

The diagnosis of pulmonary tuberculosis in children can be quite difficult. The patient may remain asymptomatic throughout much of the early phase of the disease, and bacteriologic confirmation can be difficult. Adequate sputum collection in young children is difficult, and gastric washings demonstrate *M. tuberculosis* organisms in only about 30% of the cases. Primary diagnosis is highly dependent on abnormalities noted on chest radiographs and by surveying patients living in close contact with infected adults. Seventy-five to 90 percent of these patients will be noted to have pulmonary opacities due to parenchymal involvement that tend to be more heavily concentrated in the subpleural location.<sup>67</sup> Eighty-five to 90 percent of these children will be noted to have hilar or subcarinal lymphadenopathy on plain chest radiographs (Fig. 23-9).<sup>68</sup> Calcification of these nodes is rarely seen. Liberal use of CT scans may facilitate identification of these pathologic changes. Cavitory disease, so common in adult patients with pulmonary TB, is rarely seen in infected children in the first 5 years of life but becomes more common in adolescents, presumably from reinfection. Approximately 60% of adolescents with TB will be noted to have cavitory disease in one or the other of the upper lobes on a chest radiograph.<sup>69</sup> Bacterial confirmation of pulmonary TB also is easier in the adolescent. A suggestion of pulmonary TB on a chest radiograph should be supported by a skin test.

The incidence of pulmonary TB is greatest in patients with compromised immunity, such as bone marrow transplant patients, diabetics, and those with HIV infection.<sup>70</sup> Symptoms may be variable and radiologic changes more dramatic among the immunocompromised subpopulation. The mortality of HIV-infected patients with pulmonary TB approximates 70%.<sup>71</sup>

**Figure 23-9.** Chest radiograph of a 12-year-old girl with pulmonary tuberculosis demonstrates bilateral hilar infiltrates.

## Therapy

First-line therapy for patients with pulmonary tuberculosis consists of multidrug antibiotic therapy. A 6-month course of isoniazid and rifampin forms the basis for most antibiotic regimens. This may be supplemented with 2 months of pyrazinamide. These drugs appear to have an acceptable toxicity spectrum in children. Isoniazid causes changes in liver enzymes in children much less commonly than in adults. In otherwise normal children who are compliant with this regimen, a 100% cure rate should be expected. Drug treatment should be initiated as soon as the diagnosis is confirmed because a delay in treatment has been linked to increased mortality.<sup>71</sup>

Surgery for pulmonary TB in children is generally indicated to treat complications and to reduce the bacillary load.<sup>72,73</sup> In younger patients, enlargement of hilar and subcarinal lymph nodes can cause bronchial obstruction with distal atelectasis. In these patients, in addition to adding a fourth antibiotic, usually streptomycin or ethambutol, a short course of prednisone (2 mg/kg/day) may be beneficial.<sup>74</sup> Serial chest CT scans can be used to monitor the progress of this disease and its response to therapy. These scans also identify those patients with endobronchial extension of the disease who may be helped by bronchoscopy. If corticosteroids and antibiotics fail to relieve the bronchial compression, these patients should have a thoracotomy/thoracoscopy with partial resection of the hilar and subcarinal nodes to relieve the airway compression.<sup>74</sup> Actual pulmonary resection should be avoided in these young children. Indications for surgical treatment in adolescents with cavitary disease include continued positive sputum cultures after 6 months of appropriate antibiotic therapy and massive hemoptysis. In all of these patients, operative management can be very challenging because of the degree of scarring from the chronic infection. Blood loss may be substantial.<sup>75</sup>

In the past decade, the emergence of antibiotic-resistant strains of *M. tuberculosis* organisms has become problematic. By definition, these organisms are resistant to isoniazid and rifampin, significantly limiting options for therapy. Currently, drug-resistant *M. tuberculosis* is the primary indication for TB surgery in the United States.<sup>76</sup> Although primary infection with drug-resistant organisms in young children has not yet been reported, such infection in adolescents has been encountered.

## HISTOPLASMOSIS

The lung is the most commonly involved site of clinical infection from endemic fungal organisms in North America, which include *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides*.<sup>77</sup> Histoplasmosis, a thermal dimorphic fungus found in mold within the soil, has a nearly worldwide distribution, with endemic concentrations in the eastern half of the United States and a large proportion of Latin America.<sup>77</sup> The presence

of a large concentration of bird and bat feces within the soil of these areas appears to be associated with endemic or hyperendemic rates of infection. Manipulation of this infected soil can result in airborne dissemination and infection of individuals with no other obvious source of exposure. Although outbreaks of histoplasmosis have been attributed to specific sources in the past, the fact that airborne spores can travel considerable distances is thought to be responsible for the majority of current cases having no obvious source of exposure.<sup>78,79</sup>

## Pathogenesis

The majority of infections are mild or completely asymptomatic and associated with patchy infiltrates on chest radiographs. After being inhaled into the lungs, *H. capsulatum* spores germinate into yeast forms and result in an influx of macrophages, neutrophils, and T cells. T-cell immunity typically develops 10 to 14 days after the initial exposure and is responsible for the typically self-limiting process observed among immunocompetent individuals. Although primary infection and subsequent T-cell immunity does provide some degree of protection, reinfection and/or reactivation may occur.<sup>77</sup>

## Clinical Presentation and Diagnosis

The incubation period ranges from 1 to 3 weeks and may result in an acute clinical infection. Alternatively, the patient may be completely asymptomatic. The majority of symptomatic patients have a “flu-like” illness consisting of general myalgia, malaise, a non-productive cough, headache, and fever. Progressive or diffuse disease is encountered in patients with some element of immune compromise. Chest radiographs during acute infection typically show diffuse, often bilateral, infiltrates. Cavitation and miliary processes may be observed as a result of chronic infection. As seen in [Figures 23-10](#) and [23-11](#), hilar adenopathy may be observed in both acute and chronic disease states.

**FIGURE 23-10.** Chest radiograph of a child with histoplasmosis demonstrates hilar lymphadenopathy.

**Figure 23-11.** This CT scan of the chest demonstrates hilar lymphadenopathy secondary to pulmonary histoplasmosis.

Intraoperative specimens often appear to be firm and rubbery, making them grossly indistinguishable from lymphadenopathy secondary to other infectious and noninfectious causes. Less common manifestations include acute overwhelming pulmonary infections, fibrosing mediastinitis, pericarditis, and enlargement of mediastinal lymph nodes. These processes can result in dysphagia, pleuritic chest pain, airway obstruction, and superior vena caval syndrome. Surgical intervention in the cases of major vascular and airway obstruction is hazardous. It should be considered only in severe cases in which medical therapy has failed to improve the patient's condition.

## Therapy

As previously mentioned, the majority of immunocompetent patients experience a self-limiting process and, therefore, require only supportive therapy. Treatment with antifungal agents is typically reserved for patients who have persistent symptoms (longer than 2 to 3 weeks) or demonstrate progressive disease based on serial radiologic examinations. Itraconazole has been used for treatment of mild persistent disease. Amphotericin B is strongly recommended for patients with more severe manifestations of histoplasmosis, followed by oral itraconazole or ketoconazole after achieving an adequate clinical response. Operative intervention may be required for constrictive pericarditis or to relieve obstructive airway and/or vascular complications from the disease process.

## DIFFUSE INTERSTITIAL DISEASE

Chronic interstitial lung disease (ILD) may result from infectious as well as noninfectious processes (Table 23-3). It is characterized by restrictive lung physiology and abnormal gas exchange that produces considerable morbidity and mortality. The list of differential diagnoses to consider in the etiology of diffuse ILD comprises more than 100 separate conditions in both adults<sup>80</sup> and children.<sup>81,82</sup> The clinical disease patterns range from a chronic, slowly progressive picture in a relatively stable patient to one of acute pulmonary decompensation, requiring emergency lifesaving maneuvers. Sorting through the potential causes may

 Pulmonary hemosiderosis

delay treatment, and the ability to establish a specific diagnosis can be time consuming and difficult. It is not uncommon for pediatric surgeons to be involved in such cases to help establish the correct diagnosis with lung biopsy. Prompt diagnosis, especially in the case of immunocompromised or otherwise debilitated children, may require an urgent lung biopsy to guide further therapeutic interventions. The importance of such information cannot be overemphasized. In the case of an extremely unstable patient, the use of thoracoscopy and/or thoracotomy may be needed, even in the intensive care unit setting, to obtain the necessary tissue specimens. In addition, surgical intervention may be required to deal with respiratory failure. In severe cases of acute respiratory compromise, a pediatric surgeon may also be asked to insert the cannulas for extracorporeal membrane oxygenation. In addition, the need for long-term ventilatory and prolonged airway management may require the creation of a tracheostomy.

## Pathogenesis

Although the precise pathophysiology responsible for the development of ILD remains poorly understood, current evidence suggests that the processes responsible for its development are related to inflammation at the level of the interstitial and perialveolar tissues.

This common feature appears to explain the presence of similar histologic, radiologic, and clinical characteristics among a heterogeneous group of pulmonary disorders.<sup>81</sup> Histologic evidence suggests that the establishment and subsequent progression of the interstitial process involves injury to both epithelial and endothelial structures.<sup>83</sup> Furthermore, recent studies have focused on the potential of a genetic determination in ILD, hypothesizing the existence of an aberrant immunologic defect(s), which results in a failure of the normal immunomodulatory and mucociliary functions. This paradigm results in a predisposition for development of a pathologic interstitial pulmonary process.<sup>84</sup>

## Clinical Presentation and Diagnosis

As discussed previously, the spectrum of ILD can be quite varied. Studies have attempted to correlate survival with associated symptoms and the physical examination. Determinants evaluated for correlation with survival include the patient's age, weight, duration of symptoms, presence of crackles on auscultation of the lung fields, clubbing of fingers, and severity-of-illness score (Table 23-4).<sup>84</sup>

The task of establishing the correct diagnosis relies on the combined results of several diagnostic modalities, such as radiologic studies, bronchoalveolar lavage, and lung biopsy. Although the use of plain chest radiographs can offer the ability to follow disease progression, chest films offer little specific diagnostic and/or prognostic information. One study of 39 adult patients with pulmonary fibrosis demonstrated a possible correlation between disease severity (as measured by standard pulmonary function testing) and high-resolution CT images.<sup>85</sup> Practical applications of such observations are less clear in the pediatric population.

The results of bronchoalveolar lavage are disappointing. In a prospective analysis of children with ILD undergoing bronchoalveolar lavage, a definitive primary diagnosis was made in only 5 (17%) of 29 patients. Although its use provided important information overall, its ability to determine the primary cause of diffuse ILD was limited.<sup>86</sup>

Several other invasive techniques have been outlined as useful for obtaining lung tissue in an effort

to establish the diagnosis. These techniques are generally well tolerated and include percutaneous needle biopsy, transbronchial lung biopsy, open-lung biopsy, and thoracoscopy for biopsy. Although the use of lung biopsy has been considered the most definitive method for diagnosis, it has been found to be nondiagnostic in as many as 30% of patients.<sup>86</sup> In addition to the modalities described, more-focused diagnostic modalities such as radiologic evaluation for gastroesophageal reflux disease should always be considered in newly diagnosed cases because gastroesophageal reflux disease has been cited as an important contributory process that should not be overlooked in children.<sup>87</sup>

## Therapy

The therapy for chronic ILD is often challenging and necessitates a detailed and systematic review of all historic, physical, and environmental factors that may help lead to a specific diagnosis. Because pediatric ILD is relatively rare, controlled clinical studies addressing treatment algorithms do not presently exist. The paucity of reliable diagnostic guidelines often leaves the physician with little choice but to initiate a treatment regimen based on what appears to be the most likely diagnosis. Therapeutic interventions can range from simple expectant therapy for mild or self-limited cases to the initiation of complex rescue therapy requiring high-frequency oscillating ventilation and/or extracorporeal membrane oxygenation in the most severe cases. Pharmacologic therapy with various immunosuppressants, administered after confirming the absence of a responsible bacteriologic organism, also is a common practice. Corticosteroids are the most commonly used agents in noninfectious disease, followed by hydroxychloroquine. Less commonly used agents include chloroquine, cyclosporine, colchicines, and methotrexate.<sup>86</sup> In all cases, supportive measures in the form of nutritional and psychosocial support and environmental modification (i.e., avoiding identified irritants or allergens) are important elements in treatment.

## Outcomes

The natural history of chronic ILD that is unresponsive to therapy appears to be progressive fibrosis and resultant failure of the normal gas exchange mechanisms. The morbidity and mortality as well as the long-term outcome associated with chronic ILD vary depending on the associated etiologic factors and existing comorbid conditions. Despite several attempts to identify reliable means with which to monitor the progression of the disease process and the clinical response to therapy, investigators have failed to offer a clear consensus regarding management and outcome issues.<sup>87</sup>

## PNEUMATOCELE

Pneumatoceles are defined as thin-walled, air-filled, intraparenchymal pulmonary cysts and typically occur in association with underlying bacterial pneumonia or

**Table 23-4** Severity-of-Illness Score Correlates Degree of Illness with Overall Survival Rates among Patients with Diffuse Interstitial Lung Disease

Score	Severity of Illness
1	Asymptomatic
2	Symptomatic: room air oxygen saturation normal under all conditions
3	Symptomatic: room air oxygen saturation normal during resting but abnormal (<90%) with sleep or exercise
4	Symptomatic: abnormal resting room air oxygen saturation (<90%)
5	Symptomatic: pulmonary hypertension

as a result of trauma. Although the formation of pneumatoceles is relatively infrequent and has been associated with a variety of underlying bacterial organisms, the majority appear to be the result of staphylococcal pneumonia.<sup>88,89</sup> Other pathogens that have been identified as being associated with pneumatocele formation include *Streptococcus*, *H. influenzae*, *Klebsiella*, *E. coli*, and *Pseudomonas*. In addition, pneumatoceles have been found in cases of pulmonary TB and measles.<sup>90</sup>

### Pathogenesis

Although the exact pathologic mechanisms responsible for the formation of pneumatoceles are uncertain, the development of a severe inflammatory reaction and the subsequent destruction of the alveolar and interstitial architecture have been attributed to the release of bacterial exotoxins. The resulting air leak occasionally culminates in a phenomenon whereby continued accumulation within the thin-walled defect results in the formation of a tension pneumatocele. The development of a tension pneumatocele may potentially compress adjacent structures or rupture into the free pleural space, resulting in a tension pneumothorax. Additional complications associated with pneumatoceles include the establishment of secondary infections, empyema, and bronchopleural fistulas.<sup>91</sup>

### Clinical Presentation and Diagnosis

The clinical presentation and symptoms seen in children with an identified pneumatocele are usually

indistinguishable from those encountered in the case of bacterial pneumonia without associated pneumatoceles. The diagnosis of pneumatoceles is typically made by chest radiograph and/or CT scan. In addition, they have occasionally been confused with simple pulmonary cysts and congenital diaphragmatic hernias. Serial examination and the overall clinical course often help to differentiate pneumatoceles from other pathologic abnormalities.

### Therapy

The majority of pneumatoceles appear to involute over time, requiring no specific therapy other than supportive care and appropriate antibiotic coverage. In the case of a rapidly enlarging and/or tension pneumatocele, resulting in respiratory compromise, urgent decompression may be required. In addition to closed-tube thoracostomy or cystostomy, percutaneous catheter drainage techniques, in combination with fluoroscopy and ultrasonography, have been reported to be an effective means of decompression in such patients.<sup>92,93</sup> Open drainage with decortication and oversewing of the cyst wall is rarely necessary.

### Outcomes

The majority of pneumatoceles decrease in size and resolve over a period of several weeks to months, assuming that the underlying infectious cause is adequately treated. In uncomplicated cases, no residual pulmonary compromise or radiologic sequelae are likely.

# CONGENITAL DIAPHRAGMATIC HERNIA AND EVENTRATION

KuoJen Tsao, MD • Kevin P. Lally, MD

The management and treatment of posterolateral congenital diaphragmatic hernia (CDH) remains a challenge for pediatric surgeons. Despite tremendous advances in prenatal diagnosis, surgical treatment, and neonatal critical care, CDH remains a significant cause of mortality and long-term disability. The clinical challenges lie in the broad spectrum of disease and the relative small volume of patients at individual institutions, resulting in a limited experience with the most severe CDH infants. Although some institutions have become leaders in the treatment, management, and research of CDH, the vast majority will treat fewer than 10 infants with CDH per year.<sup>1</sup> Thus, broad clinical experience is difficult to achieve.

In 1946, Gross reported the first successful repair of CDH in an infant younger than 24 hours old.<sup>2</sup> CDH was considered a surgical emergency, and immediate repair was the practice at that time, with excellent survival rates of greater than 90%.<sup>3</sup> Since then, it has become apparent that such survival rates only included infants who lived to have an operation and did not include those who died before birth or soon thereafter. Accounting for this “hidden mortality” of CDH,<sup>4</sup> actual survival may be closer to 50%.

Although surgical intervention is necessary to repair a CDH, the most recent advances have been in non-surgical therapies. Lung-protective ventilator strategies, extracorporeal membrane oxygenation (ECMO), and preoperative stabilization before surgery have all led to a significant decrease in mortality. In addition, improved understanding of pulmonary hypoplasia and hypertension associated with CDH has led to innovative therapies.

## EPIDEMIOLOGY

The incidence of CDH has been reported between 1 in 2000 to 5000 births.<sup>5-7</sup> In the United States, approximately 1000 infants are born with CDH with a prevalence of 2.4 per 10,000 live births.<sup>8,9</sup> The incidence in

stillborn infants is less clear. An estimated one third of infants with CDH are stillborn and often have other associated congenital anomalies.<sup>10</sup> Presumed to have the most severe form of CDH, infants who die in utero contribute to the “hidden mortality” of the disorder.<sup>11,12</sup>

Isolated CDH infants are typically male with one third having a major congenital anomaly.<sup>8</sup> However, when stillbirths are included, females with CDH tend to be more prevalent than males.<sup>5,13</sup> Approximately 80% of CDHs are left sided. Bilateral defects are rare and are often associated with other major anomalies.<sup>14</sup> Although the exact cause remains unknown, mothers who are thin or underweight may have an increased risk of bearing an infant with CDH.<sup>15</sup>

## GENETICS

Once thought to be only a sporadic isolated anomaly, it is becoming increasingly understood that genetics plays an important role in the development of CDH. A first-degree relative has an expected disease rate of approximately 2%.<sup>16</sup> Several structural chromosomal abnormalities including deletions, translocations, and trisomies have been identified.<sup>17,18</sup> Genetic abnormalities associated with CDH include both anomalies of chromosome number (Turner’s syndrome; trisomies 13, 18, 21, 22, and 23) and conditions with specific chromosomal aberrations (i.e., 15q24-q26 deletions).<sup>19</sup> A gene distal to the 15q21 locus may be important for normal development of the diaphragm.<sup>19,20</sup> Several specific genes have been implicated in the development of CDH based on human and animal studies, including chick ovalbumin upstream promoter-transcription factor II (COUP-TFII), Wilms’ tumor 1 gene (*WT1*), homolog of *Drosophila* slit 3 (*SLIT3*), and Friend of GATA2 (*FOG2*).<sup>21</sup>

CDH may present as an isolated defect or in association with other non-CDH-related anomalies. Several associated anomalies such as lung hypoplasia, intestinal

malrotation, some cardiac malformations, and patent ductus arteriosus are considered to be sequelae of isolated CDH. Non-CDH-related defects involving the cardiovascular, central nervous, gastrointestinal, and genitourinary systems may be a consequence of an underlying field defect of unknown etiology. Non-hernia-related anomalies associated with CDH have been estimated to occur in 40% to 60% of cases.<sup>22,23</sup>

CDH has been associated with over 50 syndromes.<sup>24</sup> In some cases, the diaphragmatic malformation is the predominant defect as in Fryns and Donnai-Barrow syndromes, in which CDH occurs in a high proportion of these patients.<sup>25,26</sup> In other cases, diaphragmatic defects occur in a small percentage but are still greater than the general population as in Simpson-Golabi-Behmel and Beckwith-Wiedemann syndromes. The inheritance patterns for these syndromes include dominant and recessive as well as autosomal and X-linked varieties.<sup>21</sup> Identifying the patterns of non-hernia-related anomalies with CDH and recognizing genetic syndromes are vital in determining the prognosis, treatments, counseling, and outcomes for these infants and their families.<sup>14,18</sup> Other syndromic patterns have been described, including Brachmann-de Lange and Pallister-Killian syndromes.<sup>27-29</sup> If an antenatal diagnosis of CDH is made by fetal ultrasonography, amniocentesis with karyotype and chromosomal analysis is warranted.

## ASSOCIATED ANOMALIES

The impact of associated anomalies with CDH on prognosis and outcome cannot be overstated. Ninety-five percent of stillborn infants with CDH have an associated major anomaly.<sup>5</sup> In addition, more than 60% of infants who do not survive the immediate neonatal period have associated anomalies.<sup>30</sup> Of those infants who survive preoperative stabilization and come to operative repair, less than 10% have additional anomalies.<sup>30</sup> Although the severity of pulmonary hypoplasia and hypertension are the major determinants of overall survival, infants with CDH with another major defect have a greater morbidity and mortality. The survival advantage for infants with isolated CDH is significant compared with those with associated non-hernia-related anomalies (43.7% vs. 7.1%).<sup>22</sup> Because of this dismal outcome, the emphasis on detailed and accurate prenatal diagnosis has influenced the management and treatment of CDH. Twenty percent of prenatally diagnosed CDH infants have a chromosomal anomaly, with 70% having an associated structural malformation. In contrast, only 35% of postnatally diagnosed CDH infants have an associated anomaly.<sup>22</sup>

Non-hernia-related anomalies have been associated with many different organ systems. Cardiac anomalies account for 63% of those identified.<sup>31</sup> Hypoplastic left ventricle with hypoplasia of the aortic arch is the most common cardiac anomaly. Often confused with hypoplastic left heart syndrome, this defect does not have the same impact as hypoplastic left heart syndrome but may exacerbate pulmonary hypertension, right-to-left

shunting, and hemodynamic instability. In addition, other common cardiac defects include atrial septal defects, ventricular septal defects, and other outflow tract anomalies (transposition of the great vessels, tetralogy of Fallot, double-outlet right ventricle, and aortic coarctation).<sup>30,32,33</sup> In a review of 2636 infants with CDH, approximately 15% of infants had an associated cardiac defect.<sup>34</sup> After eliminating those lesions that were deemed hemodynamically insignificant (patent foramen ovale, atrial septal defects, patent ductus arteriosus), only 10.6% of the cohort had significant cardiac lesions in which overall survival was 41.1%, compared with the group with nonsignificant findings (70.2%). Defects within the tracheobronchial tree have been reported, including tracheal stenosis, trifurcated trachea, and tracheal bronchus.<sup>35</sup> Neural tube defects are the most common central nervous system anomaly.<sup>36</sup>

## EMBRYOLOGY

### Diaphragm Development

The embryologic development of the human diaphragm is a combination of complex, multicellular, multiple-tissue interactions that are poorly understood. Precursors to the diaphragm begin to form during the fourth week of gestation. Historically, the diaphragm has been thought to develop from the fusion of four embryonic components: anteriorly by the septum transversum, dorsolaterally by the pleuroperitoneal folds, dorsally by the crura of the esophageal mesentery, and posteriorly by the body wall mesoderm (Fig. 24-1).<sup>37,38</sup> As the embryo begins to develop, the septum transversum migrates dorsally and separates the pleuropericardial cavity from the peritoneal cavity. At this point there is still a communication between the pleural and peritoneal cavities but the pleural and pericardial cavities are separated. The septum transversum interacts with the pleuropericardial folds and mesodermal tissue surrounding the developing esophagus and other foregut structures, resulting in the formation of a primitive diaphragmatic structure known as the pleuroperitoneal fold (PPF). Bound by pericardial, pleural, and peritoneal folds, the paired PPFs separate the pleuropericardial and peritoneal cavities. Eventually, the septum transversum develops into the central tendon.<sup>37-41</sup> Phrenic axons and myogenic cells destined for neuromuscularization migrate to the PPF and form the mature diaphragm.<sup>42</sup>

However, the exact mechanism in which the diaphragm becomes muscularized remains poorly understood. As the PPF develops during the sixth week of gestation, the pleuroperitoneal membranes close concurrently and separate the pleural and abdominal cavities by the eighth week of gestation. Typically, the right side completes closure before the left. Historically, the primitive fetal diaphragm has been thought to become muscularized by the inner thoracic musculature as the diaphragm closes.<sup>43</sup> Some have suggested that the posthepatic mesenchymal tissue

**Figure 24-1.** Historically, the diaphragm has been thought to develop from fusion of its four embryologic components. According to this theory, the septum transversum fuses posteriorly with the mediastinal mesenchyme. The pleuroperitoneal canals (*white arrow*) allow free communication between the pleural and peritoneal cavities. Closure of these canals is completed as the pleuroperitoneal membranes develop. The four embryologic components of the developing diaphragm are shown in cross section. (From Skandalakis JJ, Colborn GL, Skandalakis JE: In Nyhus LM, Baker RJ, Fischer JE [eds]: *Mastery of Surgery*, 3rd ed. Boston, Little, Brown, 1996.)

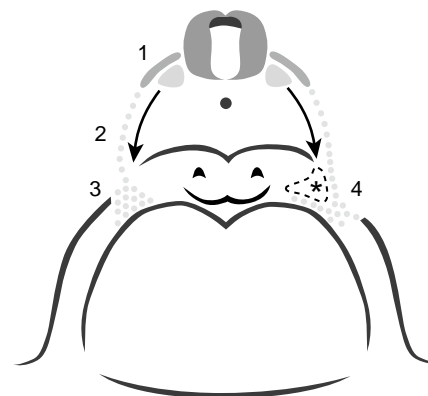

interacting with the PPF contributes to the diaphragmatic musculature development.<sup>44</sup> Others implicate a progressive development of the pleuroperitoneal membrane.<sup>45</sup>

An improved understanding of diaphragmatic muscularization has supported an alternative hypothesis for its embryogenesis. Inactivation of *c-met*, a tyrosine kinase receptor in mice, has demonstrated that the musculature of the diaphragm has a distinct origin other than the thoracic body wall.<sup>46</sup> *C-met* encodes for a receptor protein that is responsible for the delamination and migration of muscle cell precursors (MPCs) from somites.<sup>47</sup> The body wall theory of diaphragm muscularization is challenged by *c-met* null mutant mice that have an amuscular diaphragm and a normal body wall musculature. This hypothesis is further supported by the expression of *Lbx1* on diaphragmatic MPCs, a transcription factor only found on migrating MPCs and not seen on body wall myocytes.<sup>48</sup> Furthermore, immunologic staining of the diaphragm musculature revealed no MPCs from the body wall.<sup>42</sup> Thus, it appears that during the process of embryologic folding, a primitive diaphragmatic structure is formed, the PPF. Subsequently, the phrenic nerve and MPCs migrate from somatic origins, populate, and muscularize the newly formed PPF (Fig. 24-2). This process corresponds to week 10 of human gestation.

## Lung Development

Fetal lung development is divided into five overlapping stages<sup>49,50</sup>:

1. The *embryonic stage* of lung development begins during the 3rd week of gestation as a diverticular formation of the caudal end of the laryngotracheal groove. The primary lung buds and trachea

1. Muscle precursor cells delaminate from the lateral dermo-myotomal lip.
2. Delaminated cells migrate through the lateral body wall.
3. MPCs arrive in the PPF, from which point they spread out to populate the growing diaphragm.
4. In CDH, the dorsolateral region of the PPF is missing (\*) and MPCs are concentrated in the remaining tissue, ultimately leading to thickening of the diaphragm around the defect.

**Figure 24-2.** This schematic depicts a different embryologic pathway for diaphragmatic development and CDH formation than seen in Figure 24-1. On the left side (1-3) is the proposed normal pathway for diaphragm development. On the right side (4) is the pathway for CDH formation. MPC, muscle precursor cells; PPF, pleuroperitoneal fold. (From Clugston RD, Greer JJ: Diaphragm development and congenital diaphragmatic hernia. *Semin Pediatr Surg* 16:94-100, 2007.)

form from this diverticulum by the 4th week, and lobar structures are seen by the 6th week.

2. The *pseudoglandular stage* occurs between the 5th and 17th weeks of gestation with the formation of formal lung buds as well as the main and terminal bronchi.

3. The *canalicular stage* is highlighted by the development of pulmonary vessels, respiratory bronchioles, and alveolar ducts between weeks 16 and 25 of gestation. Type 1 pneumocytes begin to appear as well as the precursors for type 2 pneumocytes. At this stage, functional gas exchange is possible.
4. The *saccular stage* continues from 24 weeks' gestation to term with the maturation of alveolar sacs. Airway dimensions and surfactant synthesis capabilities continue to mature as well.
5. The *alveolar stage* begins right after birth with the appearance of mature alveoli. This stage extends well after birth with continued increase and development of functional alveoli.

Fetal pulmonary vascular development occurs in concordance with the associated lung development and follows the pattern of airway and alveolar maturation. A functional unit known as the acinus consists of the alveoli, alveolar ducts, and respiratory bronchioli. The pulmonary vasculature develops as these units multiply and evolve during the canalicular stage. The preacinar structure consists of the trachea, major bronchi, lobar bronchi, and terminal bronchioles. The pulmonary vascular development for the preacinus is typically completed by the end of the pseudoglandular stage.<sup>51-53</sup> In theory, any impedance to normal pulmonary development will concurrently hinder proper pulmonary vascular development.

Pulmonary development is recognized as a complex series of interlocking programmed events regulated by genetic signals, transcription factors, growth factors, and hormones. These events regulate the temporal and spatial interactions between epithelium and endothelium. Early transcription signals, such as thyroid transcription factor-1 and hepatocyte nuclear factor-3 $\beta$ , regulate pulmonary development from the primitive foregut mesenchyme. Other pathways of pulmonary development include Sonic hedgehog, transforming growth factor- $\beta$ , Notch-delta pathway, and Wingless-Int.<sup>21,54</sup> In addition, glucocorticoids, thyroid hormone, and retinoic acid have all been shown to regulate pulmonary organogenesis.<sup>55</sup>

## PATHOGENESIS

The development of CDH has been attributed to a defective fusion of the pleuroperitoneal membrane, to improper development of the PPF, or to a consequence of abnormal development of the posthepatic mesenchymal plate.<sup>37,38,56</sup> Others suggest that the muscular defect in CDH occurs before the complete closure of the canal as a result of abnormal formation of the diaphragm or PPFs.<sup>39</sup>

Traditionally, herniation of abdominal viscera through the diaphragmatic hernia was thought to impair lung development secondary to direct pulmonary compression resulting in pulmonary hypoplasia. Other evidence suggests that lung hypoplasia may occur early during embryogenesis before visceral herniation.<sup>57-59</sup> Still others have postulated a corollary

theory that primary lung maldevelopment leads to the fetal diaphragmatic defect, although this is not widely accepted.<sup>37</sup> This latter theory has been refuted by the transgenic mice with the *Fgf10* gene.<sup>60</sup> Inactivated *Fgf10* null-mutant mice do not develop lung tissue but have normal diaphragms suggesting independent pathways to diaphragm and lung development. This phenomenon is also seen in humans where infants with lung agenesis have normal diaphragms.<sup>61,62</sup>

Pulmonary hypoplasia is characterized by a decrease in bronchial divisions, bronchioles, and alveoli. The alveoli and terminal saccules exhibit abnormal septations that impair the air-capillary interface and its ability for gas exchange.<sup>57</sup> At birth, the alveoli are thick walled with intra-alveolar septations. These immature alveoli have increased glycogen content leading to thickened secretions that further limit gas exchange. Animal models of CDH have demonstrated pulmonary hypoplasia with decreased levels of total lung DNA and total lung protein. In addition, the pulmonary vasculature appears to be less compliant with abnormally thick-walled arterioles.<sup>63</sup> Surfactant levels are also decreased that may result in immature functioning lungs.<sup>64-66</sup> Abnormalities in pulmonary development are not limited to the ipsilateral lung of the CDH. The contralateral lung also exhibits structural abnormalities of pulmonary hypoplasia. These sequelae are most profound in cases in which mediastinal shift leads to contralateral lung compression. This supports the theory that lung compression may be the major cause of pulmonary hypoplasia.

The understanding of abnormal pulmonary development in CDH has been widely aided by the nitrofen murine model.<sup>67</sup> Nitrofen (2,4-dichloro-phenyl-*p*-nitrophenyl ether) is an environmental teratogen that is relatively harmless to adult mice. However, if given during pregnancy, it can cause pulmonary, cardiac, skeletal, and diaphragmatic abnormalities.<sup>68,69</sup> Diaphragmatic defects resulting from the administration of nitrofen in mice are very similar to those seen in humans with regard to size, location, and herniation of abdominal viscera.<sup>33,70,71</sup> Depending on the time of exposure during gestation, resultant pups will develop either right or left CDH. In addition, the offspring will exhibit features of pulmonary hypoplasia, including reduced airway branching, surfactant deficiency, pulmonary vascular abnormalities, and respiratory failure at birth. These mutations are the result of many alterations in developmental pathways of embryonic mice.<sup>55,72</sup> The nitrofen model of CDH also suggests that not all of the pulmonary hypoplasia in CDH is due to lung compression. The effect of nitrofen in causing CDH is consistent with many theories that congenital anomalies are the result of environmental insults.

Other structurally similar teratogens to nitrofen have been shown to induce CDH in animal models. Bisdiamine (*N,N'*-bis [dichloroacetyl]-1,8-octamethylenediamine) is a spermatogenesis inhibitor. BPCA (4-biphenyl carboxylic acid) is a breakdown product of a thromboxane A<sub>2</sub> receptor antagonist. SB-210661 is a benzofuranyl urea derivative and 5-lipoxygenase inhibitor. All these agents cause similar diaphragmatic defects during the same embryologic

periods in rodents. Although the exact etiology of CDH is unknown, all these compounds commonly affect the retinoic acid synthesis pathway by inhibiting retinol dehydrogenase-2 (RALDH2).<sup>73</sup> The direct correlation between nitrofen and the retinoic acid system is supported by studies using transgenic mice with a LacZ reporter linked to a retinoic acid response element (RARE). The expression of RARE is reduced with the administration of nitrofen.<sup>74</sup>

Although the etiology is not fully understood, an alternative hypothesis to traditional CDH formation has been suggested by the nitrofen model. The primary defect appears to affect **only the development of the PPF**.<sup>39</sup> In nitrofen-exposed fetuses, a defect is clearly seen in the posterolateral portions of the PPF.<sup>75</sup> This is further supported by observations of posterolateral-type CDH in vitamin A-deficient rats and mice with an inactivated *Wtl* gene.<sup>75</sup> In addition, nitrofen exposure does appear to affect muscularization of the PPF.<sup>76</sup> Studies in MPC migration and myoblast proliferation and differentiation suggest that muscularization continues and a thickened diaphragm is formed in the setting of an abnormal PPF (see Fig. 24-2).<sup>42,76</sup> This concept of abnormal PPF formation with intact muscularization as the primary etiology of CDH is in contrast to other theories that CDH is a result of failed closure of the pleuroperitoneal membranes or a defect in diaphragmatic muscularization.

Several clinical observations and molecular studies have supported the importance of the retinoic acid pathways in the development of CDH. Vitamin A-deficient rodents will produce offspring with CDH of variable severity.<sup>77</sup> Retinoic acid receptor knockout mice produce fetuses with CDH.<sup>78</sup> Lower plasma levels of retinoic acid and retinol binding protein have been found in infants with CDH compared with controls.<sup>74</sup> The conversion of retinoic acid to retinaldehyde has been prevented by inhibiting RALDH2 with nitrofen with the development of posterolateral diaphragmatic defects in rats.<sup>73</sup>

## DIAGNOSIS

### Prenatal Diagnosis

Owing to the wide discrepancy of disease severity and potential fetal therapies, accurate and timely prenatal diagnosis of CDH has become paramount. The diagnosis of CDH can be made by ultrasonography in 50% to 60% of pregnancies (Fig. 24-3).<sup>44</sup> Typically diagnosed at 24 weeks' gestation, CDH has been reported as early as 11 weeks' gestation.<sup>79</sup> In some tertiary medical centers, up to 93% of the neonates with CDH may have a prenatal diagnosis.<sup>80</sup> Fetal ultrasound findings include polyhydramnios, bowel loops within the chest, an echogenic chest mass, and an absent or intrathoracic gastric bubble. Severe or advanced CDH may exhibit intrathoracic "liver up," mediastinal shift, and hydrops fetalis.<sup>81</sup> Although most CDH can be detected during the second trimester, some sonographic features may not be exhibited until later in pregnancy.<sup>82</sup>

**Figure 24-3.** Fetal ultrasound image at the level of the four-chamber heart (dotted arrow). Gastric bubble (solid arrow) at the level of the four-chamber heart suggests CDH. This is the level used to calculate the lung-head ratio.

Independent sonographic features of CDH have not been shown to be accurate prognosticators for poor prognosis. However, two distinct features in combination have been utilized to risk stratify: (1) a low lung-to-head ratio (LHR) and (2) liver herniation into the chest. The LHR is calculated by the cross-sectional area of the contralateral lung at the level of the cardiac atria divided by the head circumference (see Fig. 24-2). Survival of CDH fetuses based on LHR has been statistically supported. In one series, there was 100% survival with LHR greater than 1.35, 61% with LHR between 1.35 and 0.6, and no survival with LHR less than 0.6.<sup>83</sup> Survival based on liver herniation alone is 56%, compared with 100% survival without liver herniation.<sup>84</sup> The combination of liver herniation and low LHR (LHR < 1.0) has a demonstrated 60% mortality for infants with prenatally diagnosed CDH.<sup>85-87</sup> Although fetal ultrasonography has been adopted as the most reliable prognostic test for CDH, its wide and inconsistent utilization has created variable results among centers. An LHR of 1.0 in one institution may be consistently different than the same results in another institution. Subsequently, LHR and liver herniation as prognosticators should be approached with some caution.<sup>88</sup>

Recently, fetal magnetic resonance imaging (MRI) of infants with CDH has been introduced as an adjunctive tool to evaluate fetal lung volume and liver location (Fig. 24-4). MRI-based fetal lung volume has been utilized in a manner similar to fetal ultrasonography. Several studies have touted the predictive value of fetal MRI in assessing risk. Lung volumes of CDH are calculated and compared with the predicted fetal lung volumes as a ratio. When the measured-to-expected fetal lung volumes ratio is less than 25%, there is a significant decrease in postnatal survival.<sup>89</sup> Fetal lung volumes predicting the need for ECMO or degree of severity are less precise.<sup>90,91</sup> Because of the nonstandardized approach to postnatal care for infants with CDH, conclusions regarding predictive outcomes using

**Figure 24-4.** Fetal MR image of a left-sided CDH at 28 weeks' gestation. A large CDH with herniation of the small bowel and stomach is found within the left hemithorax (*solid arrow*). There is dextroposition of the fetal heart (*dotted arrow*). There is no evidence of liver herniation.

all prenatal imaging modalities should be used with caution. Nonetheless, prenatal assessment can clearly identify the most severe cases.

Prenatal diagnosis in early pregnancy provides an opportunity to optimize the prenatal and postnatal care of the fetus and mother by providing accurate prenatal counseling, discussion of possible fetal intervention, and/or termination of pregnancy. Although prenatal imaging provides valuable information, it

does not consider the influences of postnatal care, especially in tertiary medical centers, on survival or overall outcome.

### Clinical Presentation

Newborns with CDH typically present with respiratory distress. Clinical scenarios may range from immediate respiratory distress with associated low Apgar scores to an initial stable period and a delay in respiratory distress for 24 to 48 hours to late presentations that may occur years into life. Initial signs include tachypnea, chest wall retractions, grunting, cyanosis, and pallor. There may be clinical signs of ongoing fetal circulation and subsequent shunting. On physical examination, infants will often have a scaphoid abdomen and an increased chest diameter. The point of maximal cardiac impulse is often displaced (contralateral to the diaphragmatic defect), suggesting mediastinal shift. Bowel sounds may be auscultated within the chest cavity with a decrease in breath sounds bilaterally. Chest excursion may be low, suggesting a lower tidal volume.

The diagnosis of CDH is typically made by chest radiography demonstrating intestinal loops within the thorax (*Fig. 24-5*). The location of the gastric bubble should be determined with the placement of an orogastric tube. In rare circumstances, a contrast radiograph is necessary. The abdominal cavity may have minimal to no intestinal gas. Right-sided CDH may be more difficult to diagnose (*Fig. 24-6*). Salient features such as intestinal and gastric herniation may not occur. Rather, features of lobar compression may be the only radiographic sign and may be confused with congenital cystic adenomatoid malformations, pulmonary sequestrations, bronchopulmonary cysts, neurogenic cysts, or cystic teratomas.

Although most infants with CDH will be diagnosed within the first 24 hours, as many as 20% may present beyond the neonatal period.<sup>92</sup> These infants usually present with milder respiratory symptoms, chronic pulmonary infections, pleural effusions, pneumonias,

**Figure 24-5.** **A,** Anteroposterior chest radiograph in a neonate with a CDH demonstrating air-filled loops of bowel within the left chest. The heart and mediastinum are shifted to the right, and the hypoplastic left lung can be seen medially. **B,** Postoperative radiograph demonstrating hyperexpansion of the right lung with shift of the mediastinum to the left. The edge of the severely hypoplastic left lung is again easily visualized (*arrow*).

**Figure 24-6.** This infant presented with respiratory distress and a right CDH.

feeding intolerance, or gastric volvulus. Older children may present with symptoms of mediastinal compression due to acute gastric distention.<sup>93</sup> Because CDH invariably causes abnormal intestinal rotation and fixation, some children may present with intestinal obstruction or volvulus. Occasionally, CDH may be asymptomatic and discovered **only incidentally**.<sup>67,94-97</sup> Patients who present later in life have a much better prognosis due to milder or absent pulmonary hypoplasia and hypertension.

## TREATMENT

### Prenatal Care

The prenatal diagnosis of CDH has increased with the greater use of fetal ultrasound examinations. Advanced-level ultrasonography may be initiated after screening ultrasonography demonstrates discordant size and dates. A comprehensive sonographic evaluation should be made to diagnose associated anomalies (cardiovascular and neurologic) as well as signs of fetal compromise (i.e., hydrops fetalis). Once diagnosed, a karyotype should be obtained via amniocentesis or chorionic villus sampling. The mother and fetus should be referred to a tertiary perinatal center with advanced critical care capabilities such as ECMO, nitric oxide (NO) therapy, and oscillating ventilators.<sup>98</sup> A prenatal diagnosis of CDH allows the mother and family to be properly informed of treatment options and outcomes.

Some highly selective patients may be candidates for fetal intervention. Historically, open fetal repair of CDH was attempted but with dismal outcomes.<sup>84</sup> Based on clinical observations in infants with congenital tracheal atresia,<sup>99</sup> fetal intervention has shifted

from direct repair of the diaphragm to lung expansion techniques. A fetoscopically placed endotracheal occlusive balloon for temporary tracheal occlusion has been introduced as a therapy for the most severe cases, LHR less than 1.0, and liver herniation.<sup>100</sup> However, the only National Institutes of Health (NIH)-sponsored, prospective, randomized trial comparing tracheal occlusion with conventional therapy did not demonstrate a survival or morbidity advantage with fetal intervention.<sup>101</sup> However, this study did suggest that a subgroup of the most severe patients (LHR < 0.9) may still benefit from tracheal occlusion. Thus, tracheal occlusion remains of great interest as potential fetal therapy but should only be performed in the setting of a clinical trial. Currently, there is no clinical evidence that supports temporary tracheal occlusion for the treatment of prenatally diagnosed CDH.

### Resuscitation and Stabilization

After the confirmation of the diagnosis of CDH, initial postnatal therapy is targeted at resuscitation and stabilization of the infant in cardiopulmonary distress. Management should be targeted at the physiologic sequelae of pulmonary hypoplasia and hypertension. Immediately after delivery, a rapid overall assessment is necessary to determine hemodynamic stability and severity of disease. In severe cases, prompt endotracheal intubation is warranted without high-pressure bag ventilation to avoid gastric and intestinal distention. A nasogastric tube should be introduced along with placement of arterial and venous catheters to assist in resuscitative maneuvers. Acid-base balance and oxygenation-ventilation status should be carefully monitored.

Invasive monitoring with arterial and venous catheters is important for accurate assessment of overall perfusion of the infant and estimation of the significance of pulmonary hypertension and hypoplasia. Umbilical venous catheters may be used and should be placed across the liver into the right atrium to measure central venous pressures, but this may be difficult to achieve. In addition, oxygen content and/or saturation that reflects cerebral perfusion should be available from a preductal source by either a right radial arterial catheter or a transcutaneous saturation probe.

Initial mechanical ventilation should be utilized for stabilization. High airway pressures with a peak inspiratory pressure (PIP) greater than 25 cm H<sub>2</sub>O should be avoided to prevent iatrogenic barotrauma. Positive-pressure ventilation should maintain the preductal arterial saturation (SaO<sub>2</sub>) above 85% with a minimal amount of PIP. In order to maintain lower PIP, a moderate level of hypercarbia (PaCO<sub>2</sub>, 45 to 60 mm Hg) is accepted without a compensatory acidosis (pH > 7.2). Occasionally, higher levels of PaCO<sub>2</sub> are tolerated.

Pulmonary hypertension and associated cardiac anomalies are evaluated with echocardiography. Clinically, pulmonary hypertension may be exhibited by differential preductal and postductal arterial saturations. However, echocardiography can better characterize the severity of disease and the degree

of pulmonary hypertension. Sonographic findings of pulmonary hypertension include poor contractility of the right ventricle, flattening of the interventricular septum, enlarged right-sided heart chambers, and tricuspid valve regurgitation. There may be right-to-left or bidirectional shunting across the ductus arteriosus.

Preductal oxygen saturations less than 85% may impair adequate tissue perfusion. In general, a preductal PaO<sub>2</sub> should be maintained above 60 mm Hg and a postductal PaO<sub>2</sub> above 40 mm Hg. Failure to provide adequate tissue oxygenation may result in metabolic acidosis, which may exacerbate the pulmonary hypertension. Pulmonary vascular resistance is increased by hypoxia and acidosis, which all should be avoided or corrected. If severe ductal shunting develops, inhaled NO can be utilized, although pulmonary hypertension in association with CDH is less responsive than other causes of pulmonary hypertension. Despite its common utilization, NO as a rescue strategy in this setting has failed to demonstrate benefit in infants with CDH.<sup>102,103</sup>

Almost all infants with CDH and severe pulmonary hypertension will exhibit some left ventricular dysfunction. Vasopressor agents such as dopamine, dobutamine, and milrinone may be utilized in hemodynamically unstable patients. These inotropic agents may augment left ventricular output and increase systemic pressures to ameliorate the right-to-left ductal shunting.

## Mechanical Ventilation

Mechanical ventilation is a critical component in the care of infants with respiratory failure secondary to CDH. The physiologic limits of the hypoplastic lung make mechanical ventilation a challenge. Hypoplastic lungs in CDH infants are characterized by a decreased number of airways and smaller airspaces. In conjunction, the pulmonary vasculature exhibits decreased vascular branching and increased adventitial and medial wall thickness.<sup>104,105</sup> This combination results in varying degrees of respiratory failure and pulmonary hypertension. Fortunately, pulmonary and vascular development continues after birth.<sup>106,107</sup> Because of this ongoing maturation, mechanical ventilation strategies have trended to less aggressive approaches with the goal of stabilizing ventilator therapy to maintain oxygenation while limiting the risks of ventilator-induced lung injury, a major contributor to mortality.<sup>108</sup>

The type of mechanical ventilator in infants with CDH is clinician preference, but most cases of CDH can be managed using a pressure-cycled mode. The initial fraction of inspired oxygen (FIO<sub>2</sub>) of 1.0 is utilized to maintain adequate oxygen saturation. Typically, the utilization of higher rates and lower peak airway pressures (18 to 22 cm H<sub>2</sub>O) while titrating the FIO<sub>2</sub> can maintain a preductal PaO<sub>2</sub> greater than 60 mm Hg or better (a preductal SaO<sub>2</sub> > 85%) and a PCO<sub>2</sub> less than 60 mm Hg. Maintaining an acceptable pH and PCO<sub>2</sub> is important in managing the pulmonary hypertension.<sup>109,110</sup> The ventilation strategy

of induced respiratory alkalosis by hyperventilation to reduce ductal shunting has been abandoned by most centers.<sup>111-114</sup> Lung-protective ventilation strategies include pressure-limited ventilation rates between 30 and 60 breaths/min along with PIP less than 25 cm H<sub>2</sub>O to minimize barotrauma.<sup>111,115</sup> Spontaneous respirations are maintained by avoiding neuromuscular paralysis and minimally set respiratory rates. This combination of spontaneous respiration and permissive hypercapnia has been a well-documented preoperative stabilization strategy with survival rates of almost 90% reported from some centers in patients with isolated CDH.<sup>111-113</sup>

If conventional ventilation fails to reverse hypercapnia and hypoxemia, high-frequency ventilation strategies may be employed. The role of high-frequency oscillatory ventilation (HFOV) in infants with CDH is based on its ability to avoid ventilatory-induced lung injury by preserving end-expiratory lung volume without overdistention. As the understanding of the CDH lungs continued to evolve, HFOV strategies also changed. Initially used in a high-pressure lung recruitment mode, this strategy demonstrated no benefit due to the nonrecruitable nature of the hypoplastic lungs.<sup>116,117</sup> High-frequency strategies as a rescue therapy for infants with profound hypoxia and refractory hypercapnia on conventional ventilators have been without much success.<sup>118,119</sup> As the concept of preoperative stabilization became better defined, HFOV began to be used as means to avoid barotrauma early in the treatment course before refractory respiratory failure, with some institutions using HFOV as primary therapy.<sup>120-122</sup> These strategies of preoperative stabilization regardless of ventilator modalities to prevent lung injury and delayed surgery have resulted in improved survival.<sup>108,120-123</sup>

To achieve lower peak airway pressures, HFOV should be maintained at a mean airway pressure less than 16 cm H<sub>2</sub>O. HFOV should be considered when PIP exceeds 25 cm H<sub>2</sub>O with conventional therapy. The PCO<sub>2</sub> should be maintained in the range of 40 to 55 mm Hg by adjusting the amplitude between 35 to 45 cm H<sub>2</sub>O. Eight rib expansion of the contralateral hemithorax has been used as an initial guide to achieve optimal lung expansion without overdistention.<sup>120,122</sup> Tidal volumes are directly related to the amplitude and inversely related to frequency. Thus, significant increases in tidal volume can be seen when frequencies are below 10 Hz. This can result in hyperinflation, which in turn may adversely affect the pulmonary vasculature, including venous return. Constant assessment of acid-base status and end-organ perfusion is necessary as lung compliance changes, or as the CDH is repaired.

## Surfactant

Several animal studies of CDH have shown altered surfactant levels and composition.<sup>63,124-129</sup> However, human data to support this have been controversial.<sup>65</sup> Experimentally, surfactant decreases pulmonary vascular resistance, improves pulmonary blood flow, and

reduces ductal shunting.<sup>130</sup> In addition, surfactant administration has been shown to augment NO delivery and improve gas exchange.<sup>131</sup> These findings led clinicians to utilize exogenous surfactant empirically. However, clinical evidence in term and preterm infants with CDH has not shown benefit. In one study, it was suggested that surfactant therapy in term infants with CDH was associated with an increased use of ECMO, an increased incidence of chronic lung disease, and higher mortality.<sup>128</sup> Similar findings were found in preterm infants despite adjusting for Apgar scores and gestational age.<sup>127</sup> Even as a rescue therapy in CDH infants on ECMO, surfactant failed to demonstrate a survival advantage.<sup>64,126</sup> Despite the lack of proven efficacy, exogenous surfactant therapy continues to be used with unknown risk and unclear benefit. Proponents of this therapy argue that the clinical evidence is based on a heterogeneous population of disease severity and that failed therapy may be due to its use in the most severe CDH infants. Given the clinical data, surfactant therapy should only be used in a randomized, controlled fashion.

### Nitric Oxide

Inhaled NO is a potent pulmonary vasodilator that has been shown to have tremendous benefit in the treatment of persistent pulmonary hypertension of the neonate (PPHN).<sup>118,132-135</sup> In clinical studies, NO improved oxygenation and decreased the need for ECMO in infants with respiratory failure secondary to PPHN.<sup>135,136</sup> However, the efficacy of NO for pulmonary hypertension secondary to CDH has not been as well supported. The need for ECMO or a reduction in mortality has not been shown with NO use in CDH infants.<sup>137</sup> In the Neonatal Inhaled Nitric Oxide Study Group trial, the CDH subgroup had a greater likelihood for ECMO or death.<sup>102</sup> The response to NO is variable and unpredictable in infants with CDH. Some may demonstrate a rebound pulmonary hypertension that is more difficult to control than the initial disease.<sup>138</sup> Furthermore, the effect appears to be transient and does not prevent progression toward ECMO use.<sup>139,140</sup> Thus, the role of inhaled NO has not been clearly defined and should not be routinely used. NO should be reserved for infants who persistently demonstrate suprasystemic pulmonary pressures in the setting of optimized pulmonary and cardiac function to reduce right ventricular pressures.<sup>115,140</sup>

Other pulmonary vasodilator agents have been utilized in the treatment of pulmonary hypertension in infants with CDH. Sildenafil is a 5-phosphodiesterase (5-PDE) inhibitor that has been utilized as a transitional medication to wean off NO for unresolving pulmonary hypertension. Widely used for PPHN and pulmonary hypertension secondary to congenital heart disease, sildenafil can be used in both oral or intravenous forms.<sup>140,141</sup> Epoprostenol (intravenous prostacyclin) and bosentan (a nonspecific endothelin-1 receptor inhibitor) have all been used in infants with CDH but the experience to date is limited.<sup>142-144</sup>

### Extracorporeal Membrane Oxygenation

ECMO for infants with CDH was first introduced as a potential therapy for infants who likely had severe ventilator-associated lung injury.<sup>145</sup> Since then, ECMO strategies have evolved as understanding of CDH with its associated pulmonary hypoplasia and hypertension has improved. CDH accounts for approximately one fourth of all infants requiring ECMO for respiratory failure. Almost 30% of CDH infants will receive ECMO during their hospital course.<sup>146-149</sup> Prior to the era of preoperative stabilization, ECMO was associated with only a modest improvement in survival in high-risk CDH infants.<sup>150-152</sup>

Initially, strict criteria were established as indications for ECMO use in CDH. These included an oxygenation index greater than 40 and persistent alveolar-arterial gradient greater than 610 mm Hg.<sup>148,153,154</sup> Today, those criteria have been softened and the most common indication for ECMO is a “failure to respond” to therapy. In efforts to maintain lung-protective ventilation, clinicians have opted for ECMO rather than escalation of positive airway pressures. Relative contraindications include significant congenital anomalies, lethal chromosomal anomalies, intracranial hemorrhage, and gestational age less than 34 weeks. Ideally, ECMO candidates should have a birth weight greater than 2 kg owing to increased risk of intracranial hemorrhage, but some have reported benefit in infants weighing less than 2 kg.

ECMO was initially utilized as a postoperative rescue therapy, but its role has evolved.<sup>155,156</sup> In combination with other adjunctive modalities such as HFOV, ECMO is now routinely used as a component of preoperative stabilization. The strategy of stabilization with ECMO and delay in surgery has been shown to be beneficial, with a reported survival of 67% in high-risk patients.<sup>10,157</sup> These findings were further supported by the CDH study group that reported 85% of infants had ECMO before repair. Of those, 54% were repaired while still on ECMO and 29% repaired after ECMO with 16% never making it to repair. Infants who underwent repair while on ECMO had a 50% mortality, compared with 17% after ECMO.

The optimal timing of CDH repair is controversial and surgeon dependent. With more repairs of CDH on ECMO, bleeding became an increasingly recognized complication.<sup>157,158</sup> The introduction of aminocaproic acid, a fibrinolysis inhibitor, has significantly decreased bleeding complications.<sup>147</sup> Bleeding may also be reduced with early repair on ECMO before the development of coagulopathy and significant edema.<sup>148</sup> Some surgeons have recommended repair when pulmonary hypertension has resolved but prior to decannulation.<sup>66</sup> This allows reinstatement of ECMO if respiratory failure and/or pulmonary hypertension recurs. Others have requested that infants be decannulated and on conventional ventilation before repair. Although rare, recurrent pulmonary hypertension can occur after surgery, requiring a second run of ECMO.<sup>159</sup> Survival for second-run ECMO patients is approximately 50%.<sup>160</sup>

Today, ECMO is routinely used to stabilize patients before operation. Although results are dependent on patient selection and entry criteria, survival has been reported between 60% and 90%.<sup>98,111,146,161,162</sup> Without ECMO, the predicted mortality in the high-risk cohort reaches 80%.<sup>146</sup> Despite these data, ECMO for CDH is not universally accepted. Some authors report no survival advantage with ECMO.<sup>163,164</sup> Others cite an increased neurologic complication rate with ECMO use in CDH infants compared with other indications such as PPHN.<sup>165,166</sup> Some institutions report an 80% survival of infants with CDH without use of ECMO.<sup>167,168</sup> Nonetheless, in most centers ECMO remains a component in the armamentarium for treating CDH infants with refractory cardiopulmonary failure.

## Surgery

The surgical approach to the repair of CDH has changed dramatically in the past 25 years. Historically, neonates with CDH were brought to the operating room almost immediately after birth to emergently relieve the compressed lung by reducing the intra-abdominal contents from the chest. Often, this maneuver was followed by a transient period of cardiopulmonary stability or improvement.<sup>169,170</sup> However, frequently, the infant would develop progressive respiratory failure, elevated pulmonary vascular pressures, right-to-left ductal shunting, unrecoverable hypoxemia, and eventually death. With improved understanding of the pathophysiology of CDH, repair of CDH is no longer considered a surgical emergency. Nonetheless, timing of the surgical repair of the diaphragm remains controversial.

The shift toward a delay in surgery after preoperative stabilization occurred after evidence was introduced that pulmonary compliance was actually worse after repair.<sup>171</sup> Several factors have been implicated, including increased intra-abdominal pressure and distortion of the repaired diaphragm. In addition, surgical repair has not been shown to improve gas exchange. Several studies have evaluated early versus delayed repair of CDH without demonstrating a difference in mortality or need for ECMO.<sup>172-174</sup> These include two randomized trials of early (<12 hours) versus delayed repair after 24 hours<sup>174</sup> and after 96 hours.<sup>172</sup> Since the adoption of the delayed repair strategy, several centers have reported improved survival rates.<sup>111,174-177</sup> Although modifications of surgical techniques and timing have contributed to this improvement, concomitant advances in neonatal critical care as well as a better understanding of the disease and outcomes have been the greater contributors to decreased mortality. Importantly, there has been no clinical evidence that specifically attributes a delay in surgery to improved outcomes over immediate repair.<sup>178</sup>

Timing of operation remains with clinical judgment and surgeon discretion. Some clinicians will opt for repair once the respiratory failure has stabilized (low peak airway pressures and inspired oxygen requirements) and after echocardiography demonstrates a resolution or stability of the pulmonary hypertension. This typically occurs 24 to 48 hours after clinical

evidence of ductal shunting has resolved. Although CDH can be repaired on HFOV, most surgeons will wait until the infant is transitioned to a conventional mechanical ventilator.

The repair of a CDH may be as variable as the clinical management. A subcostal incision on the ipsilateral side of the hernia is the traditional approach. Less than 10% of surgeons prefer a thoracic approach.<sup>179</sup> The intra-abdominal contents should be reduced out of the thorax with careful attention to the spleen, which can be caught and torn on the rudimentary rim of diaphragm. A true hernia sac, which is only present less than 20% of the time, should be identified and excised.<sup>180</sup> The thoracic and abdominal cavities should be inspected for associated pulmonary sequestrations. The extent of the diaphragmatic hernia should be examined and assessed.

The type of repair is dependent on the size of the diaphragmatic defect. If the defect is small, a tension-free primary closure should be performed with nonabsorbable sutures with or without pledgets. If the defect is large, attempted primary closure may cause significant tension or flattening of the diaphragm, resulting in decreased pulmonary compliance. Alternatively, a diaphragmatic replacement may be employed to restore a tension-free, diaphragmatic shape (Fig. 24-7). Several types of prosthetic and biosynthetic patch materials have been utilized. Traditionally, a polytetrafluoroethylene (PTFE or Gore-Tex, W. L. Gore, Newark, DE) patch has been used.<sup>179</sup> With the use of a 1-mm thickness patch, the prosthesis is cut slightly larger than the diaphragmatic defect and is sewn to the residual diaphragm or surrounding tissue with nonabsorbable suture. The disadvantage of prosthetic material is the lack of material growth, resulting in a significant recurrence rate of nearly 50%.<sup>181</sup> To prevent this, the patch is tailored in a "cone shape" that may resemble the native diaphragm. This technique has demonstrated a reduction in recurrence rate from 26% to 9%.<sup>182</sup> Large defects with an adequate

**Figure 24-7.** A large left posterolateral diaphragmatic hernia was approached through a subcostal incision. After reduction of the abdominal viscera, the large defect was closed using a biosynthetic patch (Alloderm).

posterior rim of diaphragm may require suturing the patch to the abdominal wall or encircling the ribs for adequate fixation.

Outcomes regarding the type of prosthetic patch material are mixed. Opponents of prosthetic patch material, such as PTFE, cite an unacceptable recurrence rate, chest wall deformity, and intra-abdominal complications, such as small bowel obstruction.<sup>181,183-186</sup> With a recurrence rate as high as 50%, alternative biosynthetic materials have been introduced to repair CDH. Currently, the most popular material is small intestine submucosa (Surgisis or SIS, Cook, Inc., Bloomington, IN) or human acellular dermal matrix (Alloderm, LifeCell, Branchburg, NJ). These bioactive patches may serve as a matrix for permanent tissue ingrowth.<sup>187</sup> Some institutions have adopted bioactive materials as the primary patch for repair of large diaphragmatic hernias. Proponents of biosynthetic patches claim the patch material is less adherent to small bowel and allows for tissue engraftment that grows with the patient. However, the largest series comparing SIS to Gore-Tex demonstrated similar recurrence rates and no difference in small bowel obstruction.<sup>187</sup> Long-term outcomes with biosynthetic patches for CDH remain to be seen. Certainly, the type of CDH patch material needs to be studied in a prospective fashion.

Recurrences after CDH repairs have prompted investigation into alternatives to prosthetic and biosynthetic materials. Some surgeons have utilized muscle flaps for primary and recurrence repairs. In small case series, an abdominal wall muscle flap using internal oblique and transversalis abdominal muscles has been described to cover very large primary or recurrent diaphragmatic defects.<sup>188-191</sup> Thoracic wall musculature has also been widely utilized. Latissimus dorsi and serratus anterior muscles have been described with isolated success.<sup>33,188,192</sup> Local advancement with a reversed latissimus dorsi flap with microneural anastomosis of the thoracodorsal nerve to the phrenic nerve has been described for recurrent herniations.<sup>192</sup> With this technique, the neodiaphragm was able to demonstrate nonparadoxical motion by fluoroscopy and ultrasonography. Muscle flaps may be advantageous in very large defects and in diaphragmatic agenesis.

Postoperative tube thoracostomy is not necessary and probably not indicated.<sup>111,114</sup> An exception may be CDH repair on ECMO because bleeding complications should be expected. The thoracic space will

eventually fill with air and fluid, the lung will gradually grow, and the rib spaces may narrow to decrease the overall thoracic cavity. Tube thoracostomy is used only for postoperative chylothorax or accumulation of pleural fluid causing hemodynamic compromise.<sup>193</sup> If a chest tube is warranted, the tube is placed in the thoracic cavity before final closure of the diaphragm. Chest tubes should be placed to water seal rather than suction. Aggressive negative pressure can shift the mediastinum to the ipsilateral hemithorax creating overdistention of the contralateral lung. Symptomatic pleural fluid may be treated with repeated thoracentesis. If used, chest tubes should be removed early to avoid infection.

If the CDH is repaired via laparotomy, the abdominal domain may not be able to accommodate the reduction of the intestinal contents. Closure of the abdominal wall may result in an abdominal compartment syndrome. A “tight abdomen” may cause respiratory compromise in an already tenuous infant. Careful attention should be paid to the peak airway pressures as the abdominal fascia is closed. Respiratory compromise should prompt the abdomen to be left open. This scenario is more often seen with CDH infants on ECMO.<sup>194</sup> Temporary closure can be achieved with skin, prosthetic silo, or abdominoplasty.<sup>195</sup> Delayed closure, especially in those infants on ECMO, should be attempted after the general edema has resolved or the intra-abdominal domain has enlarged.<sup>196</sup>

Special operative considerations should be made for CDH infants on ECMO. In addition to the abdominal compartment issues, hemorrhagic complications are more likely due to the anticoagulation required for ECMO. Fibrin or thrombin sealants should be liberally used to reduce suture line hemorrhage. Aminocaproic acid should be given before operation and for 2 to 3 days postoperatively to prevent bleeding complications.

The therapeutic goals of postoperative ventilation should be similar to the preoperative goals, that is, to minimize barotrauma. Infants may experience a transient period of cardiopulmonary improvement that may allow clinicians to wean ventilatory support. However, rapid decreases in  $\text{FiO}_2$  should be avoided to prevent triggering pulmonary vasospasm and recurrent pulmonary hypertension.

Advances in minimally invasive techniques have led to an increase in thoracoscopic and laparoscopic repairs of CDH (Fig. 24-8). Concerns regarding the minimally

**Figure 24-8.** A, Laparoscopic view of a left-sided CDH in a 2-week-old with respiratory distress. The bowel and spleen have been reduced. The edges of the diaphragmatic defect are well seen (arrows). A very thin sac was present. B, The sac was removed and a primary closure was possible.

invasive approaches have centered around prolonged operations precipitating respiratory complications, triggering or exacerbating pulmonary hypertension, and resulting in an unnecessary increase in mortality. With careful patient selection, minimally invasive repairs have been successfully performed, both laparoscopically and thoracoscopically.<sup>197-199</sup> This approach has been utilized with primary repair as well as prosthetic patch closure of the CDH.<sup>200</sup> Laparoscopic and thoracoscopic operations are feasible without a demonstrable advantage to either. However, patient selection remains the main determinant of success. A preoperative patient selection criteria for thoracoscopic repair of CDH has been proposed.<sup>199</sup> Preoperative requirements included minimal ventilatory support (PIP < 24 mm Hg), no clinical or sonographic evidence of pulmonary hypertension, and an intra-abdominal stomach. In a small series of seven patients, results were similar to open CDH repairs. The long-term outcomes with minimally invasive approaches to CDH remain to be seen.

## OUTCOMES

Clinical outcomes in regard to the treatment and management of infants with CDH have traditionally been difficult to interpret. Because the estimated incidence of CDH is low (1 in 2500 to 4000 live births), it has become evident that single institutions, regardless of their volume, would have difficulty in generating meaningful, evidence-based outcomes.<sup>9,10</sup> In addition, patient characteristics and clinical practices are very different and each institution's ability to offer state-of-the-art neonatal critical care is highly variable. Furthermore, data from a very heterogeneous disease population, such as CDH, are often pooled to generate single reports.

### Congenital Diaphragmatic Hernia Registry (CDHR)

The Congenital Diaphragmatic Hernia Study Group (CDHSG) was established in 1995 as an international group of clinicians and researchers interested in developing a registry of all infants born with CDH. The CDHSG recognized the limitations of individual institutions in producing meaningful data on their own. As an observational database, the CDHR was created by a network of voluntary centers to ask specific clinical questions, recommend specific therapy as needed, and monitor outcomes of various management and treatment strategies. Since 1995, more than 90 centers from 10 countries have submitted data on more than 4000 infants with CDH. Participation among centers has varied, but currently there are over 50 active centers in the CDHSG with an average total submission of 340 infants per year.<sup>1</sup>

Data from the CDHR must be used with caution as with all outcome studies of CDH. There is a wide spectrum of patients within institutions and a wide spectrum of institutions within the CDHSG. Patients are only followed until hospital discharge or death.

Thus, long-term follow-up outcomes are not available. Nonetheless, large international registries such as the CDHR offer some advantages. The CDHR is a vehicle to collect data from a large number of patients. The CDHR reflects changes in management and outcomes over time. Finally, individual institutions can compare their risk-adjusted outcomes to other institutions as a method of quality assurance.

## Survival

As with all outcomes studies regarding CDH, survival analysis remains difficult to interpret due to the tremendous variations in patient disease, management strategies, and operative techniques. Unique to individual institutions are differences in ventilation strategies, availability and entry criteria for ECMO, and operative timing. One method to achieve better comparisons of outcomes is the development of risk stratification of patient disease. In 2001, the CDHSG published the first attempt at predicting outcome based on risk stratification.<sup>201</sup> The study examined 1054 infants with CDH by applying a risk assessment tool created by a logistical equation. Patients were categorized into low-, moderate-, and high-risk groups, which correlated with actual mortality. Overall survival was 64% in which birth weight and 5-minute Apgar scores had the strongest correlation. Survival rates for CDH among institutions are highly variable even when risk adjusted. Although the overall survival of liveborn infants has been reported around 60%, individual centers have varied from 25% to 83%.<sup>9</sup> This variation may be a reflection of the increasing prenatal diagnosis of CDH in which the most severe cases are transferred to tertiary care centers.

## Pulmonary Outcomes

For many infants who survive the neonatal period with CDH, pulmonary function is excellent. Prior to the era of ECMO and lung-protective ventilation, long-term survivors were routinely reported as healthy children without respiratory disease.<sup>53,202-204</sup> However, with improved survival, more severe CDH infants are available for follow-up. Children with a history of CDH have demonstrated both functional and radiographic evidence of chronic lung disease.

Pulmonary function has been reported to be normal in 50% to 70% of CDH survivors.<sup>53,202,205,206</sup> The remainder exhibit some form of restrictive or obstructive respiratory symptoms. Approximately 25% of children beyond the age of 5 years have demonstrable signs of obstructive airway disease. One hundred consecutive CDH survivors were recently evaluated. ECMO and the need for patch repair were independent predictors of pulmonary outcome.<sup>206</sup> The use of ECMO significantly correlated with diuretic dependence at the time of discharge.<sup>81</sup> While only 16% required oxygen at discharge, 53% required at least transient usage of bronchodilators within the first year. Similarly, 41% were either dependent on or intermittently needing corticosteroids during the first year. Others have demonstrated similar pulmonary morbidities. In another

study, chronic lung disease was found in 22% of surviving infants with CDH with a 2-year follow-up.<sup>207</sup> As with previous studies, ECMO and patch repair were the dominant factors of poor outcomes.

Respiratory infections appear to have a higher prevalence in children with CDH.<sup>107,202,208-210</sup> Viral bronchiolitis, such as respiratory syncytial virus (RSV), is the most common pathogen seen in children younger than 3 years of age, suggesting a need for RSV prophylaxis.<sup>206</sup> Recurrent pneumonias have been reported in 26% to 39% of CDH survivors with at least 10 years of follow-up.<sup>107,209</sup>

Obstructive pulmonary disease is commonly reported in children with CDH. Asthma and general symptoms of bronchospasm and wheezing are well documented.<sup>155,210,211</sup> Although the severity of these symptoms appear to improve with age, most children will still exhibit some combination of obstructive and restrictive pulmonary function and are more reactive to pharmacologic agents.<sup>210-213</sup> After correcting for lung size, lower functional volumes and not primary obstruction of the airways were the cause of abnormal pulmonary function tests in one study.<sup>211</sup>

Although lung development begins early in gestation, alveolar and pulmonary vascular maturation continue well after birth. In CDH, lung hypoplasia will affect both lungs with a reduction in airway and pulmonary artery divisions. As demonstrated in ventilation/perfusion ( $\dot{V}/\dot{Q}$ ) radionuclide scans, pulmonary hypoplasia will persist despite continued lung growth.<sup>211,212,214</sup>  $\dot{V}/\dot{Q}$  mismatches are predominantly due to abnormal lung perfusion. Follow-up  $\dot{V}/\dot{Q}$  scans have demonstrated an increase in lung volume but not in lung perfusion. Because the pulmonary vasculature and alveoli grow concurrently, normalization or improvement in pulmonary function must be due to increased lung volume. This is further supported by increased alveolar size after neonatal repair of CDH.<sup>215,216</sup> Although  $\dot{V}/\dot{Q}$  scans in children with CDH have provided valuable information, their predictive value for chronic lung disease in CDH survivors remains to be determined. In a review of 137 CDH infants, 61% had  $\dot{V}/\dot{Q}$  mismatching at the time of their last scan. Patch repair and ECMO again had the strongest association, but definitive causation could not be established.<sup>217</sup>

Chest radiographs (CXR) are routinely abnormal and consistently demonstrate evidence of bronchopulmonary dysplasia.<sup>202,206,213,218</sup> Common features of chronic lung disease include hyperlucency, hyperinflation, persistent lung hypoplasia, decreased pulmonary vasculature, unknown opacities, persistent mediastinal shifts, and a chronic abnormal diaphragm position. In general, plain radiographs have no correlation with clinical symptoms in CDH with the exception of recurrent hernias. Approximately one third of CDH children will have an abnormal chest film.<sup>213</sup>

## Neurologic Outcomes

As more infants with CDH are surviving, multidisciplinary follow-up has become as important as the in-hospital care. Although most patients may resolve

their pulmonary or gastrointestinal issues, neurodevelopmental morbidities may be harder to detect. The lack of close follow-up and adequate simple tools to measure neurodevelopment may lead to undetected morbidity. Thus, close monitoring of neurodevelopment is imperative. Continued motor and language problems, even at 3 years of age, have been found.<sup>219</sup>

A significant percentage of CDH survivors will have neurodevelopmental sequelae, including developmental delay, motor and cognitive disabilities, and behavior disorder.<sup>165,166,220-222</sup> Several factors have been attributed to these outcomes, including ECMO use, disease severity with prolonged hypoxia, and prolonged hospitalizations. However, confounding evidence has made deciphering the root cause of neurodevelopmental sequelae from CDH difficult. In 1995, one study evaluated 82 CDH children at 1 year who had required ECMO use.<sup>220</sup> Developmental delay was significantly more prevalent when compared with children in whom ECMO was used for other indications. Another study demonstrated associated abnormal neuroimaging in children with neurodevelopmental delays in ECMO survivors of CDH.<sup>165</sup> However, other studies with large patient groups have not implicated ECMO. Stolar and colleagues reported on 51 ECMO survivors and concluded that ECMO was not a risk factor for neurologic deficits.<sup>166</sup> Another study found no differences in neurologic outcomes in 130 children who underwent ECMO for CDH compared with other diseases.<sup>207</sup> Other factors such as low socioeconomic status and prematurity have also been suggested as contributors.<sup>166,221-223</sup>

Sensorineural hearing loss (SNHL) is a common neurologic sequela of CDH. The prevalence of SNHL ranges from none in some series to 100% in others.<sup>207,224</sup> The etiology of SNHL remains difficult to decipher. SNHL is seen in patients with and without ECMO.<sup>224-226</sup> Several ototoxic medications are routinely used in the acute and chronic care of infants with CDH, such as diuretics, antibiotics, and muscle relaxants.<sup>227</sup> Even mechanical ventilation has been linked to SNHL.<sup>228</sup> Most likely, it is a combination of treatment and severity of disease. Stringent audiologic testing is warranted because SNHL may cause speech delays and further impair other aspects of neurodevelopment.

## Gastrointestinal Outcomes

Gastroesophageal reflux disease (GERD) is a common gastrointestinal sequela of CDH. The cumulative incidence has been reported to be 40% of all CDH survivors. Approximately half require surgical intervention,<sup>229</sup> although individual centers have reported higher percentages.<sup>230,231</sup> The incidence among institutions is variable, depending on the mode of diagnosis: clinical symptoms, upper gastrointestinal contrast radiographs, pH monitoring, or impedance plethysmography. Although GERD can be self-limiting, several studies have reported long-term symptoms. One study reported that 63% of patients required GERD medications after 2 years.<sup>232</sup> Another report found a

similar percentage (63%) in a long-term follow-up of 29 years.<sup>231</sup> A final study noted that 50% had symptomatic GERD after 1 year of age.<sup>208</sup>

Despite its high prevalence, the etiology of GERD in association with CDH is unclear. Certainly, anatomic changes with CDH may contribute to GERD. Esophageal ectasia may occur due to abnormal fetal development secondary to mediastinal shift, resulting in an abnormal lower esophageal sphincter.<sup>233</sup> The presence of an intrathoracic stomach due to herniation may cause the maldevelopment of the gastroesophageal junction.<sup>234,235</sup> The side of the CDH may cause a differential growth pattern and subsequent shortening of an intra-abdominal esophagus.<sup>236</sup> Distortion of the esophageal hiatus and increased intra-abdominal pressure from reduction of the viscera have also been implicated as postsurgical causes of GERD.<sup>237</sup> Owing to the frequency of symptomatic GERD, primary antireflux surgery has been recommended by some surgeons, especially for large defects.<sup>207</sup>

A significant number of CDH survivors demonstrate evidence of failure to thrive.<sup>230,238</sup> Many fall well below the 25th percentile in weight despite adequate caloric intake and aggressive feeding management (i.e., via gastrostomy). Symptomatic GERD may be a contributor, but an underestimation of the caloric needs may be the more significant reason. Survivors of CDH may have an increased metabolic demand due to chronic lung disease, resulting in increased respiratory work. These factors, in addition to oral aversion due to prolonged hospitalization, result in nutritional demands that may be underappreciated.

Gastrointestinal surgical issues are commonly seen in CDH children. Adhesive intestinal obstruction, intestinal ischemia, volvulus secondary to malrotation, and intestinal perforation are well documented. Intestinal obstruction occurs in up to 25% of patients.<sup>229</sup> Postoperative adhesions due to repair of the diaphragm or antireflux surgery have been reported, with the use of prosthetic patch material as a significant factor.<sup>186</sup> Other causes include malrotation, intestinal dysmotility, and recurrent hernia with incarceration. Recurrent CDH occurs in approximately 50% of patients within 3 years and is most commonly associated with a large defect size and subsequent use of prosthetic patch material.<sup>225</sup> Patients who underwent ECMO appear to have the highest risk of recurrence.<sup>239</sup> This is most likely due to the patients having the most severe disease secondary to the largest defects with the subsequent need for prosthetic patch repair.

## Musculoskeletal Outcomes

The relationship between musculoskeletal development and CDH is evidenced by the frequency of chest wall deformities seen in children with CDH. The estimated incidence is between 21% and 48%.<sup>225,231</sup> Pectus deformities, chest asymmetry, and scoliosis are the most common. Scoliosis may be severe and continue to progress until adulthood. Some authors have suggested that the reason for progression is due to tension on the diaphragm, thoracotomies without

muscle-sparing techniques, or a small hemithorax due to hypoplastic lungs.<sup>12,231</sup> Most patients are asymptomatic and do not require surgical intervention.

## Follow-up Guidelines

Critically ill infants with CDH often require prolonged and intensive therapies such as ECMO during hospitalization. These result in long-term sequelae that require medical attention after discharge. Pulmonary, neurologic, gastrointestinal, and musculoskeletal complications necessitate a multidisciplinary team of surgical, medical, and developmental specialists. In 2008, the Section on Surgery and Committee on Fetus and Newborn for the American Academy of Pediatrics established a series of guidelines for the follow-up care of infants with CDH.<sup>240</sup> These recommendations begin before discharge and extend through age 16 years. The guidelines include a formal follow-up plan to facilitate the early recognition of co-morbidities (Table 24-1).

## NOVEL INTERVENTIONS

Even with advances in neonatal critical care, the treatment of infants with CDH remains a challenge to pediatric surgeons, neonatologists, and intensivists. Despite increased survival rates in the past 25 years, many infants with CDH die or develop debilitating morbidities. Thus, researchers continue to investigate novel therapies for infants with CDH.

## Fetal Intervention

The impetus for fetal therapy for CDH coincided with the advances in prenatal diagnosis. Improvements in fetal ultrasonography revealed the true natural history of CDH and the hidden mortality during gestation and soon after birth. These poor outcomes prompted the researchers at the University of California, San Francisco, to explore fetal surgery for CDH. Subsequently, fetal CDH intervention evolved from open fetal surgery to the current state of endoscopic endoluminal tracheal occlusion.

The prerequisite for any fetal intervention is the ability to accurately diagnose CDH and predict severity of disease and survival. The most widely accepted prenatal sonographic prognosticators have been liver herniation and LHR, which have been discussed previously. Liver herniation and an LHR less than 1.0 are recognized as fetal characteristics that portend the poorest outcomes.<sup>241</sup>

After years of unfavorable outcomes with open fetal repair of CDH, prenatal intervention evolved to tracheal occlusion. Based on clinical observations that tracheal atresia causes pulmonary hyperplasia, novel animal experiments of lung distention, and an improved understanding of fetal lung growth, therapeutic tracheal occlusion was introduced as a treatment for pulmonary hypoplasia secondary to CDH.<sup>99,242-244</sup> Current techniques involve endoscopic placement of an occlusive balloon without

maternal laparotomy or general anesthesia.<sup>245</sup> Tracheal balloons are placed between 24 and 28 weeks' gestation and deflated at 34 weeks. This strategy of temporary tracheal occlusion is based on avoiding the need for an ex-utero intrapartum treatment (EXIT) procedure at delivery. In addition, prolonged tracheal occlusion has been demonstrated to differentiate type II pneumocytes into type I pneumocytes, resulting in surfactant deficiency and necessitating the need for balloon removal.<sup>246-248</sup>

An NIH-sponsored randomized trial comparing fetal tracheal occlusion versus standard postnatal care was reported in 2003.<sup>101</sup> After 24 cases (11 by tracheal occlusion), the study was terminated early due to comparable survival outcomes (77% by postnatal care, 73% by tracheal occlusion) during interim analysis. The hazard ratio for mortality associated with tracheal occlusion, as compared with conventional therapy, was 1.2 (95% confidence interval [CI]: 0.29 to 4.67). However, when stratified based on LHR, survival was significantly better for LHR greater than 0.9. In fact, the hazard ratio for death with tracheal occlusion was 0.13 (95% CI: 0.03 to 0.64). This study recognized the wide spectrum of disease based on LHR and speculated that the patients with the most severe disease may still benefit from tracheal occlusion. Despite these results from the randomized trial, tracheal occlusion continues to be investigated owing to the significant mortality of infants with LHR less than 1.0 and liver herniation.

The FETO (Fetoscopic Tracheal Occlusion) task group, a European perinatology organization, created a multicenter prospective observational study.<sup>100</sup> In an attempt to select a more severe subset based on data from the NIH trial, the study included fetuses with liver herniation and LHR less than 1.0. In the initial 21 patients (15 left-sided CDH and 6 right-sided CDH), the investigators reported a survival of 48% for tracheal occlusion compared with 8% in the non-occlusion group. In addition to the survival advantage, the study also demonstrated an improvement in perinatal complications such as prematurity and premature rupture of membranes. The latest series reported overall survival of 57% for tracheal occlusion with survival greater than 62% for LHR between 0.6 and 1.0.<sup>241</sup> Although impressive, these results warrant further investigation in that the survival for LHR of 0.8 to 0.9 (78%) was higher than survival for LHR greater than 1.0 treated postnatally (65%). Furthermore, study limitations have prevented the widespread adoption of tracheal occlusion based on the European data. Control cases were taken from multiple centers that could not provide a standardized postnatal approach or reflect recent advances in postnatal care.

Long-term outcome with morbidity has yet to be reported for tracheal occlusion. However, one study examined pulmonary function in 20 patients (9 with conventional therapy and 11 with tracheal occlusions) from the NIH-sponsored randomized trial.<sup>249</sup> Infants were evaluated during the first 24 hours of life, before and after operative repair, and before elective

extubation. The study demonstrated slight improvements in respiratory compliance and alveolar-arterial oxygenation gradients in patients who had undergone tracheal occlusion. However, other long-term outcomes remain to be seen. Based on the only randomized clinical trial, there appears to be no significant benefit from tracheal occlusion for the treatment of CDH. Although proponents of fetal intervention suggest that a subgroup of the most severe patients (liver herniation and LHR < 0.9) may still benefit from fetal intervention, the true efficacy of fetal tracheal occlusion for these severely affected infants will require a prospective randomized trial before its universal acceptance.

## Prenatal Glucocorticoids

The hypoplastic lungs of CDH infants are structurally and functionally immature. Biochemical markers for lung maturity demonstrate decreased total lung DNA, total lung protein, and desaturated phosphatidylcholine in addition to deficiency of surfactant.<sup>63</sup> In animal models of CDH, prenatal administration of glucocorticoids has demonstrated a reduction in alveolar septal thickness, increased DNA synthesis, and increased total lung protein production.<sup>250,251</sup> Thus, antenatal administration of glucocorticoids has been used to improve lung function.<sup>252,253</sup> Initial results from small patient studies seemed promising. However, a prospective randomized trial conducted by the CDHSG failed to demonstrate any benefit to antenatal corticosteroid therapy for CDH.<sup>254</sup> In the multicenter trial, mothers received three weekly administrations of prenatal betamethasone. The study, which included 32 patients (15 on placebo and 17 on steroids), failed to show a difference in overall survival benefit, length of mechanical ventilation, length of hospitalization, or need for supplemental oxygen at 30 days. The study compared its results with a large cohort from the CDHR with comparable outcomes.

## ANTERIOR HERNIAS OF MORGAGNI

Anterior diaphragmatic hernias of Morgagni account for less than 2% of all congenital diaphragmatic hernias. The foramen of Morgagni hernia results from the failure of the crural and sternal portions of the diaphragm to fuse. This can occur on either side at the junction of the septum transversum and thoracic wall where the superior epigastric artery (internal mammary artery, intrathoracically) traverses the diaphragm. Approximately 90% of unilateral hernias occur on the right.<sup>255</sup> Only 7% occur bilaterally.<sup>256</sup> Operatively, these may communicate in the midline and appear as a very large anterior hernia. Typically, a hernia sac is present with herniation of omentum, small intestine, and/or large intestine but may also contain liver and spleen. Malrotation may also be found. The majority of children with Morgagni hernia are asymptomatic and thus are rarely diagnosed during the neonatal period. When these hernias become symptomatic, pulmonary symptoms are usually not

**Figure 24-9.** A, Chest radiograph in a neonate with a retrosternal hernia. Anteroposterior film demonstrates air-filled loops of bowel above the diaphragm and posterior to the sternum (arrow). B, Lateral projection confirms the retrosternal position of the herniated viscera (arrow).

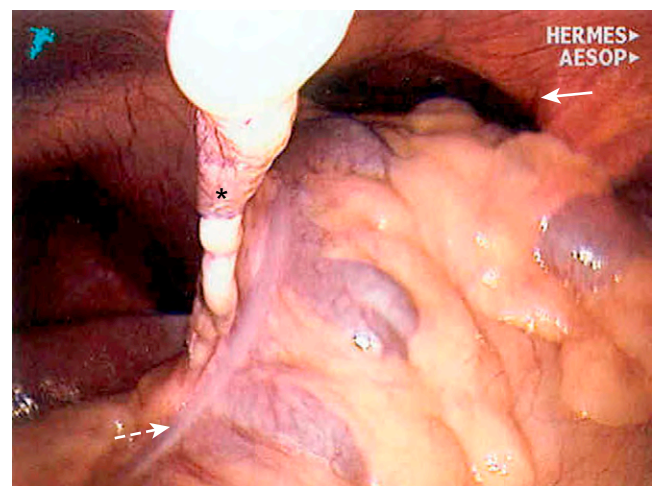

the primary complaint. Children may have general epigastric discomfort such as vomiting and coughing due to intermittent obstruction.<sup>255,257</sup> Acute cases may present as intestinal ischemia with necrosis and perforation as well as gastric volvulus.<sup>258,259</sup> Herniation into the pericardium causing tamponade has been reported.<sup>260</sup>

Chest radiographs of Morgagni hernias may exhibit a well-defined air-fluid level in the midline of the chest. A lateral chest radiograph will demonstrate the hernia in the retrosternal space (Fig. 24-9). Small hernias may require a contrast radiograph or CT scan to confirm the diagnosis. Because of the risk of incarceration and strangulation, these hernias should be repaired relatively soon after diagnosis. Operative repair usually entails reduction of herniated viscera, excision of the hernia sac, and closure of the diaphragm to the posterior rectus sheath at the costal margin. Open procedures can be performed through an upper transabdominal incision. Laparoscopic techniques have been well documented (Fig. 24-10).<sup>261,262</sup> Although most defects can be repaired primarily, large defects may require patch repairs. The use of PTFE and biosynthetic (Surgisis, Cook Inc., Bloomington IN) patches has been described.<sup>197,263</sup> The long-term outcome regarding recurrence is yet to be defined.

An anterior diaphragmatic hernia may be found in association with a pentalogy of Cantrell due to a failure in the development of the septum transversum.<sup>264</sup> Pentalogy of Cantrell is a rare cluster of congenital anomalies that include omphalocele, cardiac defects, ectopic cordis, and an anterior diaphragmatic defect extending into the pericardium. The cardiac defect is the most severe problem and is the main cause of mortality.

## DIAPHRAGMATIC EVENTRATION

Eventration is the abnormal elevation of the diaphragm resulting in a paradoxical motion during respiration that interferes with proper pulmonary mechanics and function.<sup>265,266</sup> Congenital eventration results from the incomplete development of the central tendon or muscular portion of the diaphragm. Most commonly left sided, bilateral congenital eventration has been reported.<sup>267</sup> The muscle is typically present but does not move in a coordinated fashion. The diaphragm is

**Figure 24-10.** Laparoscopic view of a Morgagni hernia. This anterior hernia (white arrow) is to the left of the falciform ligament (asterisk) with a deep sac that was excised. The large bowel (dotted arrow) was reduced from the hernia defect, and the defect was closed with a biosynthetic patch. (From Holcomb GW III, Ostlie DJ, Miller KA: Laparoscopic patch repair of diaphragmatic hernias with Surgisis. *J Pediatr Surg* 40:e1-e5, 2005.)

thin, which may be indistinguishable from a hernia sac in CDH. Large eventrations may interfere with lung development due to the paradoxical motion, and the elevated diaphragm may decrease the thoracic space. Similar to CDH, congenital eventration can result in lung hypoplasia, although this is uncommon. Persistent fetal circulation and pulmonary hypertension are usually not seen with eventration. Diaphragmatic eventration may also be acquired due to paralysis of the phrenic nerve. This can occur secondary to mediastinal tumors, congenital heart surgery, or birth trauma. The incidence after congenital cardiac surgery has been reported to be approximately 5%, with the highest incidence after Fontan and Blalock-Taussig shunt procedures.<sup>268,269</sup>

Diaphragmatic eventration may be asymptomatic but typically presents acutely as respiratory distress and tachypnea in the newborn or more indolently with recurrent respiratory infections and wheezing. Neonates may have feeding intolerance due to dis-coordinated sucking and breathing. Older children may demonstrate exercise intolerance. Both lungs are usually affected by the paradoxical motion. On inspiration, the eventrated diaphragm rises, which causes the mediastinum to shift and compress the contralateral lung.

Eventration is typically suspected on a plain radiograph when an elevated hemidiaphragm is seen (Fig. 24-11). The diagnosis is subsequently confirmed by ultrasonography or fluoroscopy. Motion studies demonstrate a paradoxical movement of the diaphragm during respiration with a shift of the mediastinum.<sup>270</sup> Prenatal diagnosis of congenital eventration has been reported using fetal ultrasonography and MRI.<sup>271,272</sup> Occasionally, CT is required to distinguish eventration from pleural effusions, mediastinal tumors, bronchogenic cysts, and pulmonary sequestrations.

Small eventrations may be left untreated. Eventually, the child will overcome and compensate for the abnormal diaphragmatic dynamics. Initial treatment should include respiratory support, but mechanical ventilation is usually not necessary. However, larger

**Figure 24-11.** Anteroposterior chest radiograph of a 4-week-old male neonate demonstrates a left-sided diaphragmatic eventration (*arrow*) after repair of total anomalous pulmonary venous return. The abdominal viscera remain beneath an intact left hemidiaphragm.

defects that cause functional pulmonary impairment or promote recurrent infections should be repaired. Neonates with large eventrations benefit from early repair rather than a course of conservative treatment.<sup>270,273</sup> Acquired eventrations may require repair for the patient to be weaned from mechanical ventilation.

Surgical repair can be accomplished through the chest or abdomen. The eventrated diaphragm is plicated with a series of nonabsorbable sutures. The sutures should imbricate generous amounts of the diaphragmatic tissue without injury to the phrenic nerve. Edges of the diaphragm should overlap until the plicated muscle is taut. Subsequently, the diaphragm becomes immobilized, resulting in an increased tidal volume and preventing mediastinal shift. Minimally invasive techniques have been well described using thoracoscopic and laparoscopic approaches.<sup>274-276</sup>

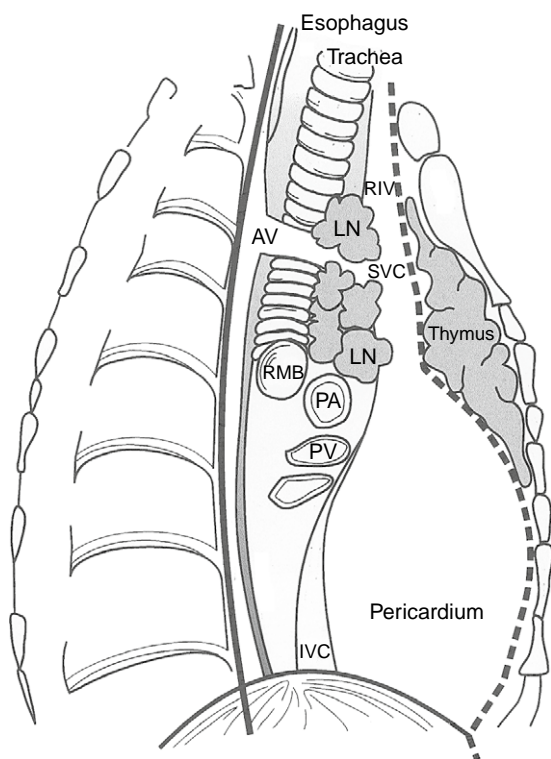

# MEDIASTINAL TUMORS

Juan A. Tovar, MD, PhD

The mediastinum is the body compartment limited by the sternum, the spine, the diaphragm, and both lungs. For teaching purposes, it is divided into three parts: anterior, middle, and posterior (Fig. 25-1). The boundaries of the anterior mediastinum are the sternum anteriorly; the trachea, great vessels, and pericardium posteriorly; and the pleurae and the lungs laterally. This compartment contains the thymus, lymphoid structures, and nerves and vessels embedded into a mesenchymal and fatty environment. The

middle mediastinum contains the trachea, main-stem bronchi, the heart and great vessels, as well as the hilar lymph nodes. The posterior mediastinum accommodates the aorta, the thoracic esophagus, and the sympathetic nerve chains.

Developmentally, the foregut runs longitudinally in the middle of the embryonal mediastinum and differentiates to form the esophagus and trachea. The tracheobronchial tree and the lungs originate from a ventral bud from the foregut that subsequently grows and branches while interacting with the surrounding mesenchyme to produce the lungs. Neural crest cells migrate along the foregut axis to innervate the gastrointestinal tract and form the sympathetic chains. The anterior mediastinum is one of the regions through which embryonal germ cells migrate toward their final settlement in the gonads. The thymus is derived from paired primordia located in the third pharyngeal pouches that subsequently migrate into the anterior mediastinum where they fuse to form a single organ. All these events explain why tracheobronchial and esophageal malformations, neural crest and germ cell tumors, and thymic tumors and cysts are located in this compartment. Finally, the lymphaticovenous confluence and the vascular structures in the upper mediastinum account for the presence of some vascular tumors and malformations in this area. The most frequent location of the different mediastinal tumors is summarized in Table 25-1.

**Figure 25-1.** Anatomic division of the mediastinum: anterior compartment extends from the sternum to the dotted line anterior to the pericardium. Middle mediastinum extends posteriorly to the anterior border of the vertebrae (solid line). Compartment	Benign	Malignant
Anterior	Teratoma Thymic hyperplasia Thymic cysts (rare)	Non-Hodgkin's lymphoma Hodgkin's lymphoma Thymic tumors (rare)
Middle	Lymphangioma Foregut cysts and duplications	Non-Hodgkin's lymphoma Hodgkin's lymphoma
Posterior	Ganglioneuroma	Neuroblastoma

## CLINICAL FEATURES

Mediastinal tumors and cysts are occasionally diagnosed before birth and may even benefit from prenatal instrumentation.<sup>1,2</sup> Most mediastinal masses seen during infancy and childhood do not produce symptoms and are discovered with imaging performed for concurrent conditions. Respiratory embarrassment, orthopnea, stridor, wheezing, or even severe distress and/or superior vena cava syndrome are seen in some instances. Sternal bulging may appear in young infants with large anterior tumors. Recurrent laryngeal or phrenic nerve palsies or Horner syndrome may reveal the presence of the tumor when it involves the nerve trunks. Sudden paraplegia or paraparesia is occasionally observed in dumbbell-shaped tumors involving the spinal cord. Finally, secretion of catecholamines,  $\alpha$ -fetoprotein, or gonadotropins may also uncover the tumor.

## DIAGNOSTIC METHODS

Modern imaging allows accurate preoperative diagnosis in most cases. Plain radiographs of the thorax show widening of the superior mediastinal shadow or masses in either hemithorax. Ultrasonography may be useful as well.<sup>3</sup> Computed tomography (CT) helps to locate the tumor and to provide information about its cystic or solid nature, revealing calcifications, necrotic areas, and other details such as occasional widening of the spinal foramina in cases with intraspinal extension. Calcifications are suggestive of neuroblastoma or teratoma, but other tumors, such as lymphangiomas or some histiocytoses, may have calcified areas that should be taken into account upon diagnosis.<sup>4-6</sup> CT is also important for assessing the patency of the airway and the risks of anesthesia.<sup>7</sup> Magnetic resonance imaging (MRI) is used to better define the nature of the masses of vascular origin, but it may be very useful in other tumors as well, particularly for evaluating the intraspinal space.<sup>8,9</sup>

In some tumors, particularly those for which surgery is not the primary treatment, histology, cell markers, and molecular biology features must be ascertained before undertaking therapy. Cells can be obtained by biopsy of distant lymph nodes in the cervical or suprasternal notch areas, or by fine-needle aspiration (FNA) guided by ultrasonography or CT, or by pleural or pericardial fluid aspiration.<sup>10-12</sup> When this is not feasible, operative biopsy may be required. Thoracoscopy or anterior mini-thoracotomy through the bed of the second or third rib (the Chamberlain approach) may provide material for biopsy.<sup>13-15</sup> Mediastinoscopy is rarely needed in children.<sup>16,17</sup>

## PRINCIPLES OF MANAGEMENT

It is vitally important for all involved in the care of a child with an anterior mediastinal mass to remember the possible respiratory collapse that may occur

after induction and even before relaxation. Ventilation can be critically difficult, particularly in children with lymphoma in whom thorough preanesthetic assessment using CT sections of the upper chest and respiratory tests is necessary. The anesthetic risk is high if the cross-sectional surface of the tracheal lumen is decreased by 50% or more on the CT scan.<sup>14</sup> These patients also have marked reductions in the maximum expiratory flow rates, and special modalities of anesthesia (e.g., spontaneous ventilation, laryngeal mask, rigid tubes) may be required.<sup>7</sup>

Except for lymphomas that respond to chemotherapy and/or radiotherapy and in which surgery is usually adjuvant, all other mediastinal masses in children should be removed. Excision can be accomplished by median sternotomy, which is an excellent approach in terms of exposure and postoperative pain,<sup>17</sup> but thoracotomy on either side might be better depending on the anatomic extent of the mass. Thoracoscopy is an alternative in some cases, although it must be adapted to the principles of oncologic surgery and avoid spillage of tumor cells or fluids (particularly true for germ cell tumors).<sup>17-19</sup>

## LYMPHOMA

### Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphoma (NHL) is one of the more frequent tumors of the mediastinum. It is a systemic disease in which there is massive proliferation of lymphoblasts in the lymph nodes. Lymphoblasts can ontogenically divide into B cells (related to tumoral immunity and produced in the bone marrow) and T cells (involved in cellular immunity that are processed in the thymus). In children, B cells cause undifferentiated Burkitt's or non-Burkitt's lymphomas, which constitute about 50% of all lymphomas. These lymphomas are found in the abdominal organs, whereas T cells cause lymphoblastic lymphomas (about 40% of all) and are generally located in the thymus and/or lymph nodes of the anterior mediastinum. Finally, the remaining 10% correspond to large cell lymphomas. These are similar to undifferentiated tumors but may be of T- or B-cell origin and appear on either side of the diaphragm.

Undifferentiated lymphomas express surface IgM and CD19 and CD20 antigens, whereas lymphoblastic lymphomas contain the enzyme TdT (terminal deoxynucleotidyl transferase) and express T-cell markers such as CD5 and CD7.<sup>19</sup> Burkitt-type lymphomas often have 8:14, and less often 8:22 or 2:8 translocations, involving the *MYCC* proto-oncogene, whereas T-cell lymphomas occasionally have 14q11 translocations.<sup>20,21</sup>

At the time of diagnosis, these tumors have usually spread beyond the original site and involve the regional nodes and distant organs such as the pleural or pericardial spaces or the bone marrow. (In this case, they are practically indistinguishable from acute lymphoblastic leukemia.) The liver and other abdominal

organs and the central nervous system may occasionally be involved as well.

Rapid growth of mediastinal lymphomas may distort the airway, causing respiratory distress, wheezing, and orthopnea. The vena cava may be compressed, generating cervicofacial edema and jugular distention. Systemic symptoms are possible, and hematologic disturbances may appear when the bone marrow is invaded. Lymph nodes may be enlarged and palpable elsewhere, particularly in the neck, axillae, and supraclavicular or suprasternal regions.

Imaging depicts an enlargement of the mediastinum with or without involvement of the airway. Sometimes fluid can be seen in the pleural or pericardial spaces and obtained for cytologic analysis.<sup>12,22</sup> If neither peripheral lymph nodes nor fluids are available for biopsy or puncture, fine-needle aspiration under ultrasonography or CT is required for cytologic analysis. If this is still not diagnostic, biopsy by thoracoscopy or the anterior Chamberlain approach may be necessary. In both cases, the anesthetic risks and precautions should be emphasized.<sup>23,24</sup>

Staging of NHL takes into account the extent of the disease in terms of overall bulk of the tumoral tissue. The most used classification includes mediastinal cases as stage III except when the bone marrow and/or the central nervous system are involved (stage IV).<sup>25</sup> Standard imaging procedures and tissue and cell investigations allow proper staging, but other procedures such as gallium-67 isotopic scanning may be helpful as well.<sup>26,27</sup> The role of combined positron emission tomography (PET) and CT in children is still undefined.

Surgery is not a primary option in the treatment of mediastinal NHL because this disease responds well to chemotherapy and corticosteroids, limiting the contribution of the surgeon to providing adequate biopsy material for cytologic assessment. Chemotherapy based on acute lymphoblastic leukemia protocols leads to long-term survival in more than 80% of these children.<sup>25,28</sup>

## Hodgkin's Lymphoma

Hodgkin's lymphoma is less frequent in this location and occurs more often in preadolescent and adolescent individuals. The main feature is the Reed-Sternberg cell, which is probably the malignant counterpart of the dendritic interdigitating cell that has a role in antigen presentation. These cells are embedded in lymph nodes in which the proportions of fibrous stroma, lymphocytes, and plasma cells are variable, allowing classification into the following types: lymphocyte predominant, lymphocyte depleted, mixed cellularity, and nodular sclerosis. Most children with Hodgkin's lymphoma have the nodular sclerosis type, but the youngest ones may have lymphocyte predominant or mixed cellularity varieties.<sup>29</sup>

Hodgkin's lymphoma originates in one group of lymph nodes but extends to contiguous or distant nodes after lymphatic pathways. Confirmation of the diagnosis and a detailed histology assessment require biopsies that are probably impossible from frozen section analysis alone. The extent of the disease determines the modality and the intensity of the treatment. Therefore, accurate staging is imperative before selection of the treatment protocol. The Ann Arbor classification of four stages with subgroups, according to the presence or absence of systemic symptoms, remains the most widely used system, but the mapping of the involved organs or lymph node groups requires refined imaging tools.

Hodgkin's lymphoma may be localized primarily in the anterior and middle mediastinum in children and may cause the same compressive effects as NHL (Fig. 25-2). Biopsies are sometimes possible from extrathoracic nodes. If not, the Chamberlain operation or thoracoscopy usually allow retrieval of enough tissue for diagnosis. The widespread preference for chemotherapy over radiotherapy in children, perhaps except in some adolescents, has limited the use of staging laparotomy. Staging laparotomy should be reserved for those cases with stage II thoracic involvement in which

**Figure 25-2.** Imaging studies in an 11-year-old boy with Hodgkin's lymphoma. **A**, Widening of the mediastinum is accompanied by compression of the upper trachea that is seen on the chest radiograph. **B**, Transverse section on a CT scan of the upper mediastinum shows the extent of this tracheal compression by adenopathy that displaces the vessels laterally.

localized radiotherapy as the sole treatment requires excluding transdiaphragmatic involvement.<sup>30</sup> PET/CT seems promising as a noninvasive staging modality.<sup>29</sup>

Like NHL, surgery is not the primary treatment of Hodgkin's lymphoma, except in very localized cases. However, it may be occasionally performed in children in whom unusual imaging pictures, such as cystic spaces within the enlarged thymus, are suggestive of other diagnoses and lead to removal of the organ.<sup>31</sup>

## GERM CELL TUMORS

The primitive germ cells may produce various types of tumors. Tumors from the gonadal germ cells (seminoma and dysgerminoma) and those of the totipotential cells may be either in the line of extraembryonic tissues (yolk sac tumors and choriocarcinoma) or in the line of embryonic tissues (teratomas). In fact, these different tissues can be found sometimes in the same tumor.

### Teratomas

These tumors comprise only 8% to 16% of the tumors in this region at all ages and are uncommon in children.<sup>32-35</sup> They consist of solid or organoid masses containing tissues derived from all three blastodermic layers (ectoderm, endoderm, and mesoderm). Their histologic features are heterogeneous and may include cystic or solid areas as well as mature and immature components. Their incidence is higher in individuals with Klinefelter's syndrome.<sup>36,37</sup>

Mediastinal teratomas originate most often from the thymus or pericardium and are therefore located almost invariably in the anterior compartment of the mediastinum. They are as frequent in girls as in boys, in contrast to the situation in adults in whom there is a clear male predominance.<sup>38-40</sup> They develop relatively early in fetal life, and may cause hydrops and fetal demise.<sup>2,41</sup> These masses can be diagnosed prenatally. However, in most cases, they are detected after birth because of respiratory distress or later in life because of vague symptoms (thoracic or cervical pain, dyspnea) that are more frequent in children than in adults. The diagnosis is often an incidental finding from chest radiographs performed for other causes. Mediastinal teratomas should be suspected whenever a mass with or without calcifications is seen in the anterior mediastinal compartment. However, this diagnosis often is not made until the operation.

Most mediastinal teratomas are benign in children, but the prognosis is definitely worse if they contain elements of other germ cell tumors such as yolk sac, embryonal carcinoma, seminoma, germinoma, or choriocarcinoma.<sup>35,37</sup> Some of these lesions may induce precocious puberty or detectable pancreatic secretions.<sup>37,42</sup>

Surgical excision is the treatment of choice for mediastinal teratomas. Median sternotomy provides excellent exposure, but lateral thoracotomies may be preferred when the tumor extends into either hemithorax. Thoracoscopy has been described for removal of some benign

mediastinal tumors.<sup>43</sup> Chemotherapy with carboplatin, bleomycin, and etoposide, which is very effective in malignant germ cell tumors, may allow secondary surgery after tumor shrinkage in cases that cannot be initially removed.<sup>37</sup> Although wide adherence to adjacent tissues usually makes a complete resection difficult, it is essential to avoid recurrence. In fact, these tumors have an excellent prognosis when resection is complete.  $\alpha$ -Fetoprotein is a good tumor marker because it is usually elevated in malignant and immature tumors and very seldom in mature ones.<sup>44</sup>

### Nonteratomatous Germ Cell Tumors

Very rarely, pure extraembryonal germ cell tumors (seminoma/dysgerminoma, embryonal carcinoma, yolk sac tumor, or choriocarcinoma) may appear in the anterior mediastinum. These are malignant and require complete removal and chemotherapy, as explained earlier for the malignant components of teratomas.<sup>37,44</sup>

## TUMORS AND CYSTS OF THE THYMUS

During their migration, the thymic primordia leave behind thymopharyngeal ducts (not unlike the thyroglossal duct of the migrating thyroid gland) that progressively obliterate and disappear. Epithelial tumors and cysts are therefore possible in this organ along with lymphocytic and mesenchymal tumors.

### Thymic Hyperplasia

The thymus plays an important role in the development of cellular immunity in infancy. Therefore, its size is larger at this age and regresses later in life. Sometimes real hyperplasia may suggest the development of a thymic mass. However, the absence of symptoms and clinical compromise of the mediastinal vessels as well as some radiologic features (e.g., the absence of compression of the airway or the "boat sail" shape of the inferior boundaries of the organ) rule out this suspicion. Treatment with corticosteroids is usually enough to make the enlarged thymus regress, and observation may be a better choice.

### Thymic Cysts

Cysts derived from the thymopharyngeal ducts may appear in the anterior mediastinum and/or in the neck. They are lined by pharyngeal epithelium, which is often ciliated. They have secretory and thymic elements (Hassall's corpuscles) and may be inflamed or infected. When they reach a certain size, they are either palpable (in the neck) or detected on imaging of the mediastinum.<sup>45,46</sup> Also, they may cause respiratory symptoms by compression.<sup>47</sup> Thymic cysts can also be found in rare instances of malignant lymphoma and in patients with human immunodeficiency virus (HIV) infection in whom they can be multilocular.<sup>31,48</sup> These cysts require surgical excision through a cervical or transsternal approach.

## Malignant Thymic Tumors

In contrast with adults, malignant neoplasia of the thymus is exceedingly rare in children. However, some instances of malignant thymoma without or with myasthenia gravis and thymic carcinoma have been reported.<sup>33,49,50</sup>

## VASCULAR TUMORS AND ANOMALIES

Modern classifications of vascular anomalies and tumors have facilitated the understanding of their apparently unpredictable clinical course. It is currently accepted that the vascular tumors of congenital hemangioma with its two varieties (noninvoluting [NICH] and rapidly involuting [RICH]), hemangioma, kaposiform hemangioendothelioma, and the capillary, venous, arteriovenous, or lymphatic vascular malformations have very different clinical behaviors and require an individualized approach.<sup>51</sup> Although rare, these conditions may locate in the mediastinum where they may pose difficult therapeutic problems. Pathologic reviews of these mediastinal tumors at all ages illustrate the wide range of stable or regressive behavior.<sup>52</sup>

### Vascular Tumors

Most hemangiomas located in the anterior mediastinum are in continuity with cervicofacial components. They may be asymptomatic or cause respiratory compromise when they extend into the airway. If they are asymptomatic, they should not be treated because they tend to regress over time. However, if airway compression is present, active anti-angiogenic treatment with corticosteroids and/or interferon-2 $\alpha$  or vincristine must be promptly used. Interferon-2 $\alpha$  has been found to cause severe neurologic complications.<sup>51</sup>

Kaposiform hemangioendothelioma is dangerous because when it is large, it may be accompanied by a Kasabach-Merritt syndrome in which there is massive platelet trapping with risks of hemorrhage. These tumors involve the thoracic wall and often the mediastinum. Full anti-angiogenic therapy together with close hematologic

monitoring and eventually surgery are required. This tumor has a mortality rate close to 20%.<sup>51</sup>

## Vascular Malformations

Venous and arteriovenous malformations are very rarely located in the mediastinum, and the vast majority are lymphangiomas. They may be located anywhere in the body but particularly near the confluences of large venous and lymphatic collections that are found in the mediastinum.<sup>53,54</sup> The tumor may extend into either hemithorax and eventually into the neck and the base of the mouth. Lymphangiomas are multicystic and infiltrate the anatomic structures (Fig. 25-3). Reaction to local infections may make the mass swell or even suppurate. Respiratory symptoms may arise in cases with airway compromise.<sup>55</sup> Modern imaging is very helpful for diagnosis, particularly MRI.

Mediastinal lymphangiomas do not tend to involute spontaneously. The treatment strategy must take into account that they are benign, that total removal is often impossible, and that a too radical operation may endanger nerve trunks or other structures.<sup>56,57</sup> Sclerosis with OK-432 or bleomycin is an alternative or a complement in cases in which incomplete removal has already reduced the volume of the tumor.<sup>51</sup> Only in cases of single, wide cysts is the result of sclerosing procedures generally satisfactory.<sup>58</sup> For masses with multiple infiltrating cysts of small size, partial debulking may be satisfactory to reduce symptoms.<sup>56</sup>

## FOREGUT CYSTS AND DUPLICATIONS

Abnormal branching of the tracheobronchial anlage from the ventral face of the foregut may form closed spaces lined by either esophageal or bronchial mucosa. These cysts are located in the mediastinum in close contact with either the trachea and main-stem bronchi or the esophagus. The secreting mucosa progressively enlarges the cysts, which can then become symptomatic. In rare instances, the foregut malformation is more extensive and involves both the respiratory and digestive tracts and combine esophageal duplications with

**Figure 25-3.** A 3-year-old girl presented with a left cervicomeastinal lymphangioma. **A**, Chest radiograph depicts the large mass. **B**, CT scan shows displacement of the trachea and other mediastinal structures by cysts of variable density.

**Figure 25-4.** This newborn with the prenatal diagnosis of an upper mediastinal cyst had respiratory distress at birth. These T2-weighted MR images show a large prevertebral mucus cyst that displaces the trachea forward (**A**) and extends to both sides (**B**). In **A**, deformation of the anterior vertebral bodies due to prolonged prenatal compression can be seen. This bronchogenic cyst was successfully removed thoracoscopically.

airway malformations.<sup>59,60</sup> When the foregut cyst is due to a persistence of the embryonic neuroenteric communication, it involves both the foregut and the neural tube. It splits the notochord and, as a consequence, is accompanied by split vertebral bodies. This rare variety is termed a neuroenteric cyst.<sup>61-63</sup>

Prenatal diagnosis of mediastinal cysts is possible.<sup>64</sup> However, most cases are diagnosed because of symptoms of respiratory or gastrointestinal compression that become evident at birth (Fig. 25-4) or later in life, or are found during imaging for unrelated symptoms. Very seldom, these mediastinal cysts may bleed due to mucosal ulceration.

When the cysts are located close to the trachea and main-stem bronchi, they are usually lined by ciliated epithelium and are considered to be “bronchogenic cysts” (Fig. 25-5).<sup>65,66</sup> Those located in contact or

within the wall of the esophagus are lined by esophageal or mixed epithelium and are known as “esophageal duplication cysts.” Both types are filled with more or less mucoid fluid depending on the proportion of secretory glands in their lining.

Plain chest radiographs may show paramediastinal round opacities, and esophagograms depict esophageal compression from outside or intraluminal imprinting by the cyst. CT and/or MRI depict precisely the size and location of the cysts and the nature of their content. Endoscopy may be useful in cases in which the cyst is within the wall of the esophagus, and it can demonstrate external compression in other cases.

The treatment of foregut cysts and duplications should be surgical because of their secretory nature. Prenatal diagnosis may allow intrauterine treatment, which has been described.<sup>67</sup> Thoracoscopy has become

**Figure 25-5.** This 12-year-old developed some respiratory distress that prompted the chest radiograph (**A**), which shows a right bronchogenic cyst (arrows). **B**, The lesion (asterisk) is seen at thoracoscopy. **C**, After removal of the cyst, the esophagus (arrow) is seen to lie in the posterior bed of the resection. The cyst was intimately adherent to the right main-stem bronchus (asterisk).

the preferred approach in recent years.<sup>68-72</sup> Most esophageal duplications and bronchogenic cysts can be removed by this approach. Dissection from the esophageal wall may be delicate, but, because these cysts are generally not communicated with the esophageal lumen, they can be mobilized without damage to the mucosa. Intraoperative esophageal fiberoptic observation may be helpful.<sup>73</sup> As in other duplications, it is essential to completely remove the secreting mucosa to prevent recurrence or cancer later in adulthood.<sup>65</sup>

## NEURAL TUMORS

These tumors originate from the sympathetic chains located on both sides of the spine and may exhibit different degrees of differentiation, ranging from malignant neuroblastomas to mature ganglioneuromas (Fig. 25-6). These two components may appear together in the same tumor. For unknown reasons, thoracic neural tumors are less malignant than those located in the abdomen.<sup>74</sup> Also, thoracic neuroblastomas tend to behave less aggressively. The proportion of INSS stages 1 and 2 and of favorable histologic pattern are definitely higher than in other locations. Moreover, these tumors are less likely to have biologic and molecular predictors of malignancy, such as *MYCN* amplification.<sup>74-77</sup>

The tumors involve the sympathetic trunks and a variable number of ganglia. Sometimes they may extend into the spinal canal through one or several foramina (dumbbell- or hourglass-shaped tumors).<sup>78,79</sup> The upper or apical tumors may extend to the neck and often involve the stellate ganglion. The lower ones may extend into the abdomen through the posterior diaphragmatic insertions and/or the aortic hiatus. The aorta and the esophagus on the left side and the azygos vein on the right may be in close contact with the tumor, which sometimes passes across the midline. Intercostal arteries and veins are often intratumoral.

Horner syndrome and/or heterochromia of the iris may lead to the diagnosis.<sup>80,81</sup> Paraplegia due to spinal cord compression may occur suddenly.<sup>82</sup> However,

most cases are silent and are discovered by imaging procedures for concurrent conditions or vague symptoms. The proportion of secreting tumors in this location is low and paraneoplastic symptoms such as hypertension and diarrhea are rare. A limited number of malignant tumors spread from the primary site and metastasize to distant regions such as the bone marrow or the bones.<sup>77</sup>

Imaging reveals a round or fusiform mass with paraspinal extrapleural signs and sometimes hemorrhagic, necrotic, or calcified areas. The ribs and the spinal pedicles may be distorted, with the foramina enlarged. In hourglass-shaped tumors, the intraspinal component is better depicted by MRI (Fig. 25-7).<sup>78</sup>

All tests required for neuroblastoma workup (e.g., metaiodobenzylguanidine scan, catecholamine metabolite excretion) are routinely used for tumors in this location as well.

In cases with paraplegia, emergency laminectomy or laminotomy with removal of the intraspinal extension is generally preferred,<sup>82,83</sup> although some groups advise chemotherapy initially.<sup>84</sup> Except in very extensive tumors and in those with bone metastases in which chemotherapy should precede surgical removal, mediastinal neural tumors are primarily excised.<sup>85</sup> This operation may be difficult, particularly when the tumor extends beyond the midline or into the neck, the spinal canal, or below the diaphragm. Mobilization of the aorta with division of several intercostal vessels may be required. Clearance of the tumor should be as complete as possible, although in many cases minimal macroscopic residual disease is unavoidable. In cases of thoracoabdominal tumors, splitting the diaphragm and dissecting the retroperitoneal mass from above at the same operative setting is advantageous. Thoracoscopic excision is increasingly being utilized.<sup>18,86,87</sup>

Irrespective of their histology, the survival of patients with thoracic neuroblastoma is encouraging and always better than that of their abdominal counterparts. Some sequelae are unavoidable. Paraplegia may persist when the cord has been permanently damaged (this happens in tumors that cause prenatal compression).<sup>88,89</sup>

**Figure 25-6.** A 16-year-old presented with a Horner syndrome and was found to have a right superior mediastinal mass. **A**, MR image of the mass. **B**, At thoracoscopy, the mass can be visualized cephalad to the azygos vein and just lateral to the superior vena cava (asterisk). This ganglioneuroma was able to be removed thoracoscopically.

**Figure 25-7.** This 7-year-old patient had a long-standing history of neuroblastoma that was treated with chemotherapy but the lesion was not resected. The tumor is seen as a fusiform mass extending to both sides of the thorax on the plain radiograph (A) and MR image (B). C, CT scan shows rib and vertebral body deformations with widening of the foramina and displacement of the great vessels. D, MR image depicts the dumbbell-shaped nature of the tumor, which invaded the spinal canal, although without paraplegia. Combined spinal and right thoracotomy approaches allowed complete resection of the mass.

Permanent paraplegia may occasionally occur due to intraoperative spinal cord ischemia.<sup>90</sup> Division of the segmental vessels may cause localized paralysis of upper abdominal or thoracic muscles. Removal of the stellate ganglion usually leads to permanent Horner syndrome. Finally, scoliosis may ensue after laminectomies and should be avoided whenever possible.

### OTHER RARE MEDIASTINAL TUMORS

Rarely, other mediastinal tumors have been reported in children. These include pseudoinflammatory tumor,<sup>91</sup> Langerhans' cell histiocytosis with calcification,<sup>5,92</sup> thymolipoma,<sup>93</sup> sarcoma,<sup>94</sup> and liposarcoma.<sup>95</sup>

# THE ESOPHAGUS

Nicole Chandler, MD • Paul M. Colombani, MD

The esophagus is a hollow muscular tube consisting of mucosa, submucosa, and muscularis layers. The esophagus lacks a serosal layer. The upper one third of the esophagus is striated muscle under voluntary control, and the distal two thirds of the esophagus is composed of smooth muscle under autonomic control. Two sphincters control passage of contents into the gastrointestinal tract: an anatomic upper esophageal sphincter (UES) and a physiologic lower esophageal sphincter (LES). The UES consists of the cricopharyngeus and inferior pharyngeal constrictors. The LES is histologically similar to the muscular component of the esophagus.

The blood supply to the proximal esophagus is derived from the fourth brachial arch. The fourth brachial arch gives rise to the subclavian artery and its branches, including the inferior thyroid artery, which supplies the cervical esophagus. The thoracic esophagus is supplied directly from branches of the aorta. The excellent submucosal plexus of the proximal esophagus allows for extensive mobilization without compromise to the blood supply, whereas caution should be taken distally because of the segmental distal esophageal blood supply. The abdominal esophagus has a generous blood supply from the phrenic branches and gastric vessels.

Embryologically, the trachea and esophagus are intimately related. The trachea and esophagus both develop from the foregut as a median ventral diverticulum. Familiarity with the embryologic development of the esophagus and trachea is important to understand the congenital abnormalities that arise from these structures. The classic description of these malformations proposes an impaired process of septation of the trachea and esophagus.<sup>1</sup>

In humans, normal development of the foregut begins during the fourth week of gestation. At 22 days' gestation, the foregut endoderm differentiates into a ventral respiratory part and a dorsal esophageal part. The separation of the respiratory part from the esophageal part is achieved by the formation of lateral longitudinal tracheoesophageal folds. The trachea and esophagus elongate first distally and then proximally. At 6 to 7 weeks' gestation, the separation of

the esophagus and trachea is complete. At birth, the esophagus is 8 to 10 cm in length.<sup>2</sup> This length will double in the first few years of life.

Lesions of the upper esophagus are best approached through the right chest to avoid problems with the aortic arch. The azygos vein should be ligated and divided where it crosses the esophagus. As long as the superior vena cava is patent, the azygos vein can be divided without consequence. Lesions of the lower esophagus can be explored through either the right or left chest. To expose the distal esophagus via the left chest, the inferior pulmonary ligament must be divided, taking care not to injure the inferior pulmonary vein that runs in the upper part of the pulmonary ligament.

The mucosa is the strongest layer of the esophageal wall. When the esophagus is divided, the mucosa will retract proximally and distally. Meticulous approximation of the esophageal mucosa is essential for a technically sound anastomosis.

## ENDOSCOPY

In current pediatric practice, esophagoscopy is frequently used to evaluate dysphagia and gastroesophageal reflux as well as to dilate esophageal strictures, evaluate for trauma, and aid in sclerotherapy for bleeding esophageal varices and in the placement of gastrostomy tubes. Both rigid and flexible esophagoscopes are available for use in children of all ages.

Flexible endoscopy is the technique of choice for routine diagnostic esophagoscopy. The rigid esophagoscope is more versatile and provides a larger diameter that allows for better visualization and a larger channel for biopsies. It also does not require air insufflation of the esophagus, which is crucial in the setting of trauma because air will not be forced through a perforation into the mediastinum.

The main value of rigid esophagoscopy in current pediatric practice is for therapeutic procedures such as dilation of an esophageal stricture or removal of a foreign body. Rigid esophagoscopy requires general anesthesia with endotracheal intubation and muscle

relaxation. The child is positioned supine with a roll under the shoulders to extend the neck. With care taken to protect the teeth, the esophagoscope, with its bevel up, is introduced into the oral cavity along the hard and soft palates to identify the cricopharyngeus muscle and enter the esophagus. Once the most distal aspect of evaluation is reached, it is easy to examine the esophagus fully when withdrawing the scope to identify any lesions or foreign bodies missed on insertion.

Flexible endoscopes are now available for upper endoscopy in premature infants all the way to adolescents in a reliable, safe, and efficient manner. Endoscopy with a flexible scope can be performed under sedation or general anesthesia. The endoscope is passed through the pharynx and cricopharynx into the upper esophagus. This is most safely done under direct vision. The scope should be advanced down the esophagus carefully, making sure to always maintain visualization of the esophageal lumen. The endoscope should never be advanced blindly. If the lumen is not apparent, the scope should be withdrawn slightly with gentle insufflation until the lumen is identified. Once the stomach is entered, it should be insufflated to allow inspection of the mucosa. In small infants, overdistention of the stomach may lead to respiratory distress.

Complications related to passage of a rigid or flexible endoscope are typically at the level of the cricopharyngeus muscle. Perforation of the cricopharyngeus occurs in about 0.03% with flexible endoscopy and 0.1% in rigid esophagoscopy.<sup>3</sup> Perforation during diagnostic esophagoscopy is exceedingly rare.

An emerging technique uses the natural orifices of the body, such as the mouth, anus, or vagina, to access the peritoneal cavity and pelvis. Natural orifice transluminal endoscopic surgery is expected to further reduce pain, scarring, and recovery time associated with intraperitoneal surgery. The size limitations imposed by existing technology will limit the applicability of these techniques in children.

A more thorough description of pediatric esophagoscopy and emerging therapeutic endoscopic techniques can be found elsewhere.<sup>4-7</sup>

## FOREIGN BODY ESOPHAGEAL INJURY

Coins are the most frequently ingested foreign body.<sup>8,9</sup> When foreign bodies become lodged in the esophagus, they may cause serious complications. Ten to 20 percent of foreign bodies may lodge in the esophagus and place the patient at risk for developing complications such as aortoesophageal fistula,<sup>10</sup> esophageal perforation,<sup>11</sup> esophageal stricture,<sup>12</sup> tracheoesophageal fistula,<sup>13</sup> and respiratory distress.<sup>14</sup> There are four sites of physiologic narrowing in the esophagus: (1) the cricopharyngeus of the UES, (2) the aortic notch, (3) the left main-stem bronchus, and (4) the LES. The cricopharyngeus is the narrowest point in the gastrointestinal tract. Endoscopic removal has been the preferred approach in many referral centers and has been highly successful with low complication rates.

Key principles of endoscopic management of esophageal foreign bodies are to protect the airway, maintain control of the object during extraction, and avoid causing additional damage. Children are more likely than adults to be asymptomatic and have an increased frequency of respiratory symptoms. There should be a high suspicion of foreign body ingestion in infants with excessive drooling, refusal of food, and unexplained coughing or gagging. Anteroposterior and lateral chest radiographs are the best diagnostic tests for radiopaque objects. The flat surface of a coin is best seen on the anteroposterior view when it is lodged in the esophagus, whereas the lateral view will show the flat surface when it is lodged in the trachea (Fig. 26-1).

Rigid esophagoscopy has long been considered the gold standard for removal of retained foreign bodies. This procedure has been proven to be highly successful with low complication rates. Other approaches have been described to treat esophageal coins, including flexible endoscopy, bougienage, Foley balloon extraction under fluoroscopy, and brief observation trials.

A randomized, prospective study comparing limited observation versus immediate endoscopic retrieval found a 25% spontaneous passage of esophageal coins over a 16-hour observation time.<sup>15</sup> Children were considered for observation only if the patient was

**Figure 26-1.** Anteroposterior (A) and lateral (B) radiographs demonstrate a coin lodged at the cricopharyngeus muscle. Note that coins will most often orient with the flat surface facing anteroposteriorly.

asymptomatic, the ingestion was less than 24 hours before presentation, and there was no intrinsic esophageal or tracheal abnormality. There were no complications related to observation. Spontaneous passage was found to be more likely in older children and coins lodged in the lower esophagus. The authors of the study concluded that a short observation period is safe and appropriate for selected patients.

In another study, patients who presented with asymptomatic, witnessed coin ingestion were prospectively enrolled to receive bougienage treatment.<sup>16</sup> This study reported a 90% success rate with a single pass of a weighted bougie dilator to push the coin into the stomach. No complications were reported. There was a significant decrease in hospital costs as well as time to discharge for patients treated with bougienage (2 hours vs. 8 hours,  $P < .001$ ). These authors concluded bougienage is a safe, effective, and economically sound treatment for coins in the esophagus.

A decision analysis model was used to compare four strategies for managing coins in the esophagus in children: endoscopic removal under general anesthesia, esophageal bougienage, outpatient observation for 12 to 24 hours, or an inpatient observation period.<sup>17</sup> Esophageal bougienage resulted in no complications and the lowest total cost per patient of the four strategies. Both observation strategies resulted in a spontaneous passage rate of 23% and an overall complication rate of 4.2%. The endoscopic approach had the highest complication rate (5.8%) and cost. With nearly 25% of patients spontaneously passing ingested coins, a brief period of observation may reduce complications and cost compared with routine endoscopic removal of all esophageal coins.

A retrospective review looked at 555 patients with retained esophageal foreign bodies that were treated with balloon extraction under fluoroscopy (see Fig. 11-6).<sup>8</sup> Dysphagia (37%) and sialorrhea (31%) were the most common presenting symptoms of retained foreign bodies. The upper esophagus was the most common site of impaction in 73% of patients. Coins consisted of 88% of the retained foreign bodies. Other foreign bodies included round batteries, rings, keys, food particles/bones, washers, and pins. The procedure was performed by passing a 10-Fr to 12-Fr lubricated Foley balloon through the nares and advancing it beyond the foreign body. The balloon was inflated with 5 mL of diluted barium. Under fluoroscopy, the inflated balloon was withdrawn until the foreign body reached the posterior pharynx; then the patient was turned to a decubitus position to expel the foreign body. The foreign body was successfully removed in 80% of patients. In 8%, the foreign body was pushed into the stomach, for an overall success rate of 88%. There were no major complications or aspirations. Two patients had minor postprocedural epistaxis. The children in whom Foley balloon extraction was not successful underwent endoscopic retrieval of the foreign body. In infants younger than age 1 year, the failure rate of this procedure was 25%. Patients 1 to 2 years old had a 13% failure rate. Because patients did not require general anesthesia or an inpatient admission, a significant cost savings was demonstrated for patients undergoing balloon extraction.

In a meta-analysis, a total of 1706 coin removal attempts were reviewed with a 97.7% success rate and 2.1% complication rate.<sup>18</sup> The only reported failures were attempted Foley catheter retrievals. Of the 1005 endoscopic retrievals, 2.5% had complications and nearly all were airway related. No complications were reported with bougienage. There was a 1.8% complication rate with 658 attempted Foley catheter extractions. Epistaxis, vomiting, and transient respiratory distress were the most common complications.

There is much more concern for serious injury with the ingestion of button batteries. There are four mechanisms of injury caused by batteries: (1) the toxic effect due to absorption of substances, particularly batteries containing mercuric oxide; (2) electrical discharge and mucosal burn; (3) pressure necrosis; and (4) caustic injury from leakage. Severe esophageal damage may occur in as little as 4 hours after ingestion and perforation in as little as 6 hours after ingestion.<sup>19</sup> Emetics should not be given, owing to ineffectiveness and possible reflux of a battery back into the esophagus.

There have been 20 reported cases of esophageal injury from ingested button batteries from 1979 to 2004.<sup>20</sup> Complications from the ingestion of button batteries include death from vascular invasion and uncontrollable hemorrhage,<sup>21</sup> esophageal perforation,<sup>22</sup> tracheoesophageal fistula (see Fig. 11-4),<sup>23,24</sup> and bilateral vocal cord paralysis.<sup>25</sup>

A total of 2382 cases of battery ingestion was collected by a National Button Battery Ingestion Hotline.<sup>19</sup> As expected, children younger than 5 years of age were at greatest risk, accounting for 61.8% of ingestion cases. The most common batteries came from hearing aids, watches, games, and toys. Hospitalization for ingestion was infrequent. Endoscopic intervention was required in 2.1% of cases, and surgery was needed in 0.4% of cases. Two children had major morbidity from battery ingestion. In both cases, the battery became lodged in the esophagus and produced a burn injury to the esophageal mucosa, which required long-term dilations. Current management protocols call for emergent removal of all batteries lodged in the esophagus by endoscopy, because direct visualization of the mucosa is required to assess the degree of injury. Removal by the balloon technique or magnetic devices is not recommended at this time because esophageal injury cannot be assessed by these methods. Batteries that have passed beyond the esophagus need not be retrieved unless the patient shows signs of intestinal injury. However, outpatient follow-up is critical to ensure safe passage by inspection of stools and/or repeated radiographs to document clearance from the intestinal tract. Further information about esophageal foreign bodies can be found in Chapter 11.

## CHEMICAL ESOPHAGEAL INJURIES

In 2004, the U.S. Poison Control Centers reported household ingestions and related deaths with nearly 125,000 ingestions in children younger than the age of 5.<sup>26</sup> Household bleaches and oven cleaners are the

most frequently ingested substances. The mean age for ingestions was 3.7 years, and 60% of patients were male.<sup>27</sup>

The extent of injury is dependent on several factors, including the composition of the substance, volume, concentration, and duration of contact. Acidic injury results in immediate pain and coagulative necrosis with eschar formation and is more likely to result in gastric injury. Alkali ingestions more commonly result in esophageal injury. Alkalis combine with tissue proteins to cause liquefactive necrosis and saponification and generally penetrate deeper into tissues. Alkali absorption leads to vascular thrombosis, impeding blood flow to damaged tissues.

Alkali ingestions have three phases of injury: liquefactive necrosis, reparative phase, and scar retraction. In liquefactive necrosis, the injury rapidly penetrates the deep layers of the esophagus until the alkali is buffered by tissue fluids. Between 5 days and 2 weeks is considered the reparative phase. Sloughing of the necrotic debris is followed by development of granulation tissue and collagen deposition. The esophageal wall is thinnest during this subacute phase and at highest risk for perforation. Scar formation begins after 2 weeks. During this time, there is deposition of collagen, resulting in esophageal stricture.

Caustic injuries are classified similar to burn injuries (Table 26-1). The classification of injury is based on endoscopic evaluation and is used clinically to help predict subsequent clinical outcomes and course. First-degree injuries are superficial and will result in edema and erythema. The esophageal mucosa will slough, but no stricture will form. Second-degree injuries involve the mucosa, submucosa, and muscle layers. They result in deep ulceration and granulation tissue after which collagen deposition and contraction occur. If there is circumferential injury, a stricture may develop. Third-degree injuries are transmural with deep ulcerations that result in a black appearance to the lining of the esophagus. These injuries can result in perforation. Patients with grade 2b or 3 develop strictures in 70% to 100% of cases.<sup>28</sup> Grade 3b are the most severe injuries and carry a 65% mortality.<sup>28</sup> These patients may need emergent esophageal resection.

After ingestion, patients can be asymptomatic or may present with nausea, vomiting, dysphagia, odynophagia, drooling, abdominal pain, chest pain, or stridor. There have been no conclusive data to correlate laboratory values or symptoms with degree of

injury. Initial management of these patients should focus on airway management and volume resuscitation. Direct laryngoscopy can be useful for identifying laryngeal edema. Inducing emesis should be discouraged because additional exposure to the substance can cause increased mucosal damage. A chest and abdominal radiograph should be obtained to look for signs of perforation. Computed tomography (CT) of the chest can also be used in selected cases.

Endoscopic evaluation should be carried out in the first 24 to 48 hours after ingestion. Contraindications to endoscopy include shock, respiratory distress, peritonitis, mediastinitis, or evidence of perforation. Endoscopy should not be performed after 5 days, once the reparative phase has begun, because the esophagus is at its thinnest and the risk of perforation is highest. Once the degree of injury is identified, further evaluation of the distal esophagus also increases the risk of perforation.

In addition to endoscopy, endoscopic ultrasonography has been used to delineate the depth of tissue injury and a separate grading system has been proposed.<sup>29</sup> Endoscopic ultrasonography may be able to identify deeper tissue injury over endoscopy alone but has not added prognostic value over endoscopy.<sup>30</sup> Further investigations need to be carried out to determine the usefulness of this technique in evaluating corrosive esophageal injuries.

Patients with grade 1 or 2a injury are allowed oral intake and are typically discharged soon after injury. Patients with grade 2b and 3 injuries should be observed for 24 to 48 hours and then may have their diets slowly advanced. With severe injuries, esophageal strictures are common, occurring in up to 70% of patients with grade 2b injuries and up to 100% in patients with grade 3 injuries. Because of the frequency with which strictures occur, patients with grade 2 or 3 injuries should have a barium swallow performed for early detection. A barium swallow on day 21 after injury is indicated to evaluate for strictures (Fig. 26-2). Once a stricture is identified, gradual dilations are performed. Strictures refractory to dilation may need surgical resection.

A systematic pooled analysis on the use of corticosteroids in second-degree caustic burns of the esophagus from 1956 to 2006 showed the overall percentages of strictures for corticosteroid therapy and nonsteroid therapy groups were 12.3% and 19%, respectively.<sup>31</sup> In this study, there was no statistical difference. Additionally, corticosteroid therapy posed additional complications, including perforation and infection. At this time, existing data fail to support the use of corticosteroids or antibiotics in the prevention of esophageal strictures in patients with caustic-induced grade 2 esophageal injuries.<sup>32</sup>

A 30-year report from a single institution with esophageal caustic injuries was recently reported.<sup>33</sup> Eighty patients were treated over this time period. The degree of injury was first or second degree in 58%, more extensive second degree in 26%, and third degree in 16%. Overall, 29% had medical complications, including chemical pneumonitis, atelectasis, aspiration pneumonia, dysphagia, and gastroesophageal

**Table 26-1** Classification of Caustic Esophageal Injuries

Grade	Endoscopic Findings
1	Mucosal edema and erythema
2a	Friability, hemorrhage, blisters, erosions, erythema, white exudate
2b	Findings of grade 2a plus deep or circumferential ulceration
3a	Small and scattered area of necrosis
3b	Extensive necrosis

**Figure 26-2.** This barium swallow was performed 3 weeks after lye ingestion. Note the significant narrowing in the proximal two thirds of the esophagus.

reflux, and 20% developed severe esophageal strictures. Nearly 14% of patients required esophageal replacement, which consisted of gastric tube conduit reconstruction with anastomosis to the cervical esophagus. The time from initial injury to esophageal replacement ranged from 12 months to 14 years, with a mean of 5 years. Because of the heterogeneous nature of ingestions and the various substances, location, and degree of injury, the optimal management remains controversial.

Treatment modalities for esophageal strictures include bougienage, esophageal stent placement, intralesional corticosteroid injection, and endoscopic dilations after stricture formation. Once strictures have formed, patients require endoscopic balloon dilation or bougienage. Multiple dilations may be required for strictures to resolve. Surgical intervention may be necessary if these treatments fail, if malignant transformation occurs, or if lengthy or tight strictures develop.

## ESOPHAGEAL STRICTURES

In general, esophageal strictures in children do not involve malignancies. The causes of benign esophageal strictures in childhood include reflux esophagitis, corrosive ingestion, and anastomotic scarring. Anastomotic and corrosive strictures may be aggravated by gastroesophageal reflux. The incidence of stricture in patients with gastroesophageal reflux approaches 15%.<sup>34</sup> Management includes relief of the

**Figure 26-3.** This barium study was performed in a child with dysphagia and pain. There is marked narrowing (arrow) of the distal esophagus secondary to gastroesophageal reflux and a peptic stricture.

obstruction as well as correction of the reflux. Anatomotic strictures are discrete and short, whereas corrosive strictures tend to be irregular and long. Peptic esophageal strictures are short and usually located in the lower third of the esophagus (Fig. 26-3).

Uncontrolled gastroesophageal reflux can result in esophageal stricture as a consequence of repeated insults to the esophageal mucosa. Vomiting and failure to thrive are present in nearly all patients with strictures resulting from gastroesophageal reflux. Many patients will also have concomitant pulmonary disease. The majority of strictures are located in the lower third of the esophagus and less frequently occur in the middle third. In addition, a hiatal hernia may also be present.

One group reported their success in treating these gastroesophageal reflux-associated strictures with preoperative dilations and antireflux procedures.<sup>35</sup> Twelve percent of all antireflux operations performed by this group were for gastroesophageal reflux with stricture formation. Preoperative management included oral antacids, prokinetic agents, histamine-2 ( $H_2$ ) receptor blocker, maximal nutritional support, and optimization of respiratory compromise. Antireflux surgery was delayed until nutritional optimization was met and esophagitis resolved. A mean of 3.6 dilations per patient was required. Postoperative dilations were performed until the stricture was no longer present. They reported that most patients (88%) had complete resolution of the stricture and associated gastroesophageal reflux with this management protocol.

In another series, patients did not undergo preoperative dilation.<sup>34</sup> They were treated preoperatively with antacids and an H<sub>2</sub>-receptor blocker to reduce the inflammation and edema related to esophagitis and were provided nutritional support. Operative management included intraoperative dilation, Nissen fundoplication, and guided dilations postoperatively. These patients required a mean of 3.4 postoperative dilations and achieved good results with a mean follow-up of 3 years.

Chronic esophagitis related to gastroesophageal reflux is the inciting event in the formation of strictures. Characteristically, esophageal strictures produce few early symptoms, which are initially insidious in onset. Correction of gastroesophageal reflux with concomitant dilation and continued postoperative dilations is sufficient in most cases to resolve symptoms of reflux and allow strictures to heal. By utilizing this treatment approach, more aggressive forms of surgical management of esophageal strictures are not usually required.

A recent retrospective study looked at the management of 125 patients who had corrosive ingestion and the outcomes of early prophylactic bougienage for stricture.<sup>36</sup> Of the 125 patients, 54 were found to have an esophageal burn injury on endoscopy and 32 required treatment for stricture. This group's management protocol was to perform early endoscopy if the ingested substance was strongly acidic, alkaline, or unknown and if symptoms were apparent within 24 to 48 hours. In this study, 27% had symptoms at the time of admission, most commonly dysphagia, and 57% of these symptomatic patients had a normal endoscopy. Overall, 25% of the patients with esophageal burns of all degrees developed a stricture. All patients with grade 3 injury developed severe esophageal strictures. Varying degrees of stricture developed in patients with grade 2b injury. Mild strictures developed in 4 of 15 patients with grade 2a injury. No patient with a grade 1 injury developed a stricture.

Patients with severe 2b or 3 injuries were treated with either early prophylactic dilations or dilations were initiated after the formation of stricture. In the first group, 20 patients underwent early bougienage beginning the first week after injury. In the second group, eight patients started dilations based on esophagograms showing stricture at 3 weeks after ingestion. In this retrospective study, in the group who had early dilations, the strictures resolved after 6 months of dilations, whereas the group who had dilations starting later required dilations for 1 year or longer.

Stenting for esophageal strictures is commonly utilized in adults but not widely used in children. Use of a retrievable and expandable nitinol stent was used successfully in eight children with corrosive esophageal strictures.<sup>37</sup> The stents were removed after a mean of 13 days. Two patients required dilations after the stent was removed for persistent stenosis. Placement of the stent was associated with mild symptoms of chest pains and vomiting that resolved after stent removal.

Bougienage dilation has traditionally been used in children. However, balloon catheter dilation is now

being increasingly used for the treatment of esophageal strictures. One theoretical advantage of balloon catheter dilation is that the stricture is gradually dilated by a uniform radial force. In contrast, bougienage exerts an abrupt shearing axial force that may cause significant injury of the mucosa and may lead to further scarring and stricture. In one report, 77 children with mean age of 1.8 years underwent a total of 260 dilations (3.4 per patient) for treatment of an esophageal stricture for various causes, including achalasia, post-esophageal atresia repair, reflux esophagitis, post fundoplication, and caustic injury. An esophageal perforation occurred in 1.5%. Successful outcomes were seen in 97% over a 6-year follow-up period.<sup>38</sup>

## ESOPHAGEAL PERFORATION

Iatrogenic esophageal perforation is a potentially life-threatening condition if not recognized and treated promptly. Pain, fever, dyspnea, and tachycardia are early symptoms of esophageal perforation after dilation for an esophageal stricture.<sup>39</sup> Clinical findings include pneumomediastinum, pleural effusion, subcutaneous emphysema, and pneumothorax. Proximal thoracic perforations lead to signs in the left thoracic cavity, whereas distal perforations usually show findings on the right side. Complications include mediastinitis, septicemia, empyema, and death.<sup>39</sup> Perforations can occur with both bougie dilators and balloon dilators. Most perforations can be recognized at the time of dilation, especially if endoscopy is used to inspect the esophagus after dilation. Conservative treatment including nasogastric decompression, broad-spectrum antibiotics, nutritional support, and drainage of the effusion or pneumothorax has been successful in the majority of patients (Fig. 26-4).

Perforation of the esophagus in children with caustic esophageal injury is difficult to manage and typically occurs during the first dilation of an esophageal stricture. In a report of 22 children treated for esophageal perforation that occurred secondary to a caustic esophageal stricture, 80% were successfully treated with conservative therapy.<sup>40</sup> However, although the esophageal perforations healed with conservative measures, most patients were left with a residual stricture.

Operative management is still considered the mainstay of therapy in adults with esophageal perforation. Many authors have reported successful nonoperative therapy in children with esophageal perforations. In contrast to nonoperative management of esophageal perforations, minimally invasive techniques offer the advantage of identifying the perforation, debriding the necrotic tissue, and draining the pleural cavity.<sup>41</sup>

## CONGENITAL ESOPHAGEAL STENOSIS

Congenital esophageal stenosis is a rare childhood condition with an incidence of 1 in 25,000 to 50,000 live births.<sup>42,43</sup> It is associated with esophageal atresia

**Figure 26-4.** **A**, This infant developed a stricture at the anastomosis after esophageal atresia repair. Multiple balloon dilations were required. **B**, Unexpectedly, at the time of one of these dilations, an esophageal perforation developed. Note the contrast leak through the esophageal perforation. This child was managed nonoperatively, and the perforation eventually sealed without the need for operative intervention.

in one third of patients. The remaining are considered to be isolated cases.<sup>44,45</sup> Three histopathologic variants are seen: tracheobronchial remnants, membranous diaphragms or webs, and diffuse fibrosis of the muscularis and submucosa.<sup>46</sup> Most infants have normal physical findings at birth. As a result, congenital esophageal stenosis is rarely diagnosed in the neonatal period. The onset of symptoms, most commonly vomiting, dysphagia, and failure to thrive, typically develop with the introduction of solid food at ages 4 to 10 months. Respiratory symptoms are found in about 10% of patients.<sup>47</sup> An esophagogram may show an abrupt or tapered stenosis, commonly at the junction of the middle and distal third of the esophagus (Fig. 26-5). Additional workup, including pH probe and endoscopy, is necessary to exclude the more common diagnosis of gastroesophageal reflux-associated stricture and esophagitis. When associated with esophageal atresia, the stenosis is usually found in the distal one third of the esophagus.<sup>47,48</sup>

The absence of esophagitis will be confirmed on esophagoscopy. However, tracheobronchial remnants can be missed on biopsy specimens that are taken too superficially.<sup>48</sup> Endoscopic ultrasonography has been shown to be helpful in differentiating tracheobronchial remnants as the cause of the stenosis from stricture due to gastroesophageal reflux.<sup>49,50</sup>

Dilatation of a congenital esophageal stenosis does not provide long-term benefit. Case reports have described successful treatment with endoscopic electrocauterization and balloon dilation.<sup>51</sup> However, limited resection of the stenosis through the left chest (either open or thoracoscopically<sup>45</sup>) with primary end-to-end anastomosis is the treatment of choice for long-term relief.

## ESOPHAGEAL DUPLICATION

Congenital esophageal duplication is a rare anomaly of the esophagus, with an incidence of 1 in 8000 births, accounting for 10% to 15% of all gastrointestinal duplications.<sup>52</sup> Histologic criteria for diagnosis include attachment to the esophagus, enclosure of the duplication by two muscle layers, and lining of the duplication by epithelium. Patients tend to present with respiratory symptoms, vomiting, regurgitation, and a possible neck mass. Diagnosis can be made by contrast esophagography. Because the duplication may increase in size with time and compress surrounding structures, operative resection is the treatment of choice. This can be approached via posterolateral thoracotomy or thoracoscopy. Operative guidelines include preserving the vagus and phrenic nerves and reconstructing the muscular wall of the esophagus. Air insufflation of the esophagus intraoperatively with endoscopy or with a nasogastric tube should be utilized to assess the integrity of the esophageal wall after resection. See Chapter 40 for further information about esophageal duplications.

## ESOPHAGEAL ACHALASIA

Achalasia is an uncommon disorder with an incidence of 4 to 6 cases per million per year. Only 5% of cases occur in children younger than the age of 15 years.<sup>53</sup> In contrast to adults, the disease is more common in boys than girls (1.86:1) and is unusual during infancy. Achalasia is a primary esophageal motor disorder of unknown etiology, characterized by three findings: increased LES

**Figure 26-5.** This child presented with significant dysphagia and weight loss. An esophagogram revealed marked narrowing of the midesophagus (*arrow*) due to congenital esophageal stenosis. This child underwent resection of the stenosis and primary repair of the esophagus.

resting pressures, absent esophageal body contraction, and impaired LES relaxation during swallowing. In children, this has been associated with various syndromes, including trisomy 21 and triple A syndrome (achalasia, alacrima, and ACTH insensitivity).

Presenting symptoms of achalasia are age dependent. Infants present with frequent regurgitation, choking, pneumonia, and failure to thrive. Symptoms in older children are similar to those seen in adults and include vomiting, regurgitation, and dysphagia. Esophagography and the clinical history are sufficient to make the diagnosis in most cases. A barium esophagogram will show the typical dilated esophagus and a narrowed distal segment, the “bird’s beak” sign (Fig. 26-6). Decreased or absent peristalsis of the esophageal body can be noted at the time of fluoroscopy. Esophageal manometry will reveal an elevated LES pressure, failure of the sphincter to relax with swallowing, and low-amplitude, nonprogressive, or absent peristaltic contractions in the esophageal body.

The aims of therapy are to reduce the LES pressure to facilitate esophageal emptying, improve symptoms, and prevent stasis-related complications. Treatment has utilized several approaches: pharmacologic agents, dilatation, and esophagomyotomy.

Pharmacologic treatment with calcium channel blockers can result in a decrease in the LES pressure, but the response is short-lived. The need for long-term medicine limits its usefulness in children. Botulinum toxin (Botox) has become popular in recent years for the treatment of achalasia. It is a neurotoxin that binds to presynaptic cholinergic terminals in skeletal

**Figure 26-6.** This barium swallow was performed in a 16-year-old patient with dysphagia secondary to achalasia. The classic “bird’s beak” narrowing of the distal esophagus at the level of the spastic, contracted esophagus is seen. Also, note the dilated esophagus proximal to the lower esophageal sphincter.

muscle, inhibiting the release of acetylcholine at the neuromuscular junction, which creates a chemical denervation. While initially effective, there is a high recurrence rate that also limits its applicability in children.

Treatment with Botox results in inflammation and fibrosis of the LES. This can result in a significantly more difficult operation at the time of esophagomyotomy.<sup>54</sup> Even though Botox effectively initiates the resolution of symptoms associated with achalasia in children, 50% of patients are expected to need an additional procedure within 7 months after one injection. A randomized controlled trial compared adult patients treated with either Botox or laparoscopic myotomy for the treatment of achalasia.<sup>55</sup> They found that laparoscopic myotomy is as safe as Botox treatment and should be the initial treatment for achalasia. Because the results are poor and may interfere with the ability to perform an esophagomyotomy, Botox has almost no role in the treatment of achalasia in children, except perhaps those who are not candidates for general anesthesia.

In 1994, a worldwide survey collected data on 175 cases of achalasia in children.<sup>56</sup> Only 6% were infants at diagnosis even though 18% reported onset of symptoms in the first year of life. The duration of symptoms was less than 3 years before diagnosis in most (80%) patients. Operative treatment was performed in 95%. Forceful dilatation of the distal esophagus was needed in 26%. Transabdominal myotomy was

successful at alleviating symptoms in 73% of patients, and this increased to 91% with the addition of an antireflux procedure. Patients who had a transthoracic approach were less likely to have relief of symptoms, regardless of whether an antireflux procedure was performed. The apparent benefit of an antireflux procedure in this group of patients suggests some advantage to controlling post-myotomy gastroesophageal reflux in high-risk patients, although this conclusion has not been found in other reports.

The outcomes after esophagomyotomy are similar for both pediatric and adult patients, as reported in a recent retrospective review.<sup>57</sup> A total of 337 patients underwent laparoscopic myotomy with anterior fundoplication, 14 of whom were younger than 18 years of age. More than half the pediatric patients had frequent and severe dysphagia, choking, regurgitation, and chest pain. Both children and adults had similar duration of symptoms before diagnosis. A significant number of pediatric patients had initial nonoperative management consisting of Botox in 7%, dilatation in 14%, and both in 28%. Postoperatively, all patients underwent an early esophagogram to evaluate for a missed esophagotomy or gastrotomy. At median follow-up of 37 months, 77% of the pediatric patients' symptoms improved, compared with 88% improvement in adults.

A review over 21 years evaluated 19 pediatric patients who underwent a transthoracic modified anterior esophagomyotomy.<sup>58</sup> In each case, a longitudinal incision was carried down to the submucosa and the muscularis was freed laterally on each side until at least 50% of the esophageal circumference was mobilized. The esophagomyotomy began from the aortic arch and extended 1 cm onto the stomach. A minority of patients had concomitant antireflux procedures. All patients who underwent antireflux procedures required postoperative esophageal dilatations in the first postoperative year. Overall, 90% of patients had complete and permanent relief of their swallowing difficulties.

Another relatively large study reported the experience of 20 patients with achalasia who were treated with modified esophagomyotomy.<sup>53</sup> Seventy percent did not have an antireflux procedure. The incidence of postoperative gastroesophageal reflux was noted in 1 patient (5%), whereas postoperative dysphagia requiring dilation occurred in 5 patients. Complete relief of symptoms was achieved in 70%.

Esophagomyotomy is a proven intervention, but incomplete myotomy may lead to clinical failure. One study found that patients who had a myotomy without intraoperative manometry were more likely to experience recurrence of symptoms.<sup>59</sup> Performance of an adequate myotomy is a key feature to successful long-term relief of symptoms. The reasons for inadequate myotomy include a gastric component to the LES or an inadequate proximal myotomy, resulting in residual high-pressure zones.

It is the opinion of most authors that the treatment of choice for achalasia remains esophagomyotomy. The operation may be performed either through the chest

or abdomen. Both laparoscopic and thoracoscopic approaches have been used with success. The transthoracic approach may provide better exposure to perform a long myotomy, which is necessary in patients with a long proximal area of involvement. On the other hand, the transabdominal approach may be better suited for when an antireflux procedure is also needed. In children, it is still controversial whether an antireflux should be performed at the same time as esophagomyotomy. In adults, 30% to 50% of patients develop significant gastroesophageal reflux after esophagomyotomy. Studies in children have shown a lower overall rate of postmyotomy reflux of 5% to 36%.<sup>53,58</sup> As a result, concomitant fundoplication may not be necessary for every child with achalasia.

## ESOPHAGEAL REPLACEMENT

The most common indications in the pediatric population for esophageal replacement are esophageal atresia and strictures related to reflux or corrosive injury. The colon was the first conduit used as esophageal replacement and remains the most commonly used technique in practice today. Other alternatives have distinct advantages over colon interposition but require advance planning on the part of the surgeon. The alternatives include gastric tube, gastric transposition, and jejunal interposition graft. Which conduit is best for any given patient depends on multiple factors, including the location and length of the native esophagus that remains, the original diagnosis for the patient, the patient's size and age, and previous procedures on the esophagus, stomach, or colon.

Regardless of the conduit used, there are several principles that are important. First, the esophagus is the best conduit and should be preserved at all costs, provided it functions relatively normally and has no malignant potential (e.g., Barrett's esophagus). Second, a short straight tract is best because esophagoscopy and dilatations are frequently required. Almost all conduits function as passive tubes rather than by means of intrinsic peristaltic activity. A retrosternal tunnel is often the shortest and straightest route. Third, the prevention of reflux into any conduit is important. An interposition procedure that incorporates the distal normal esophagus with its gastroesophageal junction has an advantage. Fourth, persistence is exceedingly important. Anastomotic dilatations should not be necessary except during the healing phase. Strictures should be revised surgically (Fig. 26-7). Complex interpositions that do not function well should be revised to provide the straightest, lowest resistance conduit possible.

### Colon Interposition

The right, transverse, or left colon on its vascular pedicle has been used as an esophageal replacement, either in an isoperistaltic or an antiperistaltic direction. It can be placed in a substernal position or a transthoracic posterior mediastinal location. The colon is pulled

**Figure 26-7.** Barium swallow of a 28-year-old patient after successful left colon interposition for isolated esophageal atresia. The patient developed bleeding and dysphagia from peptic ulceration at the distal anastomosis, requiring revision.

up into the neck, and an end-to-side or end-to-end esophagocolic anastomosis is performed in the neck. The gastrocolic anastomosis is then performed, followed by an antireflux procedure and pyloroplasty. The steps involved with a right colon interposition for esophageal atresia are seen in [Figure 26-8](#), and the operative steps for a left or transverse colon interposition are seen in [Figure 26-9](#).

Colon interposition is a relatively straightforward procedure, and the colon is readily placed into the thorax without causing respiratory compromise. Disadvantages of this approach include the need for three anastomoses and an increased risk for anastomotic leak, strictures at the esophagocolic anastomosis, and tortuosity or redundancy of the graft over the long term.

In a study of 38 colon interpositions, 61% of surgeons utilized the right colon and 39% used the transverse left colon.<sup>60</sup> In addition, 63% were placed substernally and 37% were routed in a transthoracic posterior mediastinal location. Early complications included cervical anastomotic leaks in 29%, pneumonia, wound infection, pneumothorax/hemothorax, wound dehiscence, prolonged ventilation, and perforated graft secondary to ischemia. Late complications included significant proximal strictures, distal strictures, redundancy of the graft, intestinal obstruction, and dumping syndrome. Of significance, cervical anastomotic stricture development correlated

strongly with leak at the cervical anastomosis. The overall graft failure rate, requiring graft replacement, was 18%. Although 45% of the patients required additional procedures, 80% of patients eventually had good functional results.

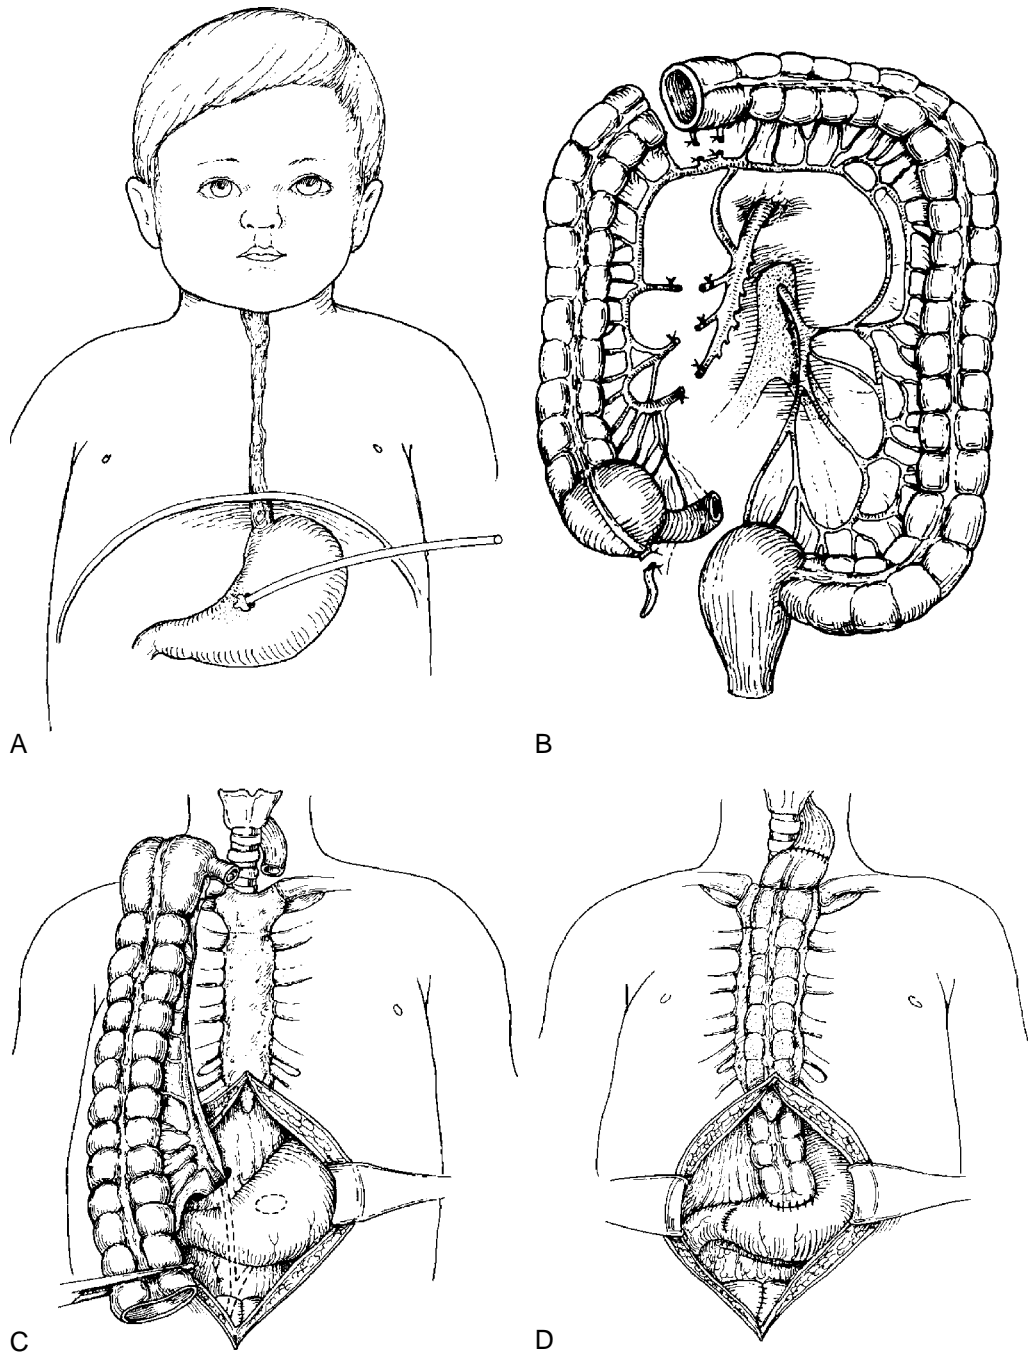

A recent report of 850 esophageal replacement procedures from one institution described a 30-year experience.<sup>61</sup> Gastric pull-up procedures were used in 75 cases, retrosternal colon interpositions in 550 cases, and posterior mediastinal colon interpositions in 225 cases. The posterior mediastinal colon interposition procedure has evolved as these authors' preferred procedure because it provides the most direct route and has a very low incidence of complications. Including the most recent 250 cases of substernal colon interpositions, the authors have had a 10% cervical anastomotic leak rate, 50% of whom developed an anastomotic stricture, and a 1% mortality rate. Only 0.6% of patients developed late graft stenosis. These remarkable statistics may reflect the value of experience rather than the intrinsic value of one procedure over another.

More intraoperative ischemic complications of colon interpositions have occurred with the right colon placed in the substernal position when compared with the left colon placed in the posterior mediastinum.<sup>62</sup> This may occur because up to 70% of patients have a right colon that lacks a marginal artery necessary to nourish the colon transplant.<sup>63</sup> Ischemia also may result from the angulation necessary for the substernal placement of the interposition. Several authors report an incidence of this complication of approximately 30%.<sup>64-66</sup> Leak at the esophagocolic anastomosis is probably caused by technical errors or minor degrees of ischemia, but stricture formation is almost undoubtedly caused by ischemia. Repeated dilatation is not often successful. Therefore, most anastomotic strictures that persist more than 6 months after the interposition procedure will ultimately require surgical revision. Both the management of an esophageal leak and the surgical management of an esophageal stricture are less difficult if the anastomosis is made in the neck.

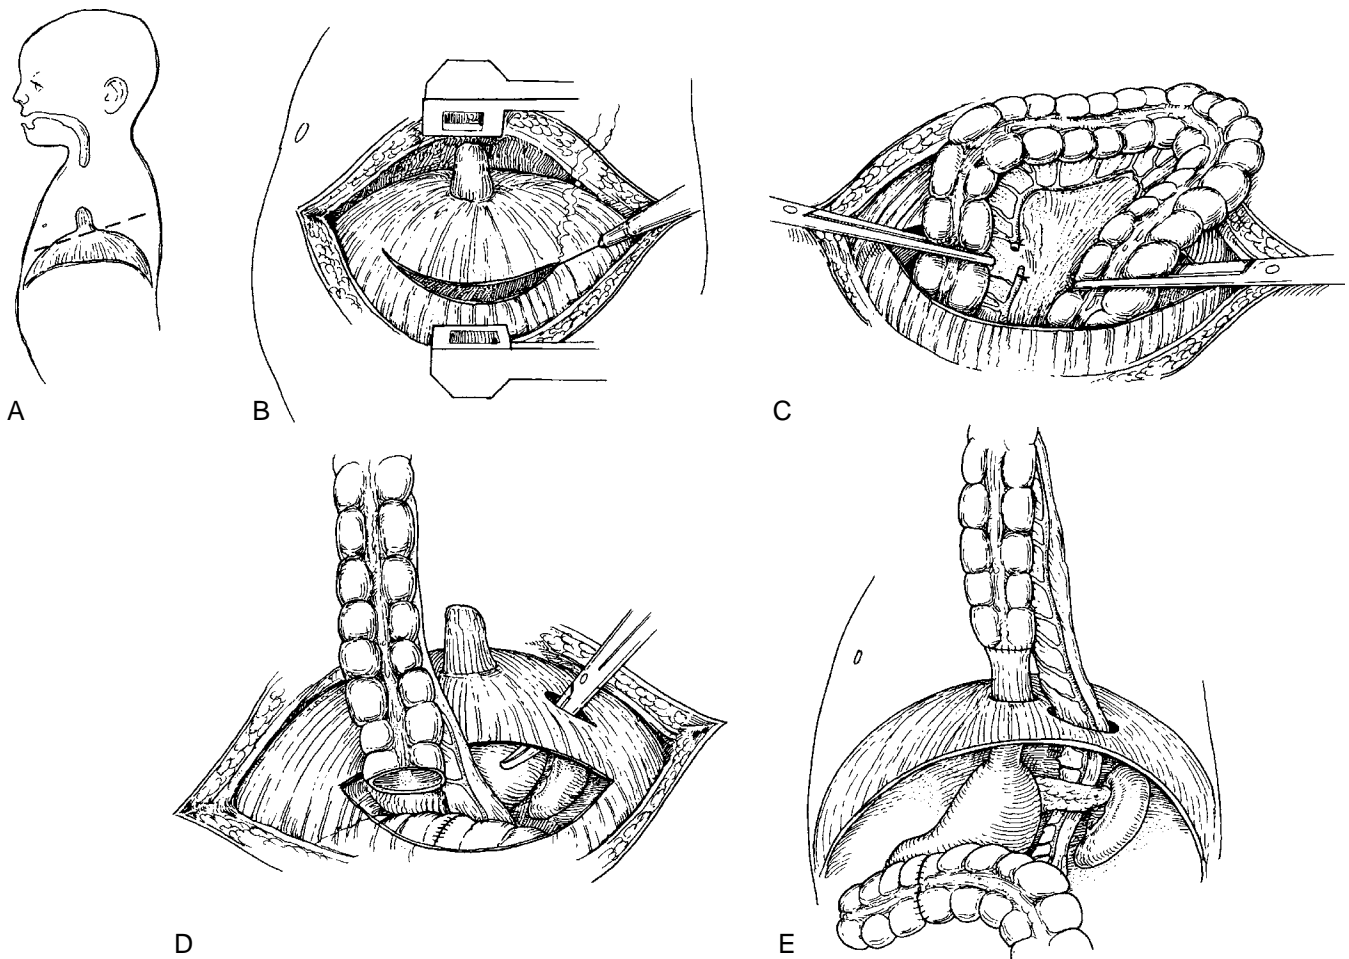

Another consideration in the selection of an interposition route is the possibility of subsequent acquired heart disease, necessitating sternotomy. The approach to access the heart is difficult in patients who have had a colon interposition in a substernal location. Similarly, patients who previously had a sternotomy for cardiac surgery usually need an alternative route for an interposition.<sup>67</sup>

### Timing of Colon Interposition

In those patients in whom esophageal atresia exists without a distal fistula and in whom attempts at stretching are successful, the colon can be interposed in the newborn period. Most pediatric surgeons, however, create a cervical esophageal fistula, place a gastrostomy, and carry out interposition when the patient is age 6 months or older. Both approaches have theoretical and practical advantages. Most

**Figure 26-8.** A, For any esophageal lesion in which a substitution procedure may be anticipated, the gastrostomy should be placed on the lesser curve at about the level of the incisura, so that a right or left colon or gastric tube interposition may be carried out without compromising the blood supply. B, The right colon and terminal ileum are isolated, based on blood supply from the arcades and from the middle colic artery. C, The colon on its pedicle is brought up through the lesser sac and positioned substernally in an isoperistaltic fashion. D, Most frequently, excision of the terminal ileum and cecum is accomplished. Careful tailoring of the distal end allows a straight conduit to be anastomosed to the antrum. Pyloroplasty may or may not be added to the procedure. The incidence of significant gastrocolic reflux is reduced by a drainage procedure.

**Figure 26-9.** The left colon or transverse colon substitution described by Waterston is illustrated in this patient with isolated esophageal atresia. However, it works equally well for other lesions requiring esophageal replacement. **A**, A standard posterolateral left thoracotomy at about the sixth intercostal space. **B**, Incision of the diaphragm peripherally. **C**, A section of colon is isolated and its vascular pedicle is developed, usually based on the left colic artery. It may be necessary to base it on the middle colic artery, in which case, this interposed colon is placed in an antiperistaltic manner. **D**, The colon and its vascular pedicle are delivered behind the spleen and pancreas and through a separate posterior opening in the diaphragm, so that the abdominal viscera do not stretch or otherwise obstruct the blood supply to this colon segment. **E**, The distal anastomosis may be made to the remnant of distal esophagus or to the posterior aspect of the stomach.

(Continued)

reported experience has been in patients who are 12 to 18 months of age. However, if the patient has been without oral intake for many months, once an esophageal substitution has been created, the infant may not want to eat. Therefore, sham feedings by mouth should accompany gastrostomy feedings so that the patient associates a full stomach with swallowing.

### Gastric Tube Esophageal Replacement

The reported experience with gastric tube esophago-plasty is much smaller than that with colon interposition, perhaps because the number of patients needing esophageal substitution has diminished in the developed world.

Gastric tubes have become popular because they can be constructed rapidly with a stapling device. The gastric tube is constructed from the greater curve of

the stomach with the blood supply based on the left gastroepiploic artery. These tubes can be constructed from the antrum up, or from the fundus down, and can be constructed so that there is enough gastric tube to reach the neck (Fig. 26-10). The advantages of a gastric tube are its excellent and reliable blood supply, its resistance to ulceration from gastric acid reflux, and its ability to bridge long gaps. The tube is also resilient and does not become tortuous or dilated over time. Theoretical disadvantages are a long suture line, continued acid production by the tube, and reduced stomach capacity.

A series of 21 patients who underwent isoperistaltic gastric tube replacement over a 12-year period has been reported.<sup>68</sup> Two patients developed cervical anastomotic leaks, which healed with conservative treatment, and two other patients developed strictures that were treated with dilatations. There were two dilatations of the intrathoracic gastric tube and two cases

**Figure 26-9—cont'd** **F**, The upper anastomosis is made to the esophagus either within the mediastinum or within the neck. Adequate drainage of the pleura is necessary to prevent empyema. A fundoplication after the method of Thal also may be added to this procedure, if the distal esophagus is used. This technique reduces the amount of reflux that can interfere with the healing or that can produce ulcers in the colon. **G**, A lateral view of an alternative method of cologastrostomy with Waterston's procedure. **H**, The segment of colon is shown within the abdominal cavity, which will possibly reduce the incidence of gastrocolic reflux.

of dumping syndrome that resolved within 2 years of operation. In another two patients who required anastomosis to the pharynx, there was loss of graft function related to an intractable stricture or a “nonfunctioning” anastomosis.

In this study, pH monitoring was performed in a majority of these patients. All probes that were placed in the gastric tube showed continued acid production. In four cases, pH monitoring showed the presence of acid reflux in the native esophagus. Evaluation with endoscopy showed four patients with mild esophagitis above the anastomosis and two had Barrett's esophagus. At median follow-up of 2.5 years, 76% of the patients were sustained entirely on oral feedings and 50% had normal growth patterns.

### Gastric Transposition

The gastric transposition (or pull-up procedure) is performed by mobilizing the entire stomach on a vascular pedicle, relocating the entire stomach into the mediastinum, and creating an anastomosis to the cervical esophagus in the neck. In addition, many surgeons will perform a routine pyloroplasty to prevent delayed gastric emptying. The advantages of this approach are the

excellent blood supply to the stomach, that only a single anastomosis is needed, and that the entire esophagus can be replaced with a low risk of necrosis, leak, or stricture. Potential disadvantages are that the stomach acts as a space-occupying mass in the chest, leading to respiratory compromise. [Figure 26-11](#) depicts a post-operative barium study after a gastric pull-up procedure for extensive strictures after lye ingestion.

A single institution recently reported its outcomes with 173 cases since 1981.<sup>69</sup> Their preference is locating the transposed stomach in a posterior mediastinal location without thoracotomy, using blunt dissection via the hiatus, and cervical incisions. An anastomotic leak occurred in 12%, and most sealed with conservative treatment. Anastomotic strictures developed in 19.6%, with all but three patients responding to endoscopic dilatations. The long-term outcome was considered good to excellent in 90%, although many patients preferred eating small frequent meals. There was no documented evidence of deterioration in the function of the gastric transposition in 72 patients who were observed for longer than 10 years.

In older patients who have had multiple procedures, the blood supply to the stomach may be compromised and a long gastric tube is not advised. These patients

**Figure 26-10.** Graphic depiction of the technique to create a reversed gastric tube for esophageal replacement. **A**, Inspection of the blood supply to the stomach and preservation of the gastroepiploic artery for creating the tube. **B**, The use of a stapler to create the tube along the greater curvature of the stomach. **C**, The completed reversed tube is brought up to the chest for the esophageal anastomosis.

also may not have adequate stomach length to reach the cervical esophagus. In such patients, a gastric pull-up, combined with a short gastric tube, may be used to get the additional stomach length required to reach the neck.

**Figure 26-11.** This infant underwent a gastric pull-up after a failed colonic interposition for isolated esophageal atresia. The native esophagus is identified by the *arrow*, and the gastric pull-up is marked with an *asterisk*.

## Jejunal Substitution

The jejunum as an esophageal substitute has been used much more commonly in adults than in children. Advantages to using jejunum include a diameter that is similar to the esophagus and does not occupy much space in the thoracic cavity. Also, the jejunum retains its peristaltic activity. Significant disadvantages include the precarious vascular supply of a pedicled jejunal graft. Also, a tension-free anastomosis may be difficult to achieve.

A recent report of eight patients who underwent esophageal substitution with free and pedicled jejunal grafts resulted in significant perioperative morbidity, including three intraoperative repeat interpositions for immediate graft loss.<sup>70</sup> There were four upper anastomotic leaks and four late anastomotic strictures. Less than 50% of patients were able to achieve a completely oral diet without reliance on gastrostomy feeds. In spite of technically sound outcomes, these authors concluded that significant complications exist, including death, graft necrosis, ischemia, and strictures.

## Complications of Esophageal Substitution

Regardless of the conduit used, substitution of the esophagus carries a number of predictable complications. The most serious one is vascular insufficiency with necrosis of the interposition. This complication is most commonly seen when using the colon and is recognized at the time of interposition as a blue, pulseless graft. Adjustment of the colon graft to relieve tension or twisting of the pedicle may be effective in improving the blood supply. Intraoperative hypotension may result in the colon graft taking on the appearance of vascular insufficiency. If the geometry

**Figure 26-12.** A stricture (*arrow*) developed at the esophago-colonic anastomosis after colon interposition for esophageal substitution. The likely cause was vascular insufficiency.

of the graft and the patient's blood pressure are both satisfactory, the graft must be abandoned because its vascularity will rarely improve after completion of the operation.

Interposition of a well-vascularized graft is sometimes followed several days later by fever, increased

leukocytosis, and drainage from the proximal anastomosis. An anastomotic leak from tension or mild ischemia may be managed expectantly if the conduit appears viable. A contrast study, however, may demonstrate that the mucosal pattern of the interposed segment is ischemic. The interposition must be inspected and removed if it is necrotic. In this case, a cervical esophagostomy should be established and a different form of substitution planned. Many investigators have reported using the left colon after failure of the right colon. Others may not be inclined to sacrifice additional colon and would perform a gastric tube or gastric interposition.

Proximal strictures between the esophagus and the interposition usually are the result of insufficient blood supply to the interposition (Fig. 26-12). Anastomosis to a scarred esophagus also results in stricture. After a reasonable healing period, persistent strictures should be revised surgically rather than dilated repeatedly.

Ulceration in either a gastric tube or interposed colon is probably the result of reflux and stasis, which may be caused by kinks in the interposition or by delayed gastric emptying. The latter can be a complication of vagal injury either from the original caustic ingestion or from the surgical attempts at previous esophageal reconstruction. Whether a pyloroplasty or a drainage procedure is necessary in all interpositions is a matter of opinion. Certainly, the elimination of "sink-trap" kinks in the interposition is important to prevent ulceration. Revision of the lower end of the interposed colon to eliminate redundancy must be performed with great care to prevent damage to the vascular pedicle and loss of the entire graft. An excellent review of esophageal replacement in children was recently published.<sup>71</sup>

# ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL MALFORMATIONS

Klaas Bax, MD, PhD

The first reports describing successful correction of esophageal atresia (EA) date to the early 1940s.<sup>1-3</sup> These described two different procedures: staged repair and primary anastomosis through a left-sided extrapleural approach. An extrapleural approach had already been reported in 1940 but the child died.<sup>4</sup> At that time, the mortality rate for this condition was nearly 100%, but it dropped rapidly in the years to come.<sup>5-9</sup>

## CLASSIFICATION

EA and tracheoesophageal fistula (TEF) present in many forms. It is clear that EA should be thought of as a spectrum of anomalies (Fig. 27-1).<sup>10</sup> A simplified classification, believed needed for daily practice, was published in 1929<sup>11</sup> and modified in 1944<sup>3</sup> and again in 1953.<sup>12</sup> These classifications tend to be confusing, however, by naming the same subclasses differently. For clarity, it is much better to give descriptive names to the major subtypes.<sup>13</sup>

### Esophageal Atresia with Distal Fistula (EA/TEF)

This is the most common subtype, accounting for about 85% of EA anomalies.<sup>14,15</sup> The very dilated proximal esophagus has a thickened wall and descends into the superior mediastinum usually to the third or fourth thoracic vertebrae. The distal esophagus is slender and has a thin wall. It enters the trachea posteriorly either at the level of the carina or 1 to 2 cm higher. The distance between the esophageal ends varies from very small to a quite wide gap. Very rarely, the distal fistula may be occluded, leading to the misdiagnosis of EA without distal fistula.<sup>16</sup>

### Pure Esophageal Atresia

Pure EA has an incidence of about 7%.<sup>15</sup> The proximal and distal esophagus end blindly in the posterior mediastinum. The proximal end is dilated and has

a thickened wall as in EA/TEF. If there is no concomitant proximal fistula, the upper esophagus ends at the level of the azygos vein. The distal esophagus is short and usually suspended by a fibrotic band. The distance between the two segments is considerable, usually precluding immediate anastomosis.

### Esophageal Atresia with Proximal Fistula

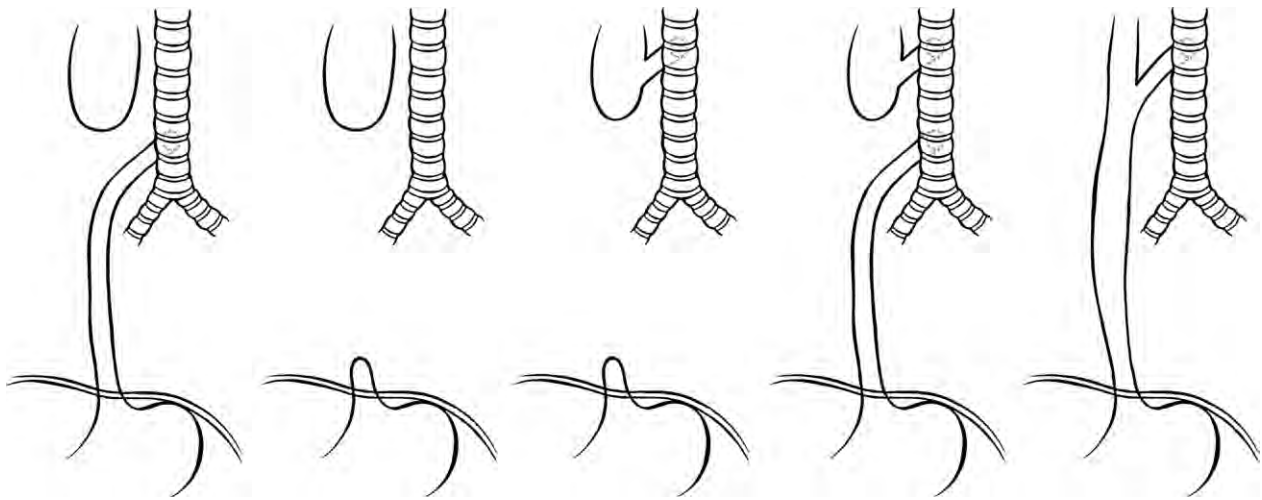

The association of a proximal fistula in a patient with pure EA seems higher than is generally appreciated. In a recent series of 13 children without distal fistula, a proximal fistula was found in 7.<sup>14</sup> An upper esophageal fistula is usually not found at the end of the pouch.<sup>3,11,12</sup> This fistula is similar to the H-type starting proximally on the trachea and ending distally in the dilated proximal esophagus. It is located at the thoracic aperture or higher in the neck. Although limited in length, its diameter may vary from tiny to large. If not diagnosed preoperatively, it may be suspected during operative repair when gas leaks out upon opening the proximal esophagus.

### Esophageal Atresia with Proximal and Distal Fistulas

The incidence of EA with proximal and distal fistulas is reported to be less than 1%.<sup>15</sup> EA with one distal fistula and two proximal fistulas has also been described.<sup>17</sup> Also reported is near-complete membranous obstruction of the esophagus in conjunction with a single TEF at the level of the membrane, communicating with both parts of the esophagus.<sup>18</sup>

### H-type Fistula without Esophageal Atresia

H-type TEF without atresia is usually discussed together with EA because it may be part of the VACTERL association. It occurs with an incidence of about 4%.<sup>15</sup> The fistula starts from the membranous trachea and runs

**Figure 27-1.** Classification of EA and/or TEF (from left to right):  
 Esophageal atresia with distal tracheoesophageal fistula: Vogt IIIb, Ladd III, Gross C  
 Esophageal atresia without fistula: Vogt II, Ladd I, Gross A  
 Esophageal atresia with proximal fistula: Vogt IIIa, Ladd II, Gross B  
 Esophageal atresia with proximal and distal fistulas: Vogt IIIc, Ladd V, Gross D  
 Tracheoesophageal fistula (H-type) without atresia: Vogt IV, Gross E

caudad to enter the esophagus. Normally it is short, although the diameter may be variable. The fistula is usually situated at the thoracic aperture or higher in the neck.<sup>19</sup>

## EMBRYOLOGY

The embryology of the foregut is still subject to controversy.<sup>20</sup> What is known, however, is that during the fourth week of gestation the foregut starts to differentiate into a ventral respiratory part and a dorsal esophageal part. The laryngotracheal diverticulum then evaginates ventrally into the mesenchyme. The traditional theory postulates that the ventral respiratory system separates from the esophagus by the formation of lateral tracheoesophageal folds that fuse in the midline and create the tracheoesophageal septum. At 6 to 7 weeks of gestation, the separation between trachea and esophagus is complete. Incomplete fusion of the folds would result in a defective tracheoesophageal septum and abnormal connection between the trachea and esophagus.

This theory of longitudinal tracheoesophageal folds merging to a septum has been challenged.<sup>21-24</sup> In chicken embryo studies, these folds could not be demonstrated. Instead, cranial and caudal folds were found in the region of tracheoesophageal separation. According to this theory, EA/TEF would then be due to an imbalance in the growth of these folds.<sup>22,23</sup> Furthermore, rat studies suggest that EA/TEF results from disturbances in either epithelial proliferation or apoptosis.<sup>24</sup>

The Adriamycin (doxorubicin) rat model has greatly helped with understanding the development of EA/TEF.<sup>25</sup> From this model, it appears the EA develops first, with the lung bud arising from the

atretic foregut dividing into three rather than two branches.<sup>26</sup> The middle branch would be the distal esophagus eventually connecting with the stomach. This hypothesis, however, has not been substantiated.<sup>23,27</sup> Also, in the Adriamycin rat model, notochord abnormalities are observed in 90% of the animals.<sup>28</sup> Abnormal ventral branches from the notochord impinging on the foregut, midgut, dorsal aorta, and kidney are common. At the same time, an ectopic expression of Sonic hedgehog occurs in the tissues between the notochord and the gut. Knock-out mice models have helped elucidate the functions of different genes in the development of the foregut and aberrations such as EA/TEF.<sup>20</sup>

## EPIDEMIOLOGY

The total birth incidence of EA/TEF varies between 2.55 and 2.82 per 10,000 births.<sup>29-31</sup> EA is usually a sporadic occurrence. There is a slight male preponderance of 1.26. There is no evidence for a link between EA/TEF and maternal age when chromosomal cases are excluded.<sup>32</sup> The recurrence risk among parents of one affected child is 0.5% to 2%, increasing to 20% when more than one child is affected. The empirical risk of an affected child born to an affected person is 3% to 4%.<sup>33</sup> The relative risk for EA/TEF in twins is 2.56 when compared with singletons.<sup>34</sup> The concordance rate in twins is low, but the same gender rate is high.<sup>30</sup>

Environmental factors that have been implicated include the use of methimazole in early pregnancy,<sup>35,36</sup> prolonged use of contraceptive pills,<sup>37</sup> progesterone and estrogen exposure,<sup>38</sup> and maternal diabetes and thalidomide exposure.<sup>39</sup> EA is occasionally seen in the fetal alcohol syndrome<sup>40</sup> and in maternal phenylketonuria.<sup>41</sup>

Chromosomal anomalies are found in 6.6% to 10% of the cases.<sup>29,30,42</sup> The lower incidence was found in a study excluding births before 28 weeks of gestation. The total number of trisomy 18 cases exceeds the total number of trisomy 21 cases. Because the incidence of trisomy 18 is higher, this would seem to indicate that trisomy 18 is a greater risk for EA development.<sup>32</sup> Three separate genes have been associated with EA/TEF: *MYCN* haploinsufficiency in Feingold syndrome, *CHD7* in CHARGE syndrome, and *SOX2* in the anophthalmia-esophageal-genital (AEG) syndrome.<sup>43-45</sup>

EA may occasionally be part of the Opitz G/BB syndrome, Fanconi anemia, oculo-auriculo-vertebral syndrome, Bartsocas-Papas syndrome, or Frijns syndrome.<sup>46</sup>

## ASSOCIATED ANOMALIES

Obviously, the factor or factors responsible for the early disturbance in organogenesis causing EA may affect the organogenesis of other organs or systems developing at the same time. EA can be divided clinically into isolated EA and syndromic EA, occurring at roughly the same rate.<sup>46</sup>

The most frequent associated malformations encountered in syndromic EA are:

- Cardiac (13%-34%)
- Vertebral (6%-21%)
- Limb (5%-19%)
- Anorectal (10%-16%)
- Renal (5%-14%)

Vertebral anomalies are confined mainly to the thoracic region. An earlier claim that the presence of 13 pairs of ribs is a good indicator of long-gap EA has not been substantiated.<sup>47</sup>

Nonrandom associations have been documented as well. Two of these are the VACTERL association (Vertebral, Anorectal, Cardiac, Tracheo-Esophageal, Renal, and Limb abnormalities) and the CHARGE association (Coloboma, Heart defects, Atresia of the choanae, developmental Retardation, Genital hypoplasia, and Ear deformities). In 1973, VACTERL was originally described as VATER, an acronym made up of Vertebral defects, Anal atresia, T-E fistula with esophageal atresia, and Radial dysplasia.<sup>48</sup> It was later extended with the C for cardiac anomalies and the L for limb anomalies.<sup>38</sup> In a cohort of 463 patients with EA, 107 (23%) had at least two additional VACTERL defects.<sup>49</sup> Seventeen of these patients had a chromosomal defect or a syndrome without a known genetic defect. Interestingly, as many as 70% of the remaining 90 patients had additional defects other than those of the VACTERL association.

The association of coloboma with multiple congenital anomalies was first described in 1961.<sup>50</sup> The name CHARGE association was first used in 1981.<sup>51</sup> EA has been observed occasionally in patients with CHARGE association.<sup>52</sup> These patients have high mortality and morbidity rates.

## DIAGNOSIS

### Antenatal Diagnosis

The prenatal diagnosis of EA/TEF relies, in principle, on two nonspecific signs: polyhydramnios and an absent or small stomach bubble. Polyhydramnios is associated with a wide range of fetal abnormalities. Most commonly, however, it pursues a benign course. Similarly, the ultrasonographic absence of a stomach bubble may point to a variety of fetal anomalies. The combination of a small stomach together with a dilated esophagus in the neck (the pouch sign) has been confirmed to be diagnostic for pure EA in a number of patients.<sup>53-55</sup> Nevertheless, it is encountered in only a few patients.<sup>54</sup> Depending on whether the pouch is confined to the neck or descends into the mediastinum, a longer or smaller gap may have to be bridged postnatally.<sup>54,55</sup> Current ultrasound technology does not allow for a definite diagnosis of EA/TEF. Therefore, counseling of the parents should be guarded.<sup>56</sup> The application of 3D power Doppler imaging seems promising, both antenatally and postnatally. Aortic arch anomalies, for example, have been diagnosed using this modality.<sup>57,58</sup>

Magnetic resonance imaging (MRI) has served to identify fetal thoracic lesions.<sup>59,60</sup> Furthermore, in a study involving 10 fetuses considered to be at risk for EA on the basis of the ultrasound findings, MRI proved 100% sensitive for the identification of the five cases of EA/TEF.<sup>61</sup> The MRI criterion for EA/TEF in this series was nonvisualization of the intrathoracic portion of the esophagus. In another study, however, fetal MRI for suspected chest lesions did not visualize the esophagus in 54 of 85 (64%) examinations.<sup>59</sup>

### Postnatal Diagnosis

When pregnancy was complicated by polyhydramnios, free passage through the esophagus should be tested with a nasogastric tube. The same holds true when the child presents with anomalies that fit in the VACTERL association (e.g., radial aplasia).

As EA prevents the passage of saliva down the esophagus, saliva accumulates in the proximal esophagus and mouth. Salivation is obvious and the child exhales through the saliva so that bubbles are formed. Under such circumstances, feeding should be withheld and esophageal continuity tested. This is best done with a stiff, wide 10-Fr catheter inserted through the nose or, in case of choanal atresia, the mouth. In EA, the catheter will stop about 12 cm from the nostrils. A plain radiograph of the chest and abdomen will show the tip of the catheter arrested in the superior mediastinum (T2-T4) (Fig. 27-2). Often, the dilated upper esophageal pouch is well visualized by the air it contains. Gas in the stomach signifies the presence of a distal TEF. Note that the catheter must be a stiff one. Otherwise it may curl up in the upper esophagus and the findings be confused with those of EA. On the other hand, the diagnosis of EA should be questioned when the tip of the catheter passes beyond the carina. Traumatic perforation of the

**Figure 27-2.** This plain radiograph depicts the classic features seen in an infant with EA and TEF. A nasoesophageal tube is seen in the upper pouch and has kinked a little at the end of the pouch. There is air in the stomach and bowel, which signifies the presence of a distal TEF.

esophagus, causing an esophageal pseudodiverticulum, may also lead to the misdiagnosis of EA.<sup>62,63</sup> Rarely, a catheter can descend through the trachea and distal fistula into the stomach.

Radiographs may reveal associated anomalies such as vertebral and rib anomalies or duodenal atresia

(Fig. 27-3). The absence of air in the stomach points to EA without distal fistula (see Fig. 27-3A). Mediastinal ultrasonography has been suggested as a helpful adjunct in the diagnosis of pure EA.<sup>64</sup>

Surprisingly, the length of the esophageal gap is usually not known preoperatively. Absence of air in the stomach has been linked with a long gap, but has also been described in association with a distal fistula occluded with mucus.<sup>16</sup> Even in true long-gap EA (atresia without distal fistula), the gap length varies. It can be measured radiologically, either with metal bougies or with a contrast agent at the time of the gastrostomy. Note that the amount of pressure on the metal bougies will affect the distance measurement. In one report, operative management was linked to the measured length of the gap: less than two vertebrae, then primary anastomosis; two to six vertebrae, then delayed primary anastomosis; more than six vertebrae, then esophageal replacement.<sup>65</sup> A long gap in EA/TEF has been associated with azygos vein anomalies and with the presence of 13 rib pairs.<sup>47,66</sup> Others have not substantiated these relationships.

In EA/TEF, a longer gap between the two esophageal ends should be expected when the distal fistula arises from the carina. The longest gaps in EA with distal fistula are seen in patients with the distal fistula originating from the carina in combination with a short proximal esophageal pouch. It is customary to push on the nasoesophageal catheter when the first chest film is made. However, this maneuver may lead to the wrong impression that a rather long proximal pouch is present. Using contrast radiographs to delineate the upper pouch is certainly more accurate but this can result in aspiration of contrast material. Even when the distance is relatively well assessed preoperatively by means of contrast imaging of the proximal pouch in combination with tracheoscopy for identification of the origin of the distal fistula, other factors may affect

**Figure 27-3.** These two radiographs depict less common presentations of EA. **A**, Isolated EA. The nasoesophageal tube (arrow) is seen in the proximal pouch. There is no air in the gastrointestinal tract. **B**, This patient has EA with distal TEF and duodenal atresia and has been endotracheally intubated. A nasoesophageal catheter (arrow) sits in the upper esophageal pouch. An endotracheal tube is also seen. The stomach and bulbous duodenum are distended with air but no air is seen distal to the duodenum.

**Figure 27-4.** This preoperative CT scan reconstruction shows EA with a distal TEF. The distal TEF (arrow) originates at the carina. The upper esophageal pouch is very dilated (asterisk). The distance between the upper pouch and lower esophagus is relatively short.

the surgical plan. Ultrasonography may reveal cardiac and/or aortic arch anomalies. A right descending aorta, which occurs in about 2.5% of the cases, makes a left-sided thoracic approach preferable.<sup>67,68</sup> Renal ultrasound images and spine radiographs should be obtained as well. Because EA may be part of a syndrome, consultation by a geneticist is recommended.

There is little doubt that better preoperative imaging of the neck and chest would allow for better preoperative planning. At present, two imaging modalities are available: CT and MRI. Although MRI would certainly be preferable for its absence of radiation exposure, it requires general anesthesia. On the other hand, MRI is better for diagnosing cardiac and aortic arch anomalies,<sup>69</sup> CT has been done in children with EA/TEF (Fig. 27-4).<sup>70-73</sup>

## MANAGEMENT

### Preoperative Management

Once the diagnosis of EA has been established, the child is taken to a pediatric surgical center in a transport incubator. A double-lumen 10-Fr suction tube is placed in the upper esophagus and set to continuous suction.<sup>74</sup> The child is in a head-up position and on his or her side. Intravenous access is important, and the vital signs are monitored.

If the child is in respiratory distress, endotracheal intubation and ventilation may be needed. Forceful ventilation will overdistend the stomach, causing diaphragmatic splinting and even gastric rupture.<sup>75,76</sup> Gentle low-pressure ventilation is therefore essential.

Alternatively, high-frequency ventilation should be attempted, but emergency ligation of the fistula may be lifesaving.<sup>65,76,77</sup> After ligation of the fistula only, a delayed primary anastomosis should not be postponed longer than 7 to 14 days because recanalization is likely to occur.<sup>65,78,79</sup>

Generally, the operative treatment of an EA/TEF is not regarded as an emergency procedure. Thus, there is time to confirm the diagnosis in the pediatric surgical center and to assess for associated anomalies.

## OPERATIVE REPAIR

### Esophageal Atresia with Distal Fistula

The operation can be performed through a thoracotomy or using a thoracoscopic approach. The side of entrance to the chest is opposite the turn of the aortic arch: right for a left descending aorta, left for a right descending aorta. If a right-sided aortic arch is not detected until surgery has begun, change to the left side is appropriate if the thoracoscopic approach has been chosen. If a thoracotomy has been performed, an anastomosis from the right should be attempted but has a higher morbidity in this setting.<sup>67,68</sup> The operation is performed with the patient under general anesthesia and with adequate venous access. A right radial artery arterial line is beneficial for monitoring the pH and blood gases, especially during a thoracoscopic approach under CO<sub>2</sub> pneumothorax.

### Laryngotracheobronchoscopy

The value of routine preoperative laryngotracheobronchoscopy is much debated because the incidence of the combination of a proximal and distal fistula is less than 1%.<sup>65</sup> With the availability of small-diameter flexible fiberscopes, tracheobronchoscopy can now be performed after intubation through the endotracheal tube.<sup>80,81</sup> Forceful ventilation must be avoided, not only to prevent lung damage<sup>82</sup> but also to prevent gastric distention and perforation of the stomach by insufflation through the distal fistula.<sup>75,76,83</sup> Laryngotracheobronchoscopy may reveal abnormalities such as a laryngotracheoesophageal cleft, tracheal stenosis, or a tracheal bronchus to the right upper lobe. The entrance of the distal fistula is usually well seen (Fig. 27-5). Its distance to the carina provides a clue as to the gap between the esophageal segments: the closer the fistula is to the carina, the longer the distance. An indication of the severity of tracheomalacia is only possible when the child is breathing spontaneously. Even then, it remains difficult to predict the severity.

### Positioning the Tip of the Endotracheal Tube

If possible, the tip of the endotracheal tube (ET) is positioned more distally than the origin of the TEF.<sup>84-87</sup> This is quite feasible when the distal fistula originates

**Figure 27-5.** At bronchoscopy, the distal TEF (arrow) is seen at the carina. It is usually found between the midtrachea and carina.

at a distance well proximal to the carina. Still, in a series of 149 patients with EA/TEF, tracheobronchoscopy revealed that 2 of the 154 fistulas were bronchial, 15 carinal, 34 just 1 cm proximal to the carina, 91 halfway up the trachea, and 12 cervical.<sup>88</sup> On the other hand, when the fistula originates too close to the carina, the slightest movement may cause the ET tip to enter the distal fistula or one of the main-stem bronchi. Inadvertent entrance of the ET into the right main-stem bronchus is especially troublesome during a right thoracoscopic operation. An appropriate depth for the tip of the tube can be predicted by measurements taken during the laryngotracheobronchoscopy, if performed. Preoperative flexible bronchoscopy through the tube is ideal when the diameter of the ET allows passage of the flexible scope. However, identifying a proximal fistula is more difficult because the ET may be occluding it. Moreover, a proximal fistula with a distal fistula is rare. Nevertheless, there are several reports describing proximal fistulas that were missed and caused significant morbidity.<sup>89,90</sup>

### Repair through Thoracotomy

In case of a left descending aorta, the child is placed in a true left lateral decubitus position close to the right edge of a shortened operating table. A small pad is placed underneath the chest to open the right-sided intercostal spaces. The surgeon stands to the right of the patient with the assistant opposite. In case of a right descending aorta, the child is placed in a right lateral decubitus position close to the left edge of the table. The surgeon then stands on the left with the assistant on the right of the table. In case the chest is opened on the right and a right descending aorta is encountered, the esophagus can be repaired to the right of the aortic

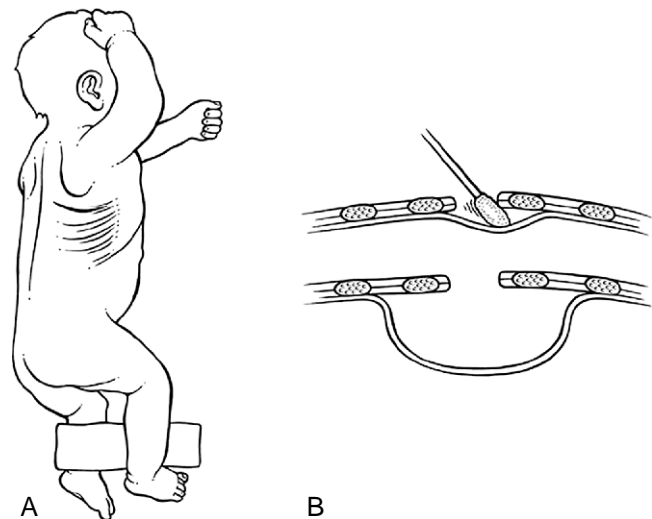

arch. However, in this situation, there is a higher anastomotic leak rate.<sup>67</sup>

The patient's arm is positioned over the head (Fig. 27-6). Suction is removed from the Repleg tube, but the tube is left in place so that it can be advanced during the operation to make identification of the proximal pouch easier.

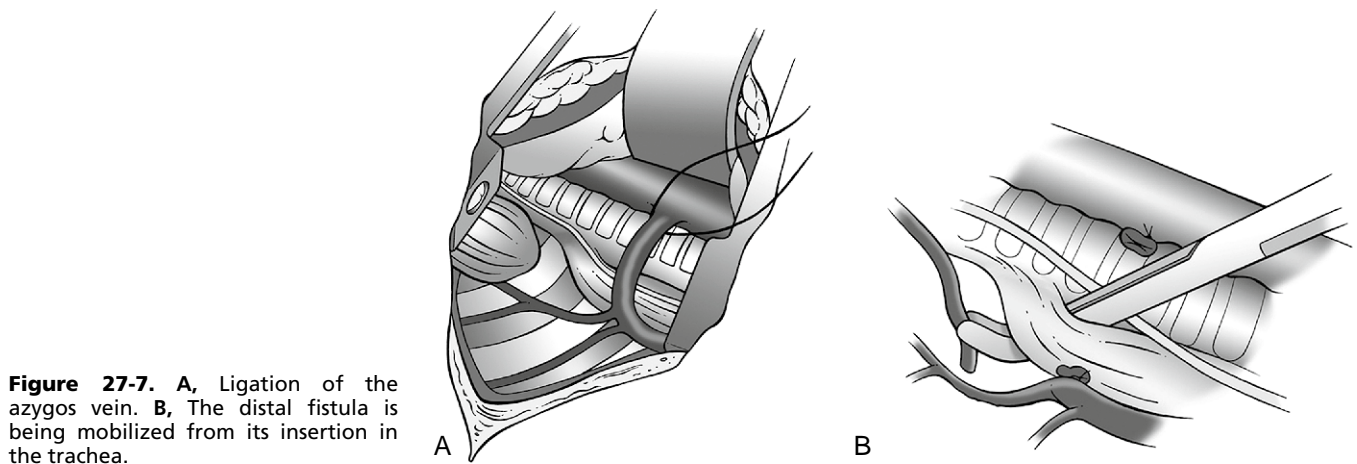

A slightly curved 4- to 5-cm long incision is made 1 cm below the inferior tip of the scapula. With the use of a muscle-sparing approach, the auscultatory triangle is opened and the muscles are retracted (i.e., the latissimus dorsi posteriorly and the serratus anterior anteriorly).<sup>91</sup> If the serratus muscle needs to be transected, this should be done as low as possible to preserve the long thoracic nerve. The fourth or fifth intercostal space is then entered.

An extrapleural approach has been suggested to protect the pleural space in case of an anastomotic leak, but there is no evidence that it is better than a transpleural one.<sup>92,93</sup> In the extrapleural approach, the pleura is gently pushed away from the endothoracic fascia, first in the middle of the incision so that an infant rib spreader can be inserted and opened (see Fig. 27-6B). With the rib spreader opened even farther, the pleura is carefully pushed away posteriorly until the posterior mediastinum is exposed.

The distal fistula may start from the trachea directly underneath the azygos vein, in which case the azygos vein is transected between 3-0 or 4-0 absorbable ligatures (Fig. 27-7). If the distal fistula originates more cephalad on the trachea, the vein can be left intact. Recently, a relationship between azygos vein transection and anastomotic leak has been suggested.<sup>94,95</sup> Rarely, there is an azygos lobe in which the azygos vein loops anteriorly and causes a fissure in the upper lung lobe. An extrapleural approach then becomes more difficult unless the anomaly is recognized and the vein divided.<sup>96</sup>

**Figure 27-6.** A, The infant is positioned for a right thoracotomy. The ipsilateral arm is positioned over the head of the patient. A 4- to 5-cm incision is made 1 cm below the tip of the scapula. B, This schematic depicts a peanut or sterile cotton swab being used to gently push the pleura away from the chest wall.

**Figure 27-7.** A, Ligation of the azygos vein. B, The distal fistula is being mobilized from its insertion in the trachea.

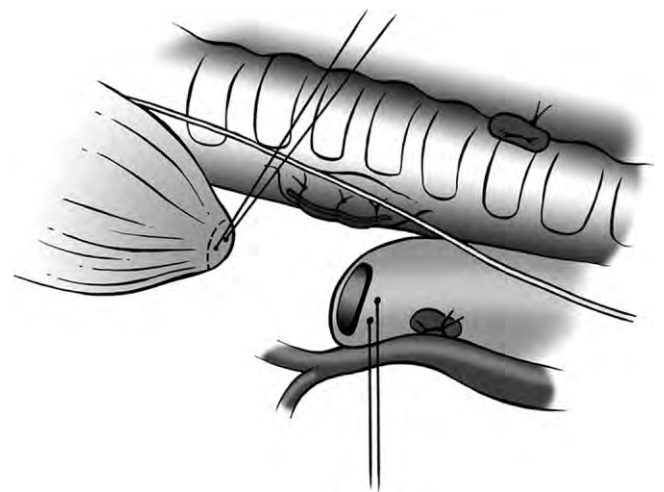

The distal esophagus is usually easily found because it looks fleshy with the glittering vagal nerve lying over it. The origin of the distal fistula is usually easy to find as the trachea and adjacent esophagus distend during each inspiration. The fistula should be dissected and mobilized close to the trachea, which will spare as many vagal nerve branches as possible (see Fig. 27-7B). The fistula can be encircled with a vessel loop. There are several ways of closing the fistula on the tracheal side. Ligation in continuity<sup>97</sup> can result in a higher recanalization rate.<sup>78,79,98</sup> To avoid slipping of the ligature on the tracheal side, a suture can be placed through the muscular layer of the upper corner of the fistula, after which the fistula is encircled, tied, and transected a few millimeters distally. This can be done with a 5-0 absorbable suture. Alternatively, the upper and lower corners of the fistula can be marked with a traction suture and the fistula is transected. The remaining hole in the trachea is then closed with interrupted 5-0 absorbable sutures. This closure can be checked by irrigating with warm water and applying a higher ventilation pressure to assess for an air leak.

The proximal esophagus is easily identified by asking the anesthesiologist to push on the Replogle tube. A traction suture, taking a good bite of the muscular wall, is placed in the most distal part of the proximal pouch (Fig. 27-8). The proximal pouch can easily be freed posteriorly and laterally by blunt dissection. Behind the trachea, however, the pouch may be strongly adherent. Usually, it is dissected sharply, staying on the esophageal side to avoid entrance into the trachea. Extensive dissection is not warranted, however, because this may damage the tracheal or esophageal walls and may interfere with innervation to the upper esophagus.<sup>99</sup> It has been documented that the recurrent laryngeal nerve gives motor branches to the upper esophagus. Extensive dissection of the proximal pouch searching for a proximal fistula should not be performed routinely because the incidence of a proximal fistula in combination with a distal one is only about 1%. If a proximal fistula is present, it is usually of the H-type. If missed at birth and diagnosed after repair of the atresia, it can be repaired through

the neck at a later date. If the trachea is opened during the dissection of the proximal pouch, one should be wary that a proximal fistula may have been opened as well. There is no common wall between the trachea and esophagus.

The distal end of the proximal pouch is now opened by amputating the most distal muscular wall together with the traction suture so that the mucosa becomes visible. The mucosa is then opened.

An end-to-end anastomosis is performed with 5-0 absorbable sutures starting in the middle of the back wall of the two esophageal segments (Fig. 27-9). It is important to include both the mucosa and the muscular wall with each suture. The sutures in the back part of the anastomosis are tied on the inside. Then the front part of the anastomosis is performed with sutures tied on the outside. Before finishing the anastomosis, a 6-Fr nasogastric tube is passed into the stomach until the esophagus stretches. The tube is then withdrawn to

**Figure 27-8.** Dissection of the proximal esophageal pouch. A traction suture has been placed in the distal end of the upper pouch, which is freed posteriorly and laterally. Freeing of the upper esophageal pouch from the trachea should not be extensive because this is usually not needed. The distal tip of the upper esophagus containing the traction suture is then amputated. The distal TEF has been divided.

**Figure 27-9.** Esophageal anastomosis. **A,** The back wall of the anastomosis has been sutured from the inside, and a small nasogastric tube has been passed through the anastomosis. The front part of the anastomosis is being sutured with knots on the outside. **B,** Completed anastomosis.

release the esophageal tension. The stomach contents are aspirated. Care is taken not to accidentally withdraw the tube entirely.

A chest drain is not routinely utilized.<sup>100,101</sup> A small nasogastric tube is inserted until the very end of the closure of the chest, enabling the removal of residual air. When a trans-rib approach is used, the periosteum should be closed in layers with fine but strong absorbable sutures. If repaired properly, the ribs will heal nicely. When an intercostal approach has been used, the adjacent two ribs should be approximated with one 3-0 absorbable suture. These sutures should be tied gently so that the intercostal space is not obliterated. The subcutis can be co-apted with a few absorbable sutures, and the skin is closed with adhesive strips.

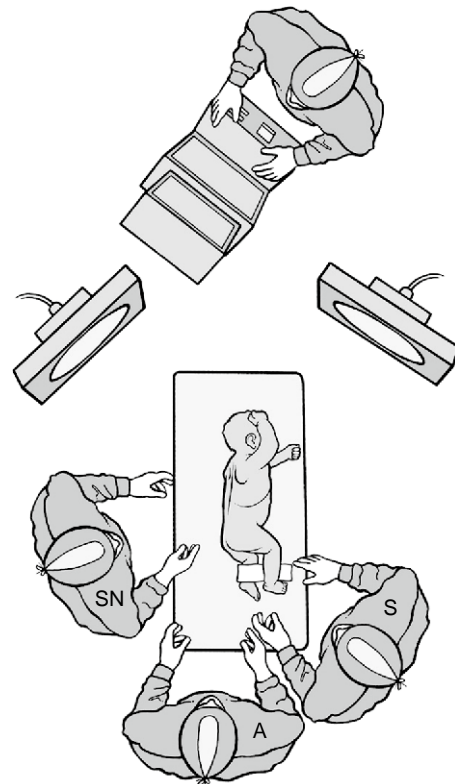

### Thoracoscopic Repair

There are several retrospective reports describing experience with the thoracoscopic approach.<sup>102-106</sup> The child is positioned in a true left lateral decubitus position close to the left edge of a shortened operating table in an infant with a left descending aorta (Fig. 27-10). A pad is placed underneath the chest to widen the right-sided intercostal spaces. The table is turned 15 degrees reverse Trendelenburg and 15 degrees tilt to the left. Thus, the lung will fall caudad and inferiorly by gravity once CO<sub>2</sub> is insufflated. The right arm is positioned over the head. The Repleg tube is released but left in place for later identification of the upper pouch. The surgeon stands to the left of the table with the camera person to his or her left and the scrub nurse at the opposite lower side of the table. The screen is at the level of the infant's right shoulder. An infant with a right descending aorta is placed in a right lateral decubitus position close to the right edge of the table. The surgeon is then on the right of the table with the screen at the level of the left shoulder.

The first cannula is inserted 1 cm distal and anterior to the tip of the scapula (Fig. 27-11). This is performed with an open technique. A small incision is made in the direction of the skin folds. With a small clamp, a small opening is made parallel with the upper

border of the rib. When loss of resistance is reached, a cannula with a blunt trocar is inserted. The sleeve of the cannula is sutured to the intercostal musculature. In infants larger than 2 kg, a 6-mm cannula with a 5-mm, 30-degree, 24-cm-long telescope is used. In infants smaller than 2 kg, a 3.8-mm cannula with a 3.3-mm, 30-degree, 24-cm-long telescope is used.

After creation of the working space, two 3.5-mm cannulas are inserted under endoscopic visualization, one more cephalad in the midaxilla and one more

**Figure 27-10.** This infant is positioned for right thoracoscopic repair. The surgeon (S) stands on the left side of the operating table when the aortic arch turns to the left. The surgeon, operative field, and screen are in line. The assistant (A) is situated to the left of the surgeon when the surgeon is right-handed. The scrub nurse (SN) stands to the right of the operating table.

**Figure 27-11.** Cannula position for thoracoscopic repair. The cannulas are inserted in triangulation. The telescope cannula (circle and dot) is inserted 1 cm below the inferior angle of the scapula and slightly anterior. One working cannula is inserted in the midaxillary line in the axilla. The second working cannula is introduced at the level of the telescope cannula but more posteriorly on the chest wall.

posteriorly behind the scapula. Two 3-mm, 20-cm-long working instruments are introduced through these ports. A lung retractor is usually not needed.

One-lung ventilation in neonates can be achieved with the use of a bronchial blocker.<sup>107-109</sup> An alternative approach is midtracheal intubation in conjunction with CO<sub>2</sub> pneumothorax. After insertion of the first cannula and telescopic verification that the cannula is in the thorax, CO<sub>2</sub> insufflation is started with a flow of 0.1 L/min and a pressure of 5 mm Hg. Initial desaturation is the rule. CO<sub>2</sub> pneumothorax is then released but is restarted when the anesthesiologist agrees. Adaptation of the ventilator settings, especially increasing the ventilation rate, is usually effective in reaching a steady state. This usually occurs after 5 to 10 minutes. End-tidal CO<sub>2</sub> is not reliable, and arterial blood gases should be monitored regularly.<sup>85,110-112</sup> How much acidosis that can be accepted is not known. Nevertheless, case reports have demonstrated that EA repair is tolerated even in neonates with complex cardiac conditions.<sup>113,114</sup>

When the fistula departs from the trachea above the azygos vein, this area will distend with each ventilation. In this case there is no need to divide the azygos vein. The anesthesiologist is asked to push on the Replogle tube. Dissection is started by opening the pleura between the upper pouch and the spinal column in a longitudinal direction. The upper pouch is dissected posteriorly and laterally but not in front, as explained earlier (Fig. 27-12).

The fistula is now dissected close to its entrance in the trachea. A 10-cm-long, 5-0 Vicryl (Ethicon, Inc., Somerville, NJ) suture on a V18 needle is introduced through the axillary cannula and is placed through the upper muscular edge of the fistula. The suture is tied, brought around the fistula, and tied again (see Fig. 27-12B). The fistula is then transected a few millimeters distal to the tie. The distal end of the fistula will retract but can be easily found later. If the entrance of the fistula in the trachea is behind the azygos vein, the vein should be divided. This can easily be done between ligatures or monopolar hook coagulation. The vein is coagulated on both sides of the initial coagulation site and transected in the middle. The fistula is then mobilized as described for the open approach.

The Replogle tube is pushed down so that the lowest point of the pouch can be identified. This point is opened with hook diathermy. The defect is then opened farther with scissors. The hole should be large enough so as to prevent stenosis. A 10-cm-long, 5-0 Vicryl suture on a V18 needle is introduced, and the first suture is placed in the middle of the back wall of the upper esophageal pouch, starting from the inside. The needle is then placed in the middle of the back wall of the distal esophagus. If a considerable distance needs to be bridged, a tumbled flat knot is made and glided until both walls appose (see Fig. 27-12C). Further sutures are placed in the back wall of the upper and lower esophagus. The knots are tied on the inside. The front part of the anastomosis is performed with the knots on the outside. Before completing the anastomosis a 6-Fr nasogastric tube is inserted, as described earlier.

A drain is not usually left. The cannulas are removed and so is residual CO<sub>2</sub>. The port sites do not need suturing, and adhesive tape for the skin will suffice.

### Wide Gap Esophageal Atresia with Distal Fistula

In almost all cases of EA with distal fistula, an anastomosis can be made. Paralysis and ventilation for 5 days have been advocated if the anastomosis is very tense.<sup>115-118</sup> The effectiveness of this strategy should be questioned, however, because the tensile strength of an anastomosis at 5 days is low. When the fistula originates at the carina, the distance may occasionally be too long for making a simple anastomosis.<sup>88,119</sup> Likewise, a short upper esophageal pouch may preclude a primary anastomosis.<sup>120</sup> Various maneuvers have been described to overcome this problem (Table 27-1).

### Esophageal Atresia without Distal Fistula

#### Initial Treatment

An airless abdomen is the signature of EA without distal fistula. Very rarely, a blocked distal fistula is responsible for the airlessness of the abdomen.<sup>16</sup> One should be aware that the incidence of a proximal fistula, in the absence of a distal fistula, is relatively high. In

**Figure 27-12.** Thoracoscopic approach. **A**, Proximal pouch (asterisk) dissection is seen. **B**, The distal fistula (asterisk) has been isolated close to the trachea and is being suture ligated. **C**, The back wall of the esophageal anastomosis has been finished with interrupted sutures knotted on the inside. The front part of the anastomosis is being performed using a tumbled square knot. A nasogastric tube can be seen in this photograph. **D**, Completed anastomosis.

one series of EA without distal fistula, the incidence of an upper pouch fistula even exceeded 50%.<sup>14</sup> A proximal fistula in EA without distal fistula is of the H-type, running from a more cranial tracheal position to a more caudal esophageal position. It is usually located at the thoracic inlet.

The initial treatment is a gastrostomy with laryngotracheobronchoscopy during the same anesthesia, aimed at ruling out a proximal fistula and other associated anomalies. In EA without a distal fistula and in the absence of a duodenal obstruction, the stomach is usually small. It may be difficult to bring the anterior gastric wall against the abdominal wall. Sometimes, even the shortest distance to the anterior wall cannot be bridged. In this situation, part of the gastrostomy tube is allowed to traverse the peritoneal cavity.<sup>121</sup> A siliconized urinary catheter of appropriate size (8 or 10 Fr) is inserted through the abdominal wall and into the stomach through a small gastrotomy. The balloon is filled with 1 mL only. Initial feeding should be with small quantities. The gastrostomy balloon must not be placed too close to the pylorus because this may cause distal obstruction.

### Esophageal Reconstruction

The first question that arises is the timing of the esophageal reconstruction. This moment will depend on the gap length to be bridged. A period of around 12 weeks is often suggested.<sup>65,122,123</sup>

During this waiting period, the proximal esophagus is emptied by continuous suction on a transnasally placed 10-Fr Replogle tube. The tube can get obstructed and should be replaced regularly. Moreover, insertion

should be occasionally changed from the one nostril to the other to avoid damage. If the child shows persisting respiratory problems, a proximal fistula should be searched for again. If possible, the proximal fistula should be closed at the time of the esophageal reconstruction. Severe respiratory problems may be a reason, however, to perform the esophageal reconstruction, including division of the fistula, at an earlier time. An alternative is cervical esophagostomy, but this may jeopardize the ability to perform a primary anastomosis in the future. Traditionally, the cervical esophagostomy is done on the left, but there is no good reason why this could not be done from the right. Home care during the waiting period has been advocated, but most of the reported patients have required a long time in the hospital before they were sent home for further observation.<sup>124,125</sup>

The gap between esophageal segments is usually expressed in terms of the number of vertebral bodies, thus taking the child's length into account. The residual gap to be bridged should be periodically measured. This can be done with a simultaneous contrast study of the upper and lower esophagus or by simultaneous insertion of a metal bougie transorally into the upper esophagus and through the gastrostomy into the lower esophagus. The metal bougie ends should overlap before attempting a primary anastomosis.

If an attempt at reconstruction is planned at 3 months of age, the surgeon should proceed according to the preoperative estimation of the feasibility of performing a primary anastomosis. Several techniques to lengthen the native esophagus have been described, such as esophageal myotomy or extensive mobilization

**Table 27-1** Maneuvers for Lengthening the Esophagus in Long-Gap Esophageal Atresia\***Nonoperative Maneuvers (in combination with delayed primary anastomosis)**

\*See references for further information.

of the proximal and even distal esophagus (see Table 27-1). There is little doubt that all these maneuvers damage the esophagus and that their long-term results may be less than optimal. If a delayed primary anastomosis with or without lengthening is not feasible, an alternative procedure is indicated, such as a gastric pull-up or a jejunal, ileal, or colonic interposition (see Table 27-1).

Thoracoscopy is ideal to have a look at the gap length to be bridged (Fig. 27-13). Moreover, the ends can be dissected and mobilized thoracoscopically. An anastomosis can be performed thoracoscopically as well. Also, a thoracoscopic Foker procedure can be accomplished.<sup>126</sup>

### Postoperative Management

Mechanical ventilation with muscle relaxation for 5 days has been advocated after an anastomosis is performed under considerable tension.<sup>115-118</sup> Again, evidence for the effectiveness of this approach is

lacking.<sup>127</sup> A chest drain is needed only when there is considerable doubt regarding the quality of the anastomosis.<sup>101</sup> Feeding can be started early through the nasogastric tube, which is the main reason for leaving such a tube. When sialorrhea ceases, oral feeding can be started. The child can then be fed ad libitum. If the child is doing well, there is no need for a routine imaging study of the esophagus postoperatively.<sup>128</sup>

## COMPLICATIONS

### Anastomotic Leaks

An overall leak rate of 17% has been reported by several authors.<sup>9,128,129</sup> Major leaks occur much less frequently—3.5% in the first study<sup>128</sup> and 4.5% in the more recent one,<sup>129</sup> which confirms the statement that most leaks are minor. Two series reported a much lower leak rate of, respectively, 6% and 7%.<sup>5,8</sup> In the largest thoracoscopic report, the leak rate was 7.6%.<sup>104</sup> Published reports often include all types of EA and do not always mention whether the leak was detected at routine esophagography only.

### Anastomotic Stricture

As with anastomotic leaks, no uniform definition is used for anastomotic stricture. It has been defined as a narrowing of more than 50% of the lumen<sup>130</sup> or as a narrowing detected on a contrast study or at esophagoscopy in combination with symptoms.<sup>131</sup> Reported incidences range from 17%,<sup>128</sup> 36%,<sup>8</sup> 40%,<sup>132</sup> 41%,<sup>133</sup> to 59%.<sup>5</sup> Four of 104 patients (3.8%) undergoing thoracoscopic repair developed a stricture, which was defined on the initial esophagogram.<sup>104</sup> Routine dilatation is certainly not indicated because many patients never require dilatation.<sup>133</sup> Anastomotic tension, anastomotic leakage, and gastroesophageal reflux<sup>134-137</sup> have been implicated as risk factors. Strictures usually respond well to dilation. Resection of the stricture is rarely required. Balloon dilatation seems superior, but there is no hard evidence.<sup>130</sup>

### Recurrent Tracheoesophageal Fistula

The reported incidence of recurrent TEF varies between 3% and 15%. In one study, the 10% incidence in the period 1986 to 1995 had dropped to 5% in the period 1996 to 2005.<sup>5</sup> In another study, it had dropped from 17% before 1980 to 3% in the period 1990 to 1999.<sup>8</sup> Yet another study reported a similar recurrence incidence of 3%.<sup>128</sup> In the 104 patients in one thoracoscopic series, 2 (1.9%) developed recurrent TEFs.<sup>104</sup>

A recurrent fistula is suspected when the child starts to cough during feeding, has apneic or cyanotic episodes, or has repeat respiratory infections. Often the abdomen is distended with air. On a chest film there may be signs of pneumonia. Sometimes, an air-filled esophagus is seen. The diagnosis can sometimes be made by video-esophagography using a water-soluble contrast medium (Fig. 27-14). Bronchoscopy confirms

**Figure 27-13.** Thoracoscopic view of esophageal atresia without fistula in a 3-month old neonate. **A**, The short distal esophageal segment (asterisk) is seen in the inferior portion of the mediastinum. **B**, The proximal pouch (asterisk) reaches to the azygos vein, which has been coagulated and transected.

the diagnosis. While pressing on the stomach, the fistula may open and become clearly visible. Alternatively, a small catheter may be fed into it. Several tracheoscopic treatment possibilities have been tried, such as electrocoagulation of the trajectory and injection of TissueCol (Baxter, Deerfield, IL)<sup>138</sup> or plugging of the fistula with Surgisis (Cook, Inc., Bloomington, IN) (Fig. 27-15).<sup>139</sup> Use of a laser, in combination with TissueCol, is another option.<sup>140</sup> Should these attempts fail, surgery should be considered, either with an open or thoracoscopic approach.

Prevention of a recurrent TEF can be difficult. Interposition of tissue between the tracheal closure and esophageal anastomosis has been advocated for this purpose. Native tissue such as pleura or pericardium can be used. Recently, a report described interposing

Surgisis between the trachea and esophagus to help prevent a recurrent TEF (Fig. 27-16).<sup>141</sup>

### Tracheomalacia

*Tracheomalacia* is defined as a generalized or localized weakness of the trachea that allows the anterior and posterior walls to come together during expiration or coughing.<sup>15</sup> The area of collapse is usually restricted to the region of the fistula. In one series, autopsy revealed structural abnormalities of the trachea in 75% of infants with EA/TEF.<sup>142</sup> The cartilage of the rings is softened, and the length of the transverse muscle is increased. As a result, the airway collapses during expiration, which produces expiratory stridor varying from a hoarse barking cough to acute life-threatening incidents of cyanosis or apnea.<sup>143</sup> In EA without fistula, tracheomalacia does not seem to occur very often,<sup>144</sup> which questions whether upper esophagus dilatation is really a causative factor. Tracheomalacia is implicated in the pathogenesis of reactive airway disease in patients with EA/TEF.

Symptoms vary from mild to life-threatening apneic spells. Severe symptoms usually appear when the child

**Figure 27-14.** On this water-soluble contrast study, a recurrent TEF (arrow) is seen.

**Figure 27-15.** This bronchoscopic view shows Surgisis (asterisk) placed into a recurrent TEF. In this patient, the fistula was successfully occluded using this technique.

**Figure 27-16.** After thoracoscopic repair of esophageal atresia and distal fistula in this infant, Surgisis was interposed between the tracheal closure and esophageal anastomosis to help prevent a recurrent TEF. (From St. Peter SD, Calkins CM, Holcomb GW III: The use of biosynthetic mesh to separate the anastomoses during the thoracoscopic repair of esophageal atresia and tracheoesophageal fistula. *J Laparoendosc Adv Surg Tech* 17:380-382, 2007. Reprinted with permission.)

is a few months old. The diagnosis is confirmed by tracheobronchoscopy. In patients with EA/TEF, it is often difficult to clinically distinguish these symptoms from those of a recurrent fistula, an anastomotic stricture, or gastroesophageal reflux.<sup>145</sup>

Treatment is required in the severely symptomatic form of tracheomalacia. The therapy of choice is aortopexy.<sup>143,146,147</sup> The principle behind this operation is that the ascending aorta and arch are suspended against the posterior surface of the sternum. By doing so, the anterior wall of the trachea, which is loosely attached to the aorta, is suspended as well. This aortic suspension opens the tracheal lumen.<sup>143</sup> If the anterior aorta cannot reach the posterior sternum, a pericardial flap based at the aortic root can be fashioned.<sup>148,149</sup> Aortopexy is classically performed through a left anterolateral thoracotomy or median sternotomy<sup>147,150</sup> but can also be performed through a low cervical incision and partial sternal split<sup>151</sup> or thoracoscopically either from the left<sup>152,153</sup> or from the right.<sup>154</sup> It is best to check the effect of the suspension during the operation by simultaneous tracheoscopy.

### Disordered Peristalsis/ Gastroesophageal Reflux

Disturbed motility of the esophagus in EA patients has been recognized for a long time.<sup>155-157</sup> Many adolescents and adults, operated on at birth for an EA with distal fistula and who considered themselves healthy, show symptoms of esophageal dysfunction, including dysphagia, episodes of foreign body impaction, heartburn, vomiting, and various respiratory disorders.<sup>158</sup> Similar findings were reported in another study as well.<sup>159</sup> Foreign body obstruction has been reported with an incidence of 13% in this study population.<sup>160</sup>

The oral phase of swallowing is normal, but the pharyngeal and esophageal phases are abnormal in all patients, both at video-fluoroscopy<sup>161,162</sup> and with manometry.<sup>163-165</sup> It is doubtful there are patients with normal peristalsis.

Whether the cause of these disturbed motility problems is congenital or acquired has been a long-standing debate. Preoperative simultaneous manometry in the upper and lower pouch in two children with EA without fistula revealed coordinated contractions in both the upper and lower esophagus on swallowing and a reflex relaxation of the lower esophageal sphincter.<sup>166</sup> Postoperatively, it revealed simultaneous, instead of coordinated, contractions in the repaired esophagus with only partial relaxation of the lower esophageal sphincter. These findings seem to favor the hypothesis that the motility disturbance is caused by surgical damage. Subsequently, the same authors confirmed their observations experimentally in a dog model.<sup>166,167</sup> A dissection study on autopsy material of EA patients also supports the hypothesis of surgical damage.<sup>99</sup> In the Adriamycin-induced EA rat model, however, a deficient extrinsic and intrinsic nerve plexus in the lower esophagus is present.<sup>168,169</sup> Achalasia-like dysmotility in EA has also been reported.<sup>170</sup>

Whatever the cause for the disturbed motility in patients with corrected EA, it brings several problems, not the least of which is gastroesophageal reflux (GER). Whereas GER in otherwise normal children has a tendency to improve during the first year of life, it does not improve in individuals with corrected EA, not even after several decades.<sup>158</sup> The incidence of significant reflux in patients with EA has been stated to be 40%, and about half will require antireflux surgery.<sup>65</sup> In one center, the incidence of significant GER rose from 39% in the period 1975 to 1984 to 63% in the period 1985 to 1988.<sup>171</sup> In another study, it rose from 25% in 1958 to 72% in 1982.<sup>8,172</sup> A progressive rise in significant reflux was seen up to the age of 5 years.<sup>173</sup> A considerable number of patients with repaired EA have complaints in adult life pointing toward GER as the etiology.<sup>159,174</sup> Early normal pH values in the esophagus do not exclude significant reflux on follow-up.<sup>175</sup> Antireflux medication including gastric acid suppression is successful in only about half of the cases.<sup>121</sup> Antireflux operations in patients with repaired EA have a high failure rate,<sup>176</sup> but there seems to be no other alternative. In view of the motility disturbances, partial wraps have been advocated,<sup>177</sup> but hard evidence for their superiority is lacking. The question remains whether patients with repaired EA should be screened as adults. However, there is no correlation between subjective and objective findings, there are no reports of treatment of Barrett's esophagus, and the incidence of cancer in EA patients seems not to be increased.<sup>159,178</sup>

### Respiratory Morbidity

Respiratory morbidity in patients with repaired EA is high. In a series of 334 patients aged 1 to 37, just under half were subsequently hospitalized with a respiratory

illness.<sup>179</sup> Two thirds of the admissions were before 5 years of age. Even a high proportion of the adult patients reported respiratory symptoms.<sup>180</sup> These symptoms can be attributed to tracheomalacia and GER. Aortopexy is effective in preventing further life-threatening spells but does not prevent the increased susceptibility to respiratory infections.<sup>181</sup>

## Thoracotomy-Related Morbidity

Thoracotomy, especially in the newborn, may lead to significant morbidity, such as winged scapula, elevation or fixation of the shoulder, asymmetry of the chest wall, rib fusion, scoliosis, and breast and pectoral muscle maldevelopment.<sup>182-189</sup> Moreover, chronic pain after thoracic surgery is a serious problem, at least in adults, and has been reported in more than 50% of patients.<sup>190,191</sup> The negative consequences of a thoracotomy can certainly be alleviated by choosing the thoracoscopic approach.<sup>104</sup>

## OUTCOME

### Short-Term Outcome

The classification system for assessing short-term outcome was first proposed by Waterston in 1962 (Table 27-2).<sup>192</sup> In later years, factors such as earlier diagnosis and referral, improvements in perioperative care (including anesthesia), and improvements in the diagnosis and treatment of associated anomalies considerably improved the outcomes. Thus, using the original Waterston classification and applying it to the cohort of patients treated at Great Ormond Street in London from 1980 to 1992, there was a 99% survival in group A, 75% in group B, and 71% in group C.<sup>6</sup> The authors then developed a new classification system based on birth weight and the presence of congenital cardiac anomalies (Table 27-3).<sup>6</sup> Another classification system from Montreal takes into account only life-threatening anomalies or major associated anomalies

Group	Birth Characteristics	Survival
A	> 5½ lb body weight and well	95%
B	1. Birth weight: 4 to 5½ lb and well 2. Higher birth weight, moderate pneumonia, and congenital anomaly	68%
C	1. Birth weight < 4 lb 2. Higher birth weight, severe pneumonia, and severe congenital anomaly	6%

Data from Waterston DJ, Carter RE, Aberdeen E: Oesophageal atresia: Tracheo-oesophageal fistula: A study of survival in 218 infants. *Lancet* 1:819-822, 1962.

**Table 27-3** New Classification System for Short-Term Outcomes after Repair of EA/TEF Based on Birth Weight and Cardiac Status

Group	Birth Characteristics	Survival*
I	Birth weight > 1500 g with no major cardiac anomaly	97% (283/293)
II	Birth weight < 1500 g or major cardiac anomaly	59% (41/70)
III	Birth weight < 1500 g and major congenital anomaly	22% (2/9)

\*Survival found in 357 infants with EA and 15 infants with an H-type TEF treated at Great Ormond Street Hospital, London, 1980-1992. Data from Spitz L, Kiely EM, Morecroft JA, et al: Oesophageal atresia: At-risk groups for the 1990s. *J Pediatr Surg* 29:723-725, 1994.

together with ventilator dependence.<sup>193</sup> Finally, two studies on gap length as a prognostic factor found significant differences in prognosis.<sup>194,195</sup>

### Long-Term Outcome

As described previously, EA is associated with high morbidity.<sup>174,189,196,197</sup> Interestingly, young adult patients with a history of EA score well on the Course of Life Questionnaire.<sup>198</sup> It seems they have learned to live with their inconveniences.

## ISOLATED TRACHEOESOPHAGEAL FISTULA

### Incidence and Associated Malformations

The incidence of isolated TEF is about 4% in series taking EA and TEF together.<sup>14,15</sup> Isolated TEF is associated with the same anomalies as seen in EA, although at lower incidences.<sup>199</sup>

### Pathology

The fistula runs from the trachea downward to the esophagus, typically intramurally (see Fig. 27-1). The trajectory is short. In a series of 20 children, the fistula was at C5-6 in 2, C6-7 in 3, C7-T1 in 8, T1-2 in 3, and T2-3 in 1.<sup>19</sup> Rarely, there is a second fistula.<sup>200</sup>

### Clinical Presentation

Respiratory symptoms, especially choking, usually occur immediately after birth during drinking. Sometimes, there are unexplained cyanotic spells. Symptoms subside when the child is fed by a nasogastric tube. Often the abdomen is distended with air, and flatulence may be present. This is caused by air going down through the fistula during crying. Older children present with recurrent pneumonia, especially of the right upper lobe. Often symptoms can be traced back to the neonatal period. Sometimes symptoms present later in life.<sup>201-203</sup>

## Diagnosis

There has been considerable debate on the optimal method for diagnosis. Obviously, awareness is of key importance. A contrast swallow using a water-soluble, low osmolar contrast medium seems to be the best initial investigation and demonstrates the fistula in 80% of the cases (Fig. 27-17).<sup>19</sup> In the remaining 20%, contrast material during swallowing is seen in the trachea. Tracheoscopy is another imaging modality to be considered, but even then the fistula can be missed.<sup>204</sup> CT esophagography is another option but has the disadvantage of radiation exposure.<sup>203</sup>

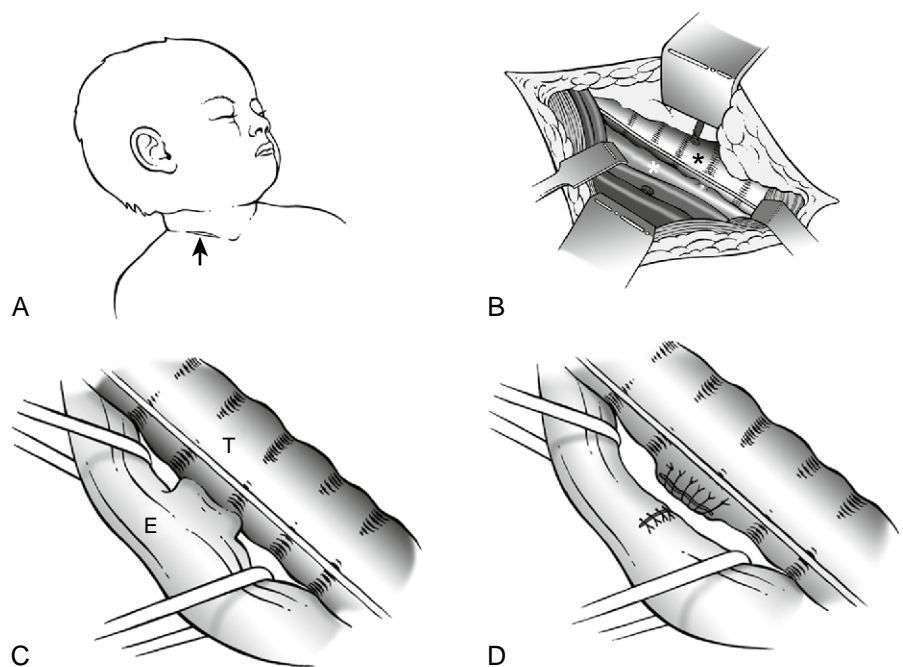

## Therapy

A cervical approach can be used in most (80%) cases.<sup>205</sup> With the use of a feeding tube placed through the fistula by tracheoscopy and pulled out of the esophagus, even these lower H-type fistulas can be pulled up and approached through the neck as well.<sup>206,207</sup> The classic approach is that from the right through a small low cervical incision (Fig. 27-18). The sternal head of the sternocleidomastoid muscle may need transection. The esophagus is easily identified and separated from the trachea, taking care not to injure the recurrent laryngeal nerve. The left recurrent laryngeal nerve is vulnerable as well. The proximal esophagus, as well as the fistula, are encircled with separate vessel loops and so is the distal esophagus. Traction sutures are placed at the upper and lower ends of the fistula, which is transected close to the esophagus. The trachea is closed longitudinally and the esophagus transversally with interrupted absorbable sutures. Because fistula recurrence is rare, there is no need for interposition of tissue.

It is obvious that less trauma is inflicted when a thoracotomy can be avoided. The availability of thoracoscopy indeed obviates the need for a thoracotomy, thus making a cervical approach for the extremely low H-fistulas less imperative. Several case reports of thoracoscopically closed fistulas have been published.<sup>208,209</sup> Alternatively, a thoracoscopically assisted approach

**Figure 27-17.** Imaging for an H-type TEF. A contrast swallow is performed using a low osmolar, water-soluble medium. The fistula (arrow) is clearly seen on the lateral chest film. The fistula is at the level of the thoracic inlet. Contrast material entered the trachea and bronchial tree.

**Figure 27-18.** Cervical approach used to repair an H-fistula. **A**, Low right transverse cervical incision (arrow). **B**, The esophagus (white asterisk) is approached medial to the carotid artery and jugular vein. Care is taken not to injure the recurrent laryngeal nerve on either side. The trachea is marked with a black asterisk. **C**, The esophagus (E) is encircled both above and below the fistula. The fistula will be transected close to the trachea (T). **D**, The tracheal opening is closed vertically, and the esophageal defect is closed transversely.

can be used in which the fistula is dissected from below but repaired from above through the neck. As a matter of interest, EA repair through the neck has been reported as well.<sup>210,211</sup> Whether a fistula should be primarily approached from the neck or the chest depends on the location of the fistula based on preoperative imaging.

## COMMUNICATING BRONCHOPULMONARY FOREGUT MALFORMATIONS

Communicating bronchopulmonary foregut malformations (CBPFMs) are rare congenital malformations characterized by a fistula between an isolated portion of the respiratory tissue and the esophagus, stomach, or even pancreas.<sup>212,213</sup> CBPFMs belong to the broader group of bronchopulmonary foregut malformations, which also includes intralobar and extralobar pulmonary sequestrations and bronchogenic cysts. The classification system for these anomalies is seen in Table 27-4.<sup>212</sup>

Patients with CBPFMs commonly have other associated malformations that contribute significantly to an increased morbidity and mortality.<sup>212,214</sup> Tracheal stenosis may be part of the anomaly.<sup>214,215</sup> Awareness of the possible existence of a CBPFM is essential for making an early diagnosis and treatment plan.

## LARYNGEAL AND LARYNGOTRACHEOESOPHAGEAL CLEFT

Laryngeal and laryngotracheoesophageal clefts are rare congenital anomalies with an incidence of approximately 1 in 10,000 to 20,000 live births.<sup>216</sup> The cleft consists of a midline communication of the larynx, trachea, and even bronchus with the pharynx and upper esophagus. Its embryology is poorly

**Table 27-4** Classification System for Congenital Bronchopulmonary Foregut Malformations (CBPFMs)

- I. CBPFMs are associated with esophageal atresia
  - A. The entire lung is involved
  - B. Only part of the lung is involved
- II. One lung originates from the lower esophagus
- III. An isolated lobe or segment of the lung communicates with the esophagus or stomach.
 

The arterial supply comes from either the pulmonary artery or an independent branch from the aorta, or both. The venous drainage is to the pulmonary vein, portal vein or azygos system.
- IV. A portion of the normal bronchial system communicates with the esophagus.
 

The communicating bronchus has a systemic blood supply.

From Srikanth MS, Ford EG, Stanley P, et al: Communicating bronchopulmonary foregut malformations: Classification and embryogenesis. *J Pediatr Surg* 27:732-736, 1992.

**Figure 27-19.** This schematic depicts the classification of laryngotracheoesophageal clefts described by Myer and colleagues.<sup>222</sup> The laryngotracheoesophageal clefts are seen in the top drawing (B-D), and the laryngotracheoesophageal clefts are seen on the bottom (E-G). A, Normal anatomy. B, Interarytenoid cleft (LI). C, Partial cricoid cleft (LII). D, Complete cricoid cleft (LIII). E, Cleft extends into trachea (LTEI). F, Cleft extends into the carina (LTEII). G, Cleft extends into the bronchus (LTEIII, proposed).

understood. Originally, it was thought to be the consequence of a failure of the tracheoesophageal septum to fuse in the caudocranial direction. However, this theory of tracheoesophageal separation by fusion of a tracheoesophageal septum has been challenged.<sup>21-24</sup>

Many congenital malformations can coexist, including congenital heart disease, gastrointestinal and genitourinary tract abnormalities, and midline defects.<sup>217</sup> Familial occurrence has been described.<sup>218</sup> Clefts may be part of the Opitz-Frias syndrome and the Pallister-Hall syndrome.<sup>219</sup> TEFs have been described in 20% to 37% of the patients.<sup>217</sup> Several classifications have been described (Fig. 27-19) and can be seen in Table 27-5.<sup>220-222</sup>

Symptoms vary according to the extension of the cleft. Patients may be symptomatic immediately from birth as a result of drowning in their saliva (Fig. 27-20). Secretions are increased, and there may be choking and cyanosis. A typical symptom is hoarseness. Drinking aggravates the symptoms, and recurrent aspiration pneumonia can occur. The clinical picture may be blurred by associated anomalies, such as EA with distal fistula.

Contrast radiographs may be diagnostic, although it can be difficult to differentiate between overflow or aspiration and the direct entrance of contrast as a result of the cleft. Tracheobronchoscopy is diagnostic. The diagnosis may well be missed, especially in less

**Table 27-5** Three Classification Systems for Laryngotracheoesophageal Clefts

Pettersson <sup>220</sup>	Ryan et al. <sup>221</sup>	Myer et al. <sup>222</sup>
I: Cleft limited to the cricoid	As described by Pettersson but with the addition of:	Laryngeal clefts
II: Cleft extending beyond the cricoid into the trachea	IV: Cleft extending the whole way down into one of the main bronchi	Interarytenoid: LI
III: Cleft involving the whole cricoid and trachea		Partial cricoid: LII
		Complete cricoid: LIII
		Laryngotracheoesophageal
		Into trachea: LTEI
		To carina: LTEII

**Comment:** The classification of Myer and colleagues seems best suited because it is more specific regarding the anatomic region involved. Extension into the bronchus, however, is not part of this classification. It could be added as LTEIII.

severe cases. A high degree of suspicion is required for making the diagnosis in these patients. Pressure of the scope on the arytenoids will open the cleft.

Management varies according to the type of cleft and the associated anomalies. Aspiration should be avoided by nasogastric feeding, antireflux medication, or gastrostomy in combination with antireflux surgery.

Using the Myer classification system,<sup>222</sup> LI may need no treatment other than antireflux therapy. If still symptomatic, these patients may need an open or endoscopic repair. LII, LIII, and LTEI are best

managed through anterior laryngotomy. LTEII and LTEIII are best treated by a combined cervical and thoracic approach.<sup>223</sup> A lateral cervical approach provides suboptimal access.<sup>224</sup> An anterior approach under cardiopulmonary bypass has also been used.<sup>224,225</sup> Repair under extracorporeal membrane oxygenation may be the best option.<sup>224,226</sup>

This is a rare anomaly, and reported series are small. Tracheal instability, tracheomalacia, and GER with recurrent aspiration have been noted. The anastomotic leak rate is high, and hospitalization is often prolonged.

**Figure 27-20.** This newborn began to have respiratory distress shortly after birth. Clinically, it was felt that the baby might have a tracheoesophageal fistula without esophageal atresia as a small nasogastric tube was able to be passed into the stomach. The bronchoscopic examination is shown. In both figures, the trachea is identified with the asterisk. On the left (**A**), the laryngotracheoesophageal cleft is visualized. The esophagus is marked with the arrow. On the right (**B**), the distal end of the laryngotracheoesophageal cleft is easily seen with the trachea anteriorly (asterisk) and the esophagus posteriorly. According to the classification of laryngotracheoesophageal clefts described by Myer, this would be an LTE-1 (see Fig. 27-19E).

# THORACOSCOPY IN INFANTS AND CHILDREN

Steven S. Rothenberg, MD

**T**horacoscopy is a technique that has been in use since the early 1900s but has undergone an exponential increase in popularity and growth over the past 2 decades. The first experience in humans was reported by Jacobeus in 1910 and consisted of inserting a cystoscope through a rigid cannula into the pleural space to lyse adhesions and cause complete collapse of a lung as treatment for patients with tuberculosis. He later reported the first significant experience with a series of over 100 patients.<sup>1</sup> During the next 70 years, thoracoscopy gained some favor, primarily in Europe, for the biopsy of pleural-based tumors and limited thoracic explorations in adults. However, widespread acceptance was minimal.<sup>2,3</sup>

In the 1970s and 1980s, the first significant experience in children was reported.<sup>4,5</sup> Equipment modified for pediatric patients was used to perform biopsies, evaluate various intrathoracic lesions, and perform limited pleural debridement in patients with empyema.<sup>6</sup> However, even though there was an increasing recognition of the morbidity associated with a standard thoracotomy, especially in small infants and children, there was little acceptance or adoption of these techniques.<sup>7</sup> It was not until the early 1990s, with the dramatic revolution in technology associated with laparoscopic surgery in adults, that more advanced diagnostic and therapeutic procedures were performed in children.<sup>8</sup> The development of a high-resolution microchip, and now digital and high-definition cameras, smaller instrumentation, and better optics, has enabled pediatric surgeons to perform even the most complicated intrathoracic procedure thoracoscopically.<sup>9</sup>

## INDICATIONS

Today there are a wide variety of indications for thoracoscopic procedures in children (Table 28-1), and the number continues to expand with advances and

refinements in technology and technique. Currently, thoracoscopy is being used extensively for lung biopsy and wedge resection in patients with interstitial lung disease and metastatic lesions.<sup>10,11</sup> More extensive pulmonary resections, including segmentectomy and lobectomy, are now being routinely performed for infectious diseases, cavitory lesions, bullous disease, lobar emphysema, congenital pulmonary airway malformations (CPAM), and neoplasms.<sup>12-17</sup> Thoracoscopy is also extremely useful in the evaluation and treatment of mediastinal masses.<sup>18</sup> It provides excellent access and visualization for biopsy and resection of mediastinal structures, such as lymph nodes, thymic and thyroid lesions, cystic hygromas, foregut duplications, ganglioneuromas, and neuroblastomas.<sup>19-21</sup> Other advanced intrathoracic procedures such as decortication for empyema, patent ductus arteriosus closure, division of vascular rings, repair of hiatal hernia and congenital diaphragmatic defects, esophageal myotomy for achalasia, thoracic sympathectomy for hyperhidrosis, anterior spinal fusion for severe scoliosis, and, most recently, primary repair of esophageal atresia have been described in children.<sup>22-31</sup>

**Table 28-1** Indications for Thoracoscopy in Infants and Children

Lung biopsy	Ligation of patent ductus arteriosus
Lobectomy	Thoracic duct ligation
Sequestration resection	Esophageal atresia repair
Cyst excision	Tracheoesophageal fistula
Decortication	Aortopexy
Foregut duplication resection	Mediastinal mass excision
Esophageal myotomy	Thymectomy
Anterior spine fusion	Sympathectomy
Diaphragmatic hernia/plication	Pericardial window

**Figure 28-1.** CT scan of a patient with interstitial lung disease. The areas of greatest involvement (arrow) can be identified for biopsy.

## PREOPERATIVE WORKUP

The preoperative workup varies significantly depending on the procedure to be performed. Most intrathoracic lesions require routine radiography as well as computed tomography (CT) or magnetic resonance imaging (MRI). A thin-cut high-resolution CT scan is especially helpful in evaluating patients with interstitial lung disease because it can identify the most affected areas and help determine the site of biopsy (Fig. 28-1), since the external appearance of the lung is usually not helpful. CT-guided needle localization can also be used to direct biopsies for focal lesions that may be deep in the parenchyma and therefore not visible on the surface of the lung during thoracoscopy. This is usually performed just before the thoracoscopy, with the radiologist marking the pleura overlying the lesion with a small blood patch or dye (Fig. 28-2). On occasion, a wire may be placed, as in breast biopsies, but it may become dislodged during collapse of the lung with the pneumothorax. As intraoperative ultrasound imaging improves, this may provide a more sensitive way for

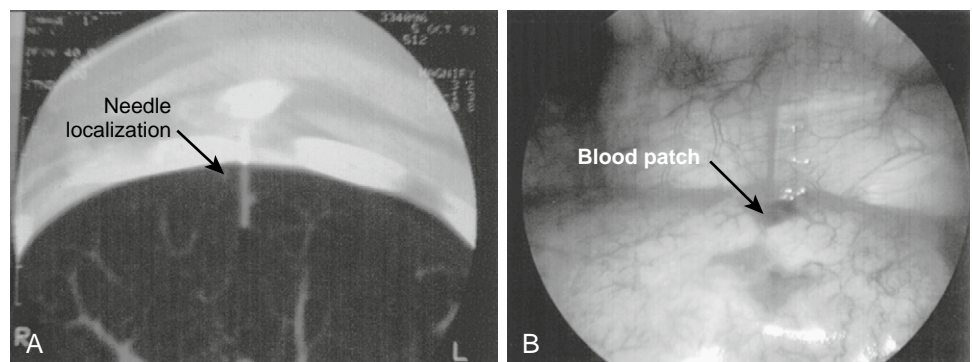

the surgeon to detect lesions deep to the surface of the lung and compensate for the lack of tactile sensation. Unfortunately, in its current state, this technology is still unreliable.<sup>32</sup> MRI may be more useful in evaluating vascular lesions or masses, which may arise from or encroach on the spinal canal, or in infants with vascular rings. These studies can be extremely important in determining positioning of the patient and initial port placement.

Another major consideration for the successful completion of most thoracoscopic procedures is whether or not the patient will tolerate single-lung ventilation, thus allowing for collapse of the ipsilateral lung to ensure adequate visualization and room for manipulation. Unfortunately, there is no specific preoperative test that will yield this answer. However, most patients, even those who are ventilator dependent, can tolerate short periods of single-lung ventilation. This should allow adequate time to perform most diagnostic procedures such as lung biopsy. In cases in which single-lung ventilation cannot be tolerated, other techniques can be used (see later).

## PREOPERATIVE PREPARATION

### Anesthetic Considerations

Whereas single-lung ventilation is achieved relatively easily in adult patients using a double-lumen endotracheal tube, the process is more difficult in the infant or small child. The smallest available double-lumen tube is a 28 Fr, which can generally not be used in a patient weighing less than 30 kg. Another option is a bronchial blocker. This device contains an occluding balloon attached to a stylet on the side of the endotracheal tube. After intubation, the stylet and tube are advanced into the bronchus to be occluded and the balloon is inflated. Unfortunately, size is again a limiting factor because the smallest blocker currently available is a 6.0-mm tube. In smaller patients, a Fogarty balloon catheter can be placed adjacent to a standard endotracheal tube or through the lumen of the tube to achieve occlusion of the desired bronchus. For the majority of cases in infants and small children, selective main-stem intubation of the contralateral bronchus with a standard uncuffed endotracheal tube is

**Figure 28-2.** A, Needle localization of a presumed metastatic lesion under CT guidance. B, Small blood patch visible on the pleural surface marking the underlying nodule.

effective. This can usually be done blindly without the aid of a bronchoscope simply by manipulating the head and neck. It is also important to use an endotracheal tube one-half to one size smaller than the anesthesiologist would pick for a standard intubation or the tube may not pass into the main-stem bronchus, especially on the left side.

At times, this technique will not lead to total collapse of the lung because there may be some overflow ventilation because the endotracheal tube is not totally occlusive. This problem is overcome by the routine use of a low flow (1 L/min), low pressure (4 mm/Hg) CO<sub>2</sub> infusion during the procedure to help keep the lung compressed. If adequate visualization is still not achieved, then the pressure and flow can be gradually increased until adequate lung collapse is achieved. Pressures of 10 to 12 mm Hg can be tolerated without significant respiratory or hemodynamic consequences in most cases. This requires the use of a valved cannula rather than nonvalved port. This technique can also be used on patients who cannot tolerate single-lung ventilation. By using small tidal volumes, lower peak pressures, and a higher respiratory rate, enough lung collapse can be achieved to allow for adequate exploration and biopsy. In neonates with esophageal atresia with or without fistula, or with other congenital malformations, CO<sub>2</sub> insufflation alone can be used to deflate the lung. Once the lung is collapsed, it will remain compressed until the anesthesiologist makes a conscious effort to re-expand it. The surface tension of the collapsed alveoli in the newborn keeps the lung collapsed without excessive pressures being used. Another option is to place the neonate on a high-frequency ventilator, which minimizes airway pressures used and may be tolerated better by some neonates than single-lung ventilation.<sup>33</sup> This may be a better solution, especially in institutions in which the anesthesiologists are not as experienced or comfortable with single-lung ventilation or isolation.

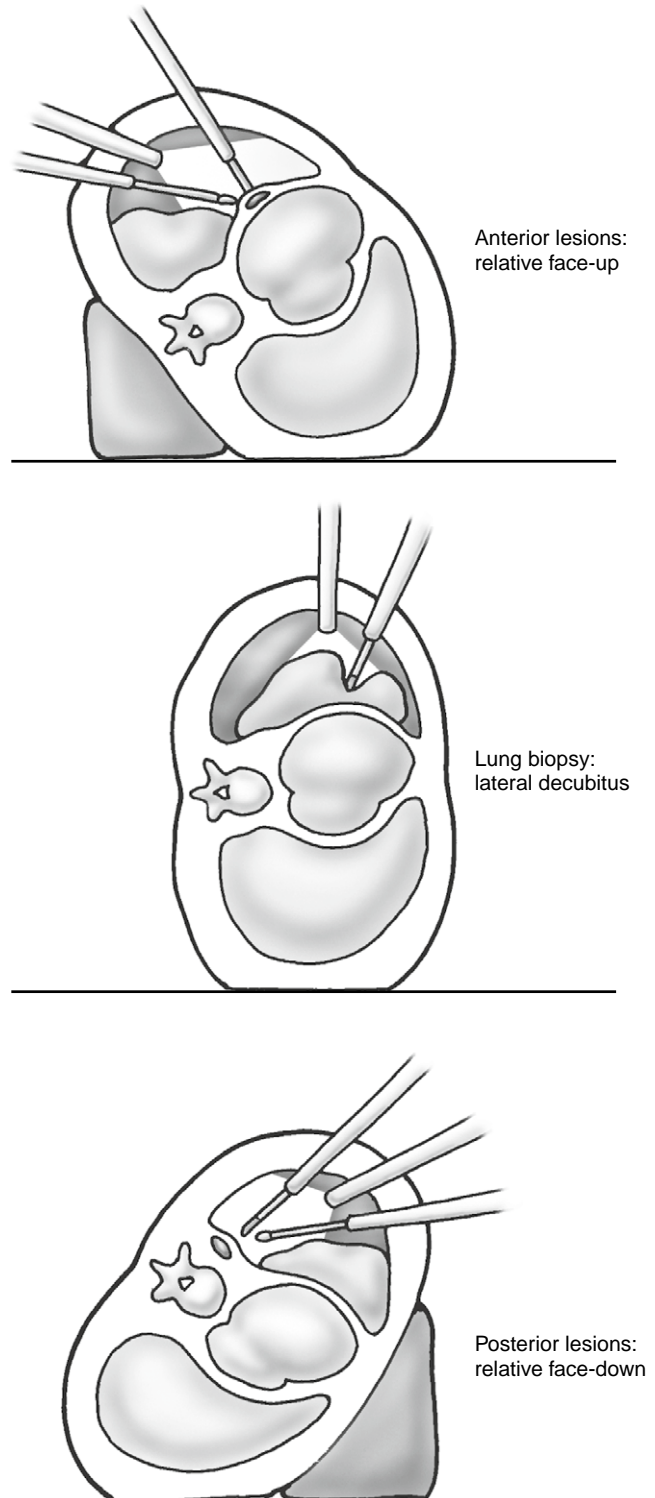

CO<sub>2</sub> insufflation is also useful if bilateral procedures are being performed, such as in the case of sympathectomy.<sup>34</sup> A slight tension pneumothorax gives adequate exposure to visualize the sympathetic chain without the need for changing the double-lumen tube or bronchial blocker. Whatever method is chosen, it is imperative that the anesthesiologist and surgeon have a clear plan and good communication to prevent problems with hypoxia and excessive hypercapnia and to ensure the best chance for a successful procedure.<sup>35</sup>

## Patient Positioning

Patient positioning depends on the site of the lesion and the type of procedure. Most open thoracotomies are performed with the patient in the lateral decubitus position. Thoracoscopic procedures should be performed with the patient in a position that allows for the greatest access to the area of interest and uses gravity to aid in keeping the uninvolved lung or other tissues out of the field of view.

For routine lung biopsies or lung resections, the patient can be positioned in a standard lateral

decubitus position (Fig. 28-3). This position provides for excellent visualization and access to all surfaces of the lung. This position is also optimal for decortication, pleurodesis, and other procedures when the surgeon may need access to the entire pleural or lung surface.

**Figure 28-3.** Patient positioning for the thoracoscopic approach to mediastinal and pulmonary lesions in children is important. The relative positions of the three cannulas also are illustrated for these lesions.

For anterior mediastinal masses, the patient should be placed supine with the affected side elevated 20 to 30 degrees (see Fig. 28-3). This allows for excellent visualization of the entire anterior mediastinum while allowing gravity to retract the lung posteriorly without the need for extra retractors. The surgical ports may then be placed between the anterior and midaxillary lines, giving clear access to the anterior mediastinum. This position should be used for thymectomy, aortopexy, or biopsy or resection of anterior tumors or lymph nodes. For posterior mediastinal masses, foregut duplications, esophageal atresia, and work on the esophageal hiatus, the patient should be placed in a modified prone position (see Fig. 28-3). This maneuver again allows for excellent exposure without the need for additional retractors. The patient can then be placed in the Trendelenburg or reverse Trendelenburg position as needed to help keep the lung out of the field of view.

Once the patient is appropriately positioned and draped, the monitors can be situated. For most thoracoscopic procedures, it is advantageous to use two monitors, one on either side of the table. The monitors should be situated between the patient's shoulders and hips, depending on the site of the lesion. As with any endoscopic procedure, the goal is to keep the surgeon in line with the camera, in line with the pathologic process, and in line with the monitor. This allows the surgeon to work in the most efficient and ergonomic way. In some cases, such as decortication, the field of interest may constantly change. In this case, the monitors should be placed at shoulder level and moved as necessary.

The majority of operations can be performed with the surgeon and one assistant. The surgeon should stand on the side of the table opposite the area to be addressed so that he or she can work in line with the camera. In most lung cases such as biopsies, it is preferential to have the assistant on the same side of the table as the surgeon so that the surgeon is not working in a paradox (against the camera). This concept is even more important when the field of dissection is localized. Cases such as resection of mediastinal masses, esophageal atresia repair, or more complicated lung resections require greater surgical skill. It is imperative that both the surgeon and the assistant are working in line with the field of view to prevent clumsy or awkward movements. In cases such as decortication, where the field of view and dissection are constantly changing and the majority of movements are relatively gross, having the surgeon and assistant on opposite sides of the table is appropriate and may actually expedite the procedure.

### Port Placement

Positioning of the cannulas varies widely with the procedure being performed and the site of the lesion. Thoughtful positioning of the ports is more important than with laparoscopic surgery because the chest wall is rigid. Therefore, the mobility of the instruments will be somewhat restricted as compared with procedures

on the abdomen. In general, the camera port should be placed slightly above and between the working ports to allow the surgeon to look down on the field of view, much as in open surgery. This will also minimize instrument "dueling," which can be a significant problem in smaller infants. For example, for lung biopsies, the cannulas should usually be placed between the fourth and eighth intercostal spaces. The camera port is usually in the midaxillary line at the fifth or sixth interspace. If an endoscopic stapler is being used, it requires a 12-mm cannula. Therefore, it should be situated in the lowest interspace possible, especially in smaller children, because these are the widest interspaces and better able to accommodate the larger port. If the lesion is anterior, it should be positioned closer to the posterior axillary line and vice versa. This is to allow the greatest amount of space between the chest wall insertion and the lesion because the working head of the stapler requires at least 45 to 50 mm of space. The third or grasping port is placed closer to the lesion and provides traction on the lesion during biopsy. This arrangement allows the surgeon, camera, and primary working port to be in line with the area to be sampled.

The midaxillary port should be placed first to allow for modification of the other two ports once an initial survey of the chest cavity has been completed. A triangular arrangement of the cannulas has also been recommended because it allows for rotation of the telescope and instruments between the three ports, giving excellent access to all areas. However, the surgeon can then be working against the camera, a situation that can make the simplest procedure very difficult. Also, especially in children, the number of large ports should be limited. Therefore, thoughtful planning regarding port placement is important. Generally, the cannula placement can be tentatively planned based on preoperative imaging studies and then modified once the initial port is inserted.

### Instrumentation

The equipment used for thoracoscopy is basically the same as that for laparoscopy. In general, 5-mm and 3-mm instruments are adequate in size. In most cases, valved cannulas are used for the reasons previously discussed. Basic equipment should include 5-mm 0-degree and 30-degree telescopes. If procedures are being performed in smaller children and infants, it is also helpful to have smaller telescopes such as a short (16 to 18 cm) 3- or 4-mm wide-angle 30-degree telescope and specifically designed shorter instruments. These tools enable the surgeon to perform much finer movements and dissection, allowing advanced procedures to be performed in infants as small as 1 kg. A high-resolution digital camera and light source are also extremely important to allow for adequate visualization, especially when using smaller telescopes that transmit less light. Basic instrumentation should include curved dissecting scissors, curved dissectors (Maryland), atraumatic clamps (i.e., 3- and 5-mm atraumatic bowel clamp), a fan retractor, a suction/irrigator, and needle holders. Disposable

**Figure 28-4.** A 5-year-old with Wilms' tumor developed suspected metastatic lesions in the left upper lobe. **A**, The lesion is visualized on the inferior border of the left upper lobe. **B**, The edge of the left upper lobe is grasped to place the desired specimen on stretch. **C**, The stapler is then situated across the base of the lung containing the desired specimen and fired. As in this case, more than one firing often is required to remove the desired lesion. (From La Quaglia MP, Rothenberg SS: Thoracoscopic lung biopsy. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 247-251.)

instrumentation that should be available includes 5-mm hemostatic clips, endoloops (pre-tied ligatures), and an endoscopic linear stapler. It lays down six to eight rows of staples and divides the tissue between them, providing an air- and water-tight seal (Fig. 28-4). This is an excellent tool for performing wedge resections of the lung. Unfortunately, its current size requires placement of a 12-mm port, precluding its use in patients much under 10 kg because of the limited size of the thoracic cavity. There are also a number of energy sources available that provide hemostasis and divide tissue. These include monopolar and bipolar cautery, the ultrasonic coagulating shears, and the Ligasure (Valleylab, Boulder, CO), all of which can be helpful in difficult dissections. It is also helpful to have one of the various tissue glues available for sealing lung and pleural surfaces.

## EMPHYEMA

Empyema is a relatively common intrathoracic problem encountered by pediatric surgeons. Traditionally, it has been treated by antibiotics and varying degrees

of chest drainage, including pleurocentesis, tube thoracostomy, mini-thoracotomy, and formal thoracotomy. Recent evidence has shown that fibrinolytic therapy is effective in 85% of patients.<sup>36,37</sup> When needed, thoracoscopic debridement offers an opportunity to diminish the morbidity and recovery period associated with an empyema while limiting the surgical trauma and recovery.<sup>38,39</sup> The patient's condition should be optimized with fluid resuscitation, aggressive pulmonary care, and antibiotics. In many cases, it is helpful to have a preoperative ultrasound evaluation or CT scan (Fig. 28-5). This will help make the decision to proceed with thoracoscopy by determining the amount of loculated fluid and inflammatory peel and to look for evidence of septations.

Although it is unusual to have significant blood loss during the procedure, the patient should undergo blood typing and crossmatching for a unit of blood as a precaution. Many of these patients are anemic, and preoperative transfusion may be necessary to help with preoperative stabilization.

The procedure is performed using general anesthesia. Single-lung isolation with either a double-lumen endotracheal tube or main-stem intubation of the

**Figure 28-5.** **A**, This 10-year-old was found to have a right parapneumonic effusion on the chest radiograph. **B**, CT revealed fluid (arrow) loculated in the right base. However, septations were also identified and the patient required thoracoscopic debridement and decortication. **C**, Six weeks after the operation, the chest radiograph is completely clear. (From Arca MJ, Holcomb GW III: Thoracoscopic decortication and debridement for empyema. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 266-269.)

contralateral side is preferable but not mandatory. Single-lung isolation may help in preventing cross contamination of the airways during manipulation of the affected side. It also aids in maintaining an adequate working space by preventing inflation of the trapped lung as the peel is removed. However, CO<sub>2</sub> insufflation usually is adequate to maintain lung collapse until attempts are made to actively re-expand the lung with positive pressure. The patient's respiratory status should not be compromised further, and excessive time should not be wasted in trying to get single-lung isolation.

The procedure is best performed with the patient in a lateral decubitus position. This allows the greatest access to the entire pleural cavity. The patient is supported on a bean bag or with rolls. As with all procedures performed in a lateral decubitus position, it is important to place an axillary roll and sufficient padding at all pressure points. Tape or a strap can be used to enhance this support. Patients with severe pulmonary disease may not tolerate having their good lung compromised by being in a dependent position. In these cases, a modified supine position can be used with the affected side elevated 25 to 30 degrees.

In this operation, the surgeon and assistant are positioned opposite each other. This facilitates the procedure as the entire pleural cavity needs to be explored. The scrub nurse may be positioned toward the patient's feet on whichever side is convenient. As previously mentioned, monitors should be placed on both sides, at approximately the level of the shoulders. Port placement can be somewhat variable depending on the size of the patient and the area of the chest cavity most involved. In general, the operation can be performed with just two ports. These are placed in the anterior and posterior axillary lines at the fifth or sixth interspace. If necessary, a third cannula can be inserted as needed to reach an area not readily accessible by the other two or if lung retraction is necessary. If the child is large enough, one of the ports should be 10 mm to facilitate removal of the infected peel. However, it is important to remember that the larger

the port size, the more limited may be the range of motion of the instrument at that site because of the thoracic cage. The primary goal of the operation is to remove as much of the infected fluid and fibrous peel as possible, break down any septa, allow for re-expansion of the lung, and provide adequate drainage. All of this should be accomplished in an efficient manner without taking excessive time.

Mobilization of the fibrous peel can begin in a systematic manner under direct vision. A blunt grasper or ring forceps is used to grasp some of the peel, and a sweeping motion is used to strip as much as possible off the lung surface or chest wall (Fig. 28-6). The more fibrous the peel, the easier it is to remove it. This inflammatory tissue can almost be removed in strips. If the peel is less fibrous, much of it may be able to be broken up and removed with the suction device alone.

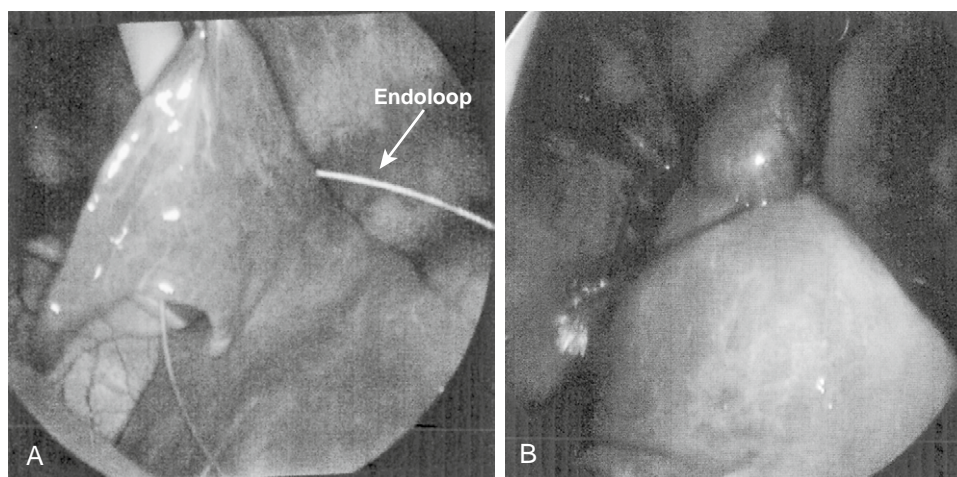

The surgeon should proceed in a clockwise fashion to ensure that all areas are addressed. When an area becomes difficult to visualize, the telescope and grasper can be exchanged, usually giving a better view and exposure to the area. If the surgeon is working through the smaller port and the peel cannot be easily exteriorized through the port, it can simply be mobilized, left in the pleural cavity, and then removed through the larger port when convenient.

The monitors may also need to be repositioned to try and keep the surgeon in line with the camera and the area of focus. Once the majority of the peel is removed and all loculations broken down, the chest cavity is irrigated with copious amounts of saline with or without antibiotics.

The goal of the operation is to remove the majority of infected fluid and tissue, lyse all loculations, free and re-expand the trapped lung, and establish adequate drainage. It is not necessary to remove every piece of the peel. The operative time should be kept to a minimum to avoid a prolonged anesthetic. If adequate drainage and lung re-expansion is achieved, then the residual infected peel will be re-absorbed as long as the patient's clinical picture improves. This procedure

**Figure 28-6.** The typical appearance of the inflammatory peel in a patient with empyema is seen. **A**, Note the thick fibrinous exudate hanging from the parietal pleura. **B**, Ring forceps have been introduced through a 10-mm incision to allow grasping of the purulent exudate. Note the collapsed lung at the bottom of the photograph. (From Arca MJ, Holcomb GW III: Thoracoscopic decortication and debridement for empyema. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 266-269.)

**Figure 28-7.** A, An endoloop is being applied to a tongue of lung tissue for lung biopsy in a small child. B, A second endoloop is being snared down to provide an air- and water-tight seal.

should not take more than 60 minutes and, in most cases, requires less time.

After irrigation, the ports are removed. A single chest tube is placed through the posterior port site and positioned posteriorly so it lies in a dependent position. Two drainage tubes are rarely needed. The small incisions are closed in layers with absorbable suture. If the patient is stable, it is best to extubate at the end of the procedure. The limited surgical trauma allows aggressive postoperative physiotherapy.

## LUNG BIOPSY

Lung biopsy is one of the most common thoracoscopic procedures, and it will be described here to illustrate basic techniques. The side for the biopsy is chosen based on the chest radiograph and CT findings. With the patient under general anesthesia, single-lung ventilation is obtained as previously described. The patient is then placed in a lateral decubitus position and prepped and draped. Low flow (1 L/min), low pressure (4 mm Hg) CO<sub>2</sub> insufflation is used to collapse the lung, allowing for better visualization. In general, three cannulas are sufficient and the ports are placed as previously described. The first port is inserted in the midaxillary line in the fifth or sixth intercostal space. This site is chosen because it allows good access to the entire pleural cavity for the initial survey and because this insertion site is unlikely to cause injury to the lung, diaphragm, or other structures. After the initial survey, the other two ports are introduced. In small children, 3- or 5-mm ports can be used. In children 10 kg or larger, a single 12-mm cannula is introduced so that the stapler may be used. If a biopsy specimen is being taken from the ventral surface of the lung, the telescope should be placed through the midaxillary cannula, the grasper in the anterior port, and the stapler in the inferior and posterior port. For biopsies on the posterior surface of the lung, the positions of the scope and grasper are reversed. In smaller patients whose chest cavity cannot accommodate the stapler, endoloops are used to snare and ligate a small area of

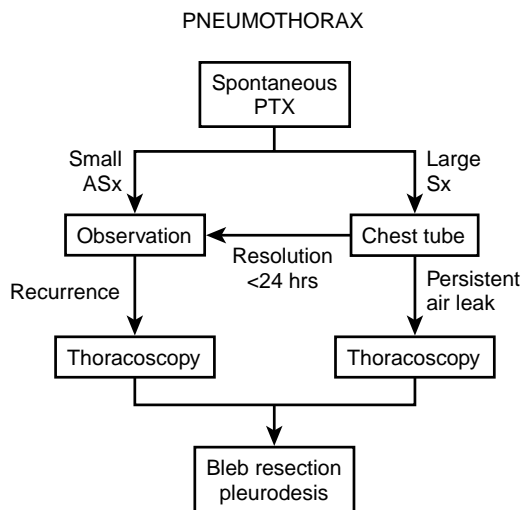

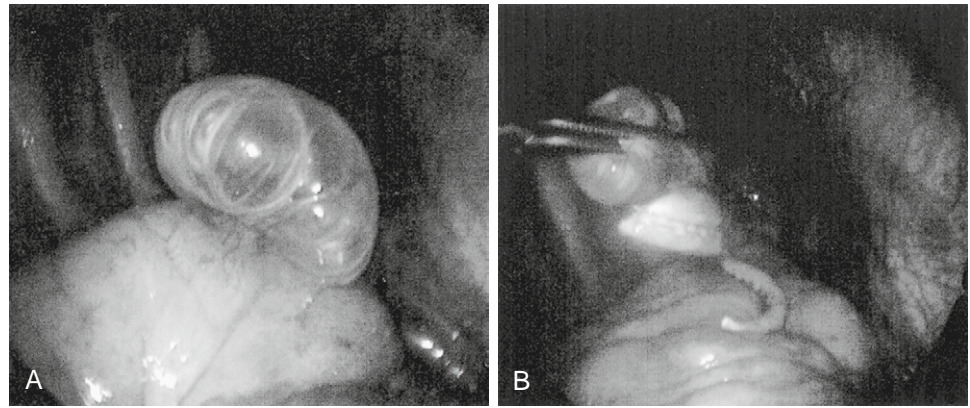

lung. Two consecutive loops are placed at the base of the specimen and the tissue is sharply excised distal to the ligatures (Fig. 28-7). This provides a hemostatic and air-tight seal equivalent to that obtained with the stapler.<sup>40</sup> Specimens of 2 to 3 cm can be obtained in this manner and are more than adequate for diagnosis. Biopsy samples can easily be obtained from all five lobes using this technique.

For metastatic lesions, port placement is altered depending on the site of the lesion. Although the majority of nodules are peripheral, lesions less than 1 cm in diameter or deep in the lung parenchyma may not be readily visible on the pleural surface. In these cases, preoperative CT-guided localization as previously described should be performed (see Fig. 28-2). At the time of surgery with the lung collapsed, the marked area can easily be identified. If the lesion itself is not visible, then the area underlying the blood patch can be wedged out. A frozen section should be performed to ensure the lesion is included with the specimen. Ongoing improvements in endoscopic ultrasound probes should eventually become the preferred technique for localization.

Resection of bullae or infectious cavitory lesions can be accomplished using a similar technique (Fig. 28-8). The minimal morbidity associated with thoracoscopy has shifted the algorithm for treatment, and earlier surgical intervention is often indicated (Fig. 28-9). In the case of bullous disease presenting as a spontaneous pneumothorax, it is usually advisable to combine excision with a limited pleurodesis or pleurectomy. This can easily be accomplished by abrading the parietal pleura (usually the apex) with an endoscopic peanut or a small sponge placed through one of the port sites. In recurrent or severe cases, a formal pleurectomy may be needed. Some surgeons prefer the use of a chemical or talc pleurodesis, and these agents can be used as well. However, only in the case of malignant effusions is chemical pleurodesis usually needed.

Any potentially malignant or infectious lesion that will not fit through the inner channel of the port should be placed in an endoscopic specimen bag to prevent possible seeding.<sup>41</sup> Once the intrathoracic

**Figure 28-8.** A, An apical bleb is seen in a patient with a spontaneous pneumothorax. B, The stapler has been used to resect the bleb.

**Figure 28-9.** Algorithm for the treatment of spontaneous pneumothorax (PTX) in children. Sx, symptomatic; ASx, asymptomatic.

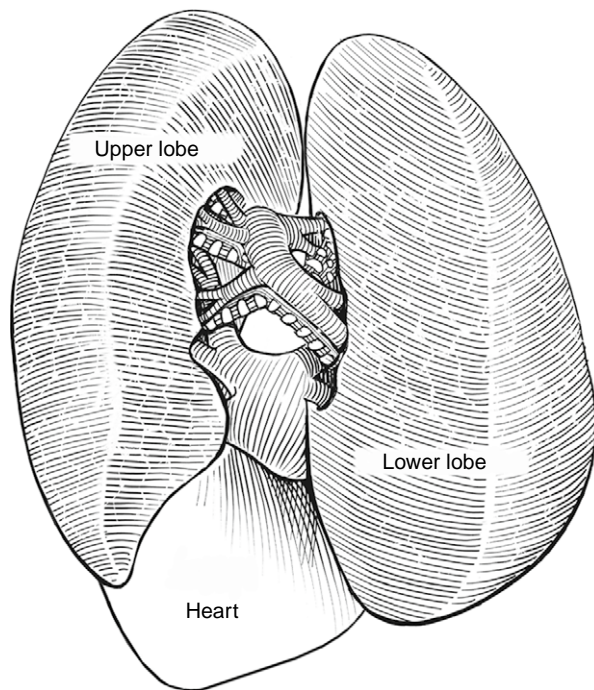

procedure has been completed, a small chest tube is introduced through one of the port sites and the collapsed lung is ventilated. In most cases, when there is no concern over adequate hemostasis or malignant effusion, the chest tube can be removed before extubation in the operating room if there is no evidence of an air leak.<sup>42</sup> This avoids the considerable discomfort associated with the chest tube in the postoperative period. A chest radiograph is obtained in the recovery room. If the lung is fully expanded, no further follow-up films are needed.

## THORACOSCOPIC LOBECTOMY

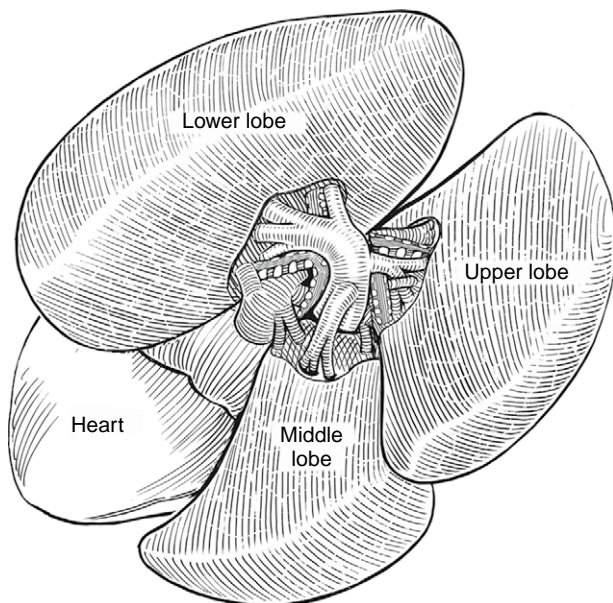

Initial experience with minimally invasive lobectomy required a video-assisted approach. This utilized two to three cannulas and standard laparoscopic instruments with a mini-thoracotomy through which standard thoracic instruments and staplers could be more easily passed.<sup>14</sup> These operations were technically demanding and often arduous but did spare the patient the morbidity of a formal thoracotomy. The

mini-thoracotomy was placed in the midaxillary line and used a muscle-sparing technique. With improvement in endoscopic staplers as well as energy sources that can seal both pulmonary vessels and lung parenchyma, the need to employ a mini-thoracotomy has been eliminated. These procedures can now be done completely thoracoscopically through 3-, 5-, 10-, and 12-mm ports in a safe and efficacious manner.<sup>15-17</sup>

Sealing devices such as the Ligasure allow the surgeon to seal the main pulmonary vessels in smaller patients without the need for suture ligation, clips, or staples. It also seals lung tissue, preventing both bleeding and air leak. In larger patients, the articulating stapler can be used to complete the fissure as well as ligate and divide the main pulmonary vessels and bronchi. These technical advances have enabled the surgeon to accomplish a lobectomy completely in an endoscopic manner. However, the surgeon's view is limited to a two-dimensional plane. Moreover, it is difficult to manipulate the lobe to look at both the anterior and posterior aspects in an attempt to gain a three-dimensional perspective. Therefore, it is critical that the surgeon have a good understanding of the anatomic spatial relationships between the vessels, lung tissue, and bronchus because these structures may not be visible and cannot be palpated (Figs. 28-10 and 28-11). The operation is performed with the patient in a lateral decubitus position, and the surgeon works from anterior to posterior. In general, the pulmonary artery branches are taken before the vein to minimize lung congestion, which can make the lobe even more difficult to manipulate (Fig. 28-12). Lower lobectomies are generally easier than upper resections because dissection can proceed along the major fissure. Any vessel or bronchus crossing it is considered an end vessel and can be ligated and divided. Upper lobectomies are much more difficult because dissection must proceed along the main pulmonary artery, sacrificing each segmental branch to the upper lobe as it comes off and taking care not to injure the main trunk. Once the lobectomy is completed, the lower port site is widened slightly and the lung is removed in a piecemeal fashion, if necessary. A chest tube is left overnight but can usually be removed on the first postoperative day.

**Figure 28-10.** The anatomy seen by the surgeon when the contents of the fissure between the left upper and lower lobes are exposed. The arteries are visualized first within the fissure, and the bronchial structures are behind the arteries. The pulmonary veins exit from the inferior portion of these lobes and drain into the heart. (From Rothenberg SS: Thoracoscopic lobectomy. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp. 253-260.)

**Figure 28-11.** The anatomy as seen by the surgeon when dissecting in the major and minor fissures of the right lung. The arteries are the first structures seen in the fissure, and the bronchial structures are behind the arteries. The pulmonary veins are inferior to the arteries and bronchial structures and drain into the heart. (From Rothenberg SS: Thoracoscopic lobectomy. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp. 253-260.)

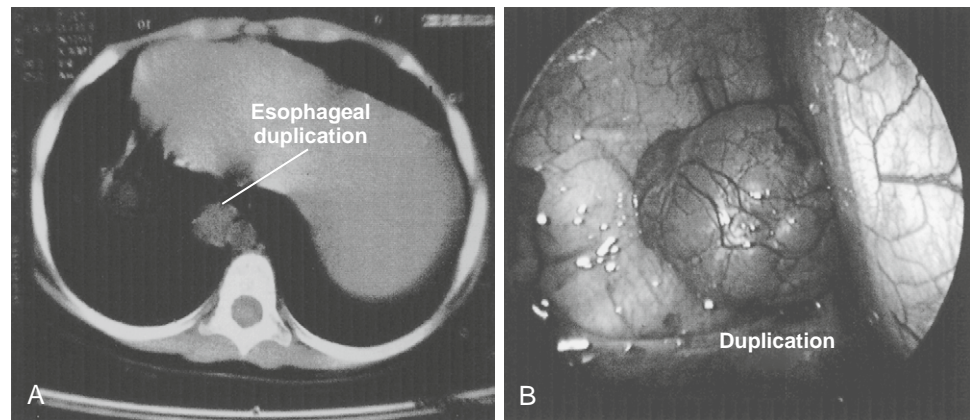

**Figure 28-12.** Isolation of the pulmonary artery as it transverses the major fissure during excision of a right lower lobe congenital pulmonary airway malformation is seen.

## POSTERIOR MEDIASTINAL AND ESOPHAGAL LESIONS

In dealing with extrapulmonary lesions such as mediastinal masses or esophageal pathologic processes, the patient should be positioned to allow gravity to retract the lung. This usually is accomplished by placing the patient in a modified supine or prone position as already described. In thinking about port placement, the surgeon should put the telescope in a position that allows the best visualization of the area to be addressed. The working ports are then positioned so that the surgeon is working in line with the camera. The cannulas should not be placed too close together because the instruments and telescope will end up “dueling,” making the dissection much more difficult. If possible, the telescope should be situated superior to the working ports to avoid this problem. A 30- to 45-degree scope allows the surgeon to look down on the instruments, much as in open surgery, and is extremely helpful when the working space is limited.

When working in the posterior mediastinum or on the esophagus, it is useful to have a flexible gastroscop, bougie, or nasogastric tube in the esophagus during the dissection. This helps to identify the esophagus by illumination or by palpation of the intraesophageal stent with the instruments. It may also be useful in identifying any iatrogenic injuries to the esophagus. This is especially true in performing a myotomy for achalasia. Having the esophagoscope in place during the myotomy not only aids in identifying the esophagus and checking for mucosal perforations but also with internal visualization, which can help to determine whether the myotomy has been extended far enough distally. This is evident by the relaxation of the lower esophageal sphincter as seen intraluminally. The myotomy can be performed using a number of different instruments, but most surgeons find a hook cautery or sharp dissection work extremely well. Care must be taken not to cause thermal injury to the mucosal lining when using the hook or other energy

**Figure 28-13.** A foregut duplication cyst is seen on a CT scan (A) and at thoracoscopy (B).

devices. The main question surrounding thoracoscopic esophagomyotomy is whether it is appropriate to perform the myotomy without the addition of a partial fundoplication to prevent postoperative gastroesophageal reflux. Most authors now believe that there is a significant risk of severe gastroesophageal reflux after myotomy and therefore recommend performing a partial wrap with the myotomy. This is best achieved using a laparoscopic approach.

The same exposure can be used to approach the esophageal hiatus in cases of hiatal or paraesophageal hernias. This is especially useful in patients who have undergone a previous abdominal fundoplication and whose wrap is intact but has herniated into the mediastinum. This technique allows the surgeon to approach the hiatus without having to go through a previously operated field and avoids the need of taking down the wrap to get adequate exposure. Both the right and left crus can be exposed from the left chest, and an excellent hiatal repair can be achieved.

Other esophageal procedures that have been successfully completed and reported include resection of duplications, diverticula, and esophageal wall tumors. Foregut duplications are relatively common entities that are easily approached thoracoscopically (Fig. 28-13). Once identified, the lesion is circumferentially freed from the overlying parietal pleura. This can be done either with sharp dissection because the plane is generally avascular or with the use of various energy sources. There is generally a well-defined stalk at the base of the cyst, although most do not have a luminal connection and can simply be dissected off the muscular wall of the esophagus without breaching the mucosal lining. If there is a connection, this can be sutured. In larger patients, an endoscopic stapler can be used to divide and seal the tract. Even if there is not a mucosal connection, there will be a defect in the muscular wall of the esophagus because of the common wall. This should be closed primarily to prevent later development of a diverticulum.

Bronchogenic cysts are approached in much the same fashion with dissection of the cyst down to its common wall with either the membranous trachea or bronchus. However, in these cases, the common wall

often cannot be separated without causing injury or perforation of the membranous portion of the trachea. Therefore, it is usually better to leave the small common portion on the back wall of the cyst intact and either excise or ablate the retained mucosal lining.

In the last few years, successful thoracoscopic repair of esophageal atresia and tracheoesophageal fistula has become commonplace.<sup>43-45</sup> A multi-institutional review of 106 patients suggested that the procedure is equivalent, if not better, than the standard open technique.<sup>31</sup> These procedures are performed with the infant in a modified prone position with the right side slightly elevated. A three-port technique with the telescope and camera in the posterior axillary line and the working ports in the midaxillary line allows excellent exposure. In general, CO<sub>2</sub> insufflation alone is adequate to cause collapse of the right lung and time should not be wasted trying to obtain single-lung isolation. The operative technique follows the same course as in open surgery with a few minor differences. The first is cauterization and division of the azygos vein, which provides a good landmark for the location of the fistula. The lower esophageal segment is isolated and dissected proximally to its insertion into the membranous trachea (Fig. 28-14). This is actually seen much better thoracoscopically than via a thoracotomy because the telescope is at right angles to the fistula and the view is magnified. A 5-mm surgical clip or suture can be used to ligate the fistula at its insertion into the trachea. The upper esophageal pouch is then identified by having the anesthesiologist provide downward pressure on the oroesophageal tube. The upper pouch is mobilized well up into the thoracic inlet. The distal tip of the upper pouch is resected, and an end-to-end anastomosis is performed. The posterior wall is approximated first with a series of interrupted simple sutures with the knots lying intraluminal. This is done with 4-0 or 5-0 PDS (Ethicon, Inc., Somerville, NJ) suture. Once the back row is secure, a small nasogastric tube is passed into the lower segment (Fig. 28-15). Then, the anterior wall anastomosis is completed. A chest drain is inserted through the lowest cannula site to a point adjacent to the anastomosis. A contrast study is obtained on day 4 to rule out a leak, and oral feedings are then started.

**Figure 28-14.** **A**, The distal esophagus is being mobilized near its insertion into the membranous fistula. **B**, The angled telescope is rotated to visualize the back side of the tracheoesophageal fistula. The distended proximal esophagus also is seen (*arrow*).

**Figure 28-15.** **A**, The posterior row of the esophageal anastomosis has been accomplished, and a small feeding catheter (*arrow*) is advanced through the anastomosis into the stomach. **B**, The completed anastomosis is seen on the right.

## ANTERIOR MEDIASTINAL PROCEDURES

The entire anterior mediastinum can be well visualized thoracoscopically and provides excellent access to anterior mediastinal, paratracheal, and hilar adenopathy. This is an excellent approach for node biopsy and can avoid a more invasive anterior mini-thoracotomy, Chamberlain procedure, or a more limited and dangerous mediastinoscopy, which provides far less visualization and access. These biopsy samples can usually be performed with three 3- or 5-mm ports. The patient is placed in a modified supine position, and the ports are situated between the third and fifth interspaces and between the anterior and midaxillary lines. The mass can usually be easily visualized, and a resection or biopsy can be obtained without difficulty (Fig. 28-16). Care should be taken in all anterior mediastinal procedures to avoid injury to the phrenic nerve, which can be easily seen. Teratomas and mediastinal thyroid tumors have also been excised using this approach with excellent results. Occasionally, a mini-thoracotomy is necessary to remove the specimen.

Thymectomy for myasthenia gravis is perfectly suited to a thoracoscopic approach.<sup>20</sup> This can be approached from either the right or left chest depending on surgeon preference. The ports are placed in a similar position as for other anterior mediastinal masses. The ipsilateral inferior horn is dissected first, taking care to avoid the phrenic nerve. Dissection is carried up to the isthmus, and then the upper pole is mobilized. There

is usually a posterior thymic vessel draining into the innominate vein. Once this is sealed and divided, the contralateral horns are easily retracted to the surgeon's side and can be fully mobilized under direct vision. The contralateral pleura should not be breached. The specimens can be removed by slightly enlarging one of the cannula sites, usually in the midaxillary line, which results in a very cosmetic incision.

## PATENT DUCTUS ARTERIOSUS CLOSURE

Closure of a persistent patent ductus arteriosus has been routinely performed through a standard posterolateral thoracotomy incision with either suture or clip ligation. Over the past decade, an increasing experience with intravascular occlusive devices such as coils and plugs developed, but this technique is often limited by the size of the patient and the diameter of the ductus.<sup>46</sup> Thoracoscopic closure offers an alternative approach and affords many of the same benefits as seen in other thoracoscopic procedures.

The procedure is performed with the patient in a modified prone position with the left side elevated approximately 30 degrees. Two 3-mm ports and one 5-mm port are used to perform the operation. A right main-stem intubation is obtained, and the collapsed left lung is retracted anteriorly by gravity, exposing the ductus. Starting in the middle of the aorta, the pleura overlying the ductus is dissected and retracted

**Figure 28-16.** **A**, In this patient the chest radiograph reveals a left mediastinal mass (*arrow*). **B**, On the chest CT scan, the vascular structures are seen to be medial and inferior to the mass (*arrow*). **C**, A silk suture has been placed in a figure-of-eight fashion through the mass to help manipulate the specimen without traumatizing it. **D**, The biopsy site is being outlined with a Maryland dissecting instrument connected to cautery. Scissors were used to excise a piece of the mass for the biopsy. (From Little DC, Holcomb GW III: Thoracoscopic biopsy of a mediastinal mass. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 275-278.)

medially. This exposes the ductus and pulls the vagus nerve out of the field of dissection. The endoscope allows excellent visualization of the ductus and the recurrent laryngeal nerve, which should help prevent injury to this structure. A 5-mm endoscopic clip can then be safely applied to the ductus, thereby occluding flow (Fig. 28-17). In some cases, it is necessary to use a larger clip or perform suture ligation. In these cases, the 5-mm port is removed and a standard hemoclip can be placed through an enlarged port incision. To date, excellent results have been obtained with this

technique with minimal morbidity and a significant decrease in recovery and hospitalization.

## SYMPATHECTOMY

Thoracic sympathectomy for hyperhidrosis is an accepted technique in patients who have debilitating sweating in their upper extremities. The ability to perform the procedure thoracoscopically has removed the majority of the morbidity associated with the

**Figure 28-17.** **A**, A patent ductus arteriosus (PDA) (*arrow*) is being isolated. **B**, The PDA has been occluded with two 5-mm endoscopic clips (*arrow*).

procedure.<sup>47</sup> Generally, bilateral sympathectomies are performed at the same operative session. These can be done either with the patient in a lateral decubitus position with ports placed in the axilla or with the patient supine and in relatively steep reverse Trendelenburg position.

The first option gives slightly better exposure but requires repositioning the patient to move to the other side. The supine position allows both sides to be accomplished without moving the patient.

CO<sub>2</sub> insufflation is usually sufficient to create lung collapse to expose the upper thoracic sympathetic chain. The procedure consists of interruption of the upper sympathetic chain, below the stellate ganglion, usually from T2 to T4. This can be accomplished by exposing the sympathetic chain and resecting a small segment or simply cauterizing the second and third thoracic ganglion. This can be performed using either two or three ports. A single-port technique utilizing a hook cautery has also been used. Care must be taken to prevent injury to the stellate ganglion to avoid Horner syndrome.

## ANTERIOR SPINAL PROCEDURES

The treatment for severe scoliosis and kyphosis in children has involved extensive dissection with significant associated pain and morbidity. These procedures are usually a joint endeavor between the pediatric surgeon and the pediatric orthopedist and consist of an anterior discectomy and release, followed by posterior correction and fixation with rods. Many of these children already have severe pulmonary compromise and these procedures can be associated with significant morbidity and even death. Over the past 10 years, the anterior part of the operation has been performed thoracoscopically.<sup>48</sup> The patient has thus avoided a painful thoracotomy.

The patient is placed in a modified lateral decubitus position tilted slightly prone to aid in keeping the lung out of the visual field. The anterior release can usually be performed through four or five small incisions ranging from 5 to 10 mm (Fig. 28-18). The position of the incisions depends on the number and level of the discs to be removed. In general, the initial port is placed near the apex of the spinal deformity in the midaxillary line. The disc spaces can then be counted and the other ports positioned appropriately. Often,

two discs can be extracted using one incision. All ports are kept in the midaxillary line so that the scope and instruments can be interchanged as the spine surgeon moves up and down along the spine.

The first step is exposure of the disc spaces by incising and then clearing the overlying pleura at each level. The segmental vessels can either be preserved or ligated and divided depending on the preference of the spine surgeon. The spine surgeon then performs the discectomy using modified spine instrumentation and packs the disc space with tricortical allograft or other bone graft to enhance fusion. The disc spaces from T2 to T12 can be extracted thoracoscopically. The diaphragm can be mobilized to give access to the first and second lumbar vertebrae, if needed.

A single chest tube is inserted through one of the lower port sites, and the other sites are closed. The operative port time for this approach is now shorter than the open operation. The postoperative recovery has markedly improved, and the time needed for chest tube drainage has significantly diminished. Some centers have even started placing anterior instrumentation using a thoracoscopic-assisted approach, but the experience is very limited. Other spinal procedures, including vertebral body biopsies and hemi-vertebrectomy can also be accomplished.

## POSTOPERATIVE CARE

The postoperative care in the majority of patients is straightforward. After biopsy or limited resection, most patients can be admitted directly to the surgical floor with limited monitoring (i.e., a pulse oximeter for 6 to 12 hours). These patients are generally 23-hour observation candidates, and a number are actually ready for discharge the same evening. If a chest tube is left, it can usually be removed on the first postoperative day. Pain management has not been a significant problem. Local anesthetic is injected at each port site before insertion of the port and then one or two doses of intravenous narcotic are given in the immediate postoperative period. By that evening or the following morning, most patients are comfortable on oral analgesics. It is very important, especially in the patients with compromised lung function, to start early and aggressive pulmonary toilet. The significant decrease in postoperative pain associated with the thoracoscopic approach results in much less splinting

**Figure 28-18.** The incisions for a thoracoscopic anterior release, discectomy, and fusion are seen. In general, four incisions are needed for release, discectomy, and fusion at five disc levels. **A**, The instruments are rotated among the ports so that the working port is at a 90-degree angle to the disc space. **B**, Operative photograph shows the incisions. The chest tube has been exteriorized through the most caudal incision.

and allows for more effective deep breathing. This has resulted in a decrease in postoperative pneumonias and other pulmonary complications.

Although a thoracoscopic approach may not always result in a significant decrease in hospitalization, it usually results in a significant decrease in the overall

morbidity for the patient. The thoracoscopic approach has clearly shown significant benefits over standard open thoracotomy in many cases. With continued improvement and miniaturization of the equipment, the procedures we can perform and the advantages to the patient should continue to grow.

# GASTROESOPHAGEAL REFLUX

Daniel J. Ostlie, MD • George W. Holcomb III, MD, MBA

**G**astroesophageal reflux (GER) is a disease that is commonly encountered in infants and children. In general, the episodes of GER that are seen in infants and children are not clinically significant and will have no identifiable etiology. In addition, 60% to 65% of children with GER will undergo spontaneous symptom resolution by 2 years of life, regardless of any medical treatment.<sup>1</sup> However, some children will have pathologic gastroesophageal reflux disease (GERD) that will result in either failure to grow appropriately, respiratory complications, or apparent life-threatening events (ALTE). This is the population that will require medical and/or surgical intervention.

## HISTORY

The effects of GERD in pediatric patients have been reported for over a century.<sup>2-6</sup> Before the introduction of proton pump inhibitors (PPIs) in the 1990s, the medical management of GER in children and adults was relatively ineffective and based on antacids and histamine antagonists. Because of this limited spectrum of medical management in the 1950s and 1960s, several surgeons developed operative approaches for GER management. Lortat-Jacob, Hill, Belsey, Nissen Rosetti, and Thal all contributed greatly to the surgical management of GERD.<sup>7-13</sup>

These antireflux procedures were initially developed in adults and were effective in controlling GER. Subsequently, they were applied to infants and children with good success.<sup>7,14,15</sup> The overall management of GERD has progressed significantly over the past 2 decades with more effective PPIs and refinement in the surgical technique. Clearly, the most important surgical advance occurred in 1991 when Dallemagne reported his experience with laparoscopic fundoplication.<sup>16</sup> An expected evolutionary cascade led to the use of laparoscopy in children by Georgeson and Lobe.<sup>17,18</sup> Because of these pioneers, and the many researchers that followed, we now know that laparoscopic fundoplication is safe and effective in treating GERD with few complications and excellent control of symptoms in infants and children.

## PATHOPHYSIOLOGY

GERD is defined as the pathologic effects of involuntary passage of gastric contents into the esophagus. Ultimately, the pathophysiologic alteration that is responsible for the development of GERD is incompetence of the antireflux barriers that exist between the lower esophagus and the stomach. The result of this incompetence is the presence of gastric refluxate (acid and pepsin) in direct contact with the esophageal mucosa. The pathologic events that occur because of GERD are due to one or multiple failures of the normal physiologic barriers that exist to prevent gastric contents from entering the esophagus, or to limit injury to the esophagus as a result of gastric refluxate, or to clear the refluxate that enters the esophagus (Table 29-1).

In adults, the consequence of this refluxate in the esophagus is primarily limited to erosive esophagitis, esophageal stricture, and Barrett's esophagitis. In children, its detrimental effects are much broader. Also, associated physiologic, anatomic, and developmental abnormalities co-exist in children that make GERD and its consequences much more complex. Many children with GERD have significant neurologic impairment. These children can have increased

**Table 29-1** Mechanisms That Either Prevent Gastroesophageal Reflux, Limit the Esophageal Injury, or Clear the Refluxate

Prevent Gastric Reflux	Limit Esophageal Injury	Clear Esophageal Refluxate
Lower esophageal sphincter	Saliva	Esophageal peristalsis
Angle of His	Amount of gastric acid	Saliva
Length of intra-abdominal esophagus	Pepsin	Gravity
Elevated intra-abdominal pressure	Trypsin	
	Bile acids	

**Figure 29-1.** This intraoperative photograph depicts a de-novo hiatal hernia in a 13-month-old infant. Note the enlarged hiatus. A portion of the upper stomach has herniated into the chest.

spasticity with retching and related increased abdominal pressures. Poor swallowing mechanisms lead to gagging and choking, which add to this intermittent increased abdominal pressure. Sometimes, a hiatal hernia develops (Fig. 29-1), further predisposing to GERD. Congenital anomalies such as esophageal atresia with or without tracheoesophageal fistula (EA/TEF), duodenal and proximal small bowel atresias, congenital diaphragmatic hernia (CDH), and gastroschisis/omphalocele all predispose to the development of GERD. The consequences of GERD in children lead to the same complications seen in adults (erosive esophagitis, stricture, and Barrett's esophagitis) but also include pulmonary effects (reactive airway disease and pneumonia), potential malnutrition secondary to the inability to maintain adequate caloric intake, and apneic episodes leading to ALTE spells.

## Barriers against GERD

The most important factor for preventing reflux of gastric contents into the esophagus is the lower esophageal sphincter (LES). Embryologically, the LES arises from the inner circular muscle layer of the esophagus, which is asymmetrically thickened in the distal esophagus. This thickened muscle layer creates a high pressure zone that can be measured manometrically. In addition, this muscular thickening extends onto the stomach more prominently on the greater than lesser curvature.<sup>19</sup> The phrenoesophageal membrane, arising from the septum transversum of the diaphragm and the collar of Helvetius, holds the LES in position. The result is an LES that lies partially in the chest and partially in the abdomen. This positioning is important for the normal barrier function against GER. Esophageal manometry can identify this transition (which is known as the respiratory inversion point) from the thoracic to the abdominal esophagus.

The LES is an imperfect valve that creates a pressure gradient in the distal esophagus. The ability

to prevent GER is directly proportional to the LES pressure and its length, provided that LES relaxation is normal. In an adult study, LES pressures greater than 30 mm Hg prevented GER, as documented by 24-hour pH study, whereas pressures between 0 and 5 mm Hg correlated with abnormal pH studies in more than 80% of patients.<sup>20</sup> Also, GER is statistically significantly more likely to develop in adults if the LES pressure falls below 6 mm Hg at the respiratory inversion point or if the overall LES length is 2 cm or less.<sup>21</sup> As noted previously, the LES is relatively fixed across the esophageal hiatus by its surrounding attachments. Malposition of the LES, which can occur with a hiatal hernia or abnormal development, results in loss of the protective function of the LES, resulting in GER. Finally, LES relaxation occurs with esophageal peristalsis initiated by the swallowing mechanism. This relaxation is normal and must occur. Inappropriate LES relaxations, referred to as transient LES relaxations, have been shown to occur sporadically, unassociated with the swallowing mechanism. Interestingly, when children with symptoms of GER were studied with pH and manometry simultaneously, reflux episodes rarely correlated with decreased LES pressures. Rather, the majority of reflux episodes occurred during transient LES relaxations, and no reflux episodes were identified during LES relaxation after swallowing with normal peristaltic sequence.<sup>22,23</sup> There continues to be growing support that these transient LES relaxations are the primary mechanism for GER.

In summary, although the barrier function of the LES is imperfect, it can be highly effective. Short LES length, abnormal smooth muscle function, increased frequency of transient LES relaxations, and LES location within the chest can contribute individually (or in combination) to LES failure and GER.

Another barrier to the development of symptomatic GER is the intra-abdominal length of the esophagus.<sup>24</sup> Although no absolute effective intra-abdominal esophageal length has been identified that prevents GER, correlation between several lengths and GER have been identified. In one report, an intra-abdominal length of 3 to 4.5 cm in adults with normal abdominal pressure provided LES competency 100% of the time.<sup>20</sup> A length of 3 cm was sufficient in preventing reflux in 64% of individuals, whereas less than 1 cm of intra-abdominal esophagus resulted in reflux in 81% of patients. It is believed that failure to mobilize adequate esophageal length for intra-abdominal positioning can lead to less than successful results or recurrent GER in adults. However, whether these data are applicable in infants and children is unclear.

A third barrier to reflux is the angle of His, which is the angle at which the esophagus enters the stomach. The usual orientation is that of an acute angle, which creates a flap valve at the gastroesophageal junction. Although the actual functional component of the angle of His is not well known, it has been shown to provide resistance to GER. Experimentally, when this angle is more obtuse, GER is more prone to develop. Conversely, accentuation of the angle inhibits GER.<sup>25</sup>

The ability of the angle of His to prevent GER may be diminished as a result of abnormal development or may be iatrogenic, as occurs after gastrostomy placement. When a normal angle of His is present, there is a convoluted fold of mucosa present at the gastroesophageal junction. This mucosa creates a rosette-like configuration that collapses on itself with increases in intragastric pressure or negative pressure in the thoracic esophagus, thus acting as an additional weak antireflux valve.<sup>26,27</sup>

Patients with increased abdominal pressure as a result of neurologically related retching, physiologic effects (ascites, peritoneal dialysis), or anatomic abnormalities (gastroschisis, omphalocele, CDH) are at increased risk for developing GERD owing to the effects of chronic pressure from the abdomen into the thorax.<sup>28-35</sup> Finally, certain congenital defects such as congenital short esophagus, congenital hiatal hernia, and EA/TEF predispose to GERD. In patients with EA/TEF, the esophagus has abnormal peristalsis and the LES is incompetent. It has been reported that up to 30% of these patients will require antireflux surgery after repair of their EA/TEF.<sup>36-38</sup> Regarding CDH, anatomic abnormalities of the esophageal hiatus and the esophagus predispose to GERD, with 15% to 20% of surviving patients undergoing an antireflux operation for GERD.<sup>33-35</sup>

Once the barrier to GER has been overcome (or failed), mechanisms for esophageal clearance become important in preventing damage associated with exposure of the esophageal mucosa to the gastric refluxate. The primary mechanism for esophageal clearance remains esophageal motility. However, gravity and saliva contribute to the ability of the esophagus to clear the refluxate.<sup>39,40</sup> There are three types of esophageal contractions: primary, secondary, and tertiary. Primary contraction waves are initiated with swallowing and are responsible for the clearance of refluxed contents in 80% to 90% of reflux episodes. Secondary waves occur when material is refluxed into the esophagus and clearance is required, especially when the reflux occurs during sleep.<sup>41,42</sup> Tertiary waves have nothing to do with esophageal clearance and are sporadic, nonpropagating contractions. When impaired esophageal motility is present as a result of either abnormal smooth muscle function, impaired vagal stimulation, or obstruction, refluxed gastric contents are not moved caudad into the stomach in a timely manner. This prolonged exposure can lead to esophageal mucosal injury and can potentiate the motility disturbance due to vagal and/or smooth muscle inflammation or injury. Saliva neutralizes refluxed material, and patients with GERD have been found to have decreased salivary function. It has also been shown that positional effects of GERD treatment may be related to gravity assisting in the clearance of esophageal refluxate.<sup>43-46</sup>

The final element for prevention of esophageal injury related to GERD is the ability to limit injury once refluxed contents have reached the esophagus. In addition to functioning as a neutralizing agent, saliva also aids in lubricating the esophageal contents, thus making it easier to clear any retained refluxate. Acid

**Table 29-2** Frequency of Symptoms in Patients with Gastroesophageal Reflux

Regurgitation/vomiting	81%
Pulmonary symptoms	41%
Dysphagia/pain	30%
Hemorrhage	7%

Adapted from Tovar JA, Olivares P, Diaz M, et al: Functional results of laparoscopic fundoplication in children. *J Pediatr Gastroenterol Nutr* 26:429-431, 1998.

exposure has been postulated to cause the most significant injury. When combined with pepsin, esophageal mucosal injury occurs.<sup>47,48</sup> The injury related to gastric acid is not strictly due to the low pH but also to the volume of acid that is refluxed. Some pediatric patients with documented GERD have been shown to have increased acid secretion.<sup>49,50</sup> To this end, the role of PPIs in controlling GERD in this population is very important because they have the dual effect of decreasing pH while simultaneously decreasing the acid volume.<sup>51-53</sup> Regarding substances that increase esophageal mucosal injury, bile salts, pepsin, and trypsin are the most important components in the refluxate that need to be neutralized. When combined with acid, bile salts are injurious to the esophageal mucosa. In addition, they increase the permeability of the esophageal mucosa to existing acid, thus further potentiating injury.<sup>54,55</sup> Pepsin and trypsin are both proteolytic enzymes that can injure the esophageal mucosa. Both of these enzymes are more toxic at lower pH levels and, hence, are more injurious in the presence of acid.<sup>56,57</sup>

## CLINICAL MANIFESTATIONS

The presentation of GERD in infants and children is variable and depends on the patient's age and overall medical condition. The surgeon must consider both this variability and the patient characteristics when evaluating a child with symptoms for possible GERD. Although the symptoms of GERD are variable for each patient, the actual frequency of symptoms seen in infants who have required surgical intervention for GERD has been reported (Table 29-2).<sup>58</sup>

When considering the symptoms associated with GERD, persistent regurgitation is the most common complaint reported by parents of children with GERD.<sup>59</sup> However, in infants, vomiting is often physiologic and can be "normal." This type of vomiting is termed *chalasia of infancy* and is seen early in life, usually during burping, after feeding, or when placed in the recumbent position.<sup>60</sup> Chalasia does not interfere with normal growth or development and rarely leads to other complications. It is a self-limited process with most infants transitioning to being asymptomatic by 2 years of age or near the time of initiating solid foods.<sup>1</sup> No treatment is necessary in patients who have chalasia, and no diagnostic evaluation should be pursued. However, when persistent regurgitation is the result of

GER, it can lead to complications, including significant malnutrition and growth failure due to insufficient caloric intake.

In infants, another presenting symptom is irritability due to pain. Painful esophagitis can be the result of the acid refluxate. Discomfort leads to crying despite consoling measures.<sup>61,62</sup> Occasionally, small volumes of feeds briefly assist in alleviating pain. However, this is generally not a lasting effect.<sup>24,25</sup> In contrast to infants, children with pathologic GER more often present with complaints of pain. As in adults, the pain is retrosternal in nature, often described as “heartburn.” Long-standing GER with esophagitis can lead to chronic inflammation or even ulcer formation with eventual scarring and stricture. Dysphagia develops as a result of a narrowed esophageal lumen, as well as possible esophageal dysmotility secondary to long-standing mucosal inflammation. Obstructive symptoms and pain are the two most common associated complaints when an esophageal stricture is present.<sup>63,64</sup>

Barrett’s esophagitis is a premalignant condition that is associated with prolonged GERD. It occurs when metaplasia develops in the esophageal squamous epithelium that is replaced with columnar epithelium. In adults, it is thought to be the result of chronic esophageal injury by gastric acid reflux.<sup>65-67</sup> Although uncommon in infants and children, when it does develop, serious complications often result. In addition to the increased risk for adenocarcinoma, approximately 50% of these patients will develop stricture and many patients will develop ulcers.<sup>68,69</sup> Aggressive GER management, along with vigilant long-term surveillance via yearly esophagogastrosocopy, must be pursued to minimize these often difficult and possibly fatal complications.

Respiratory symptoms are commonly seen in infants and children. Delineating the role of GER as an etiologic agent for ongoing respiratory complaints can be difficult because of the similarity of the symptoms that are seen with other pulmonary diseases. Chronic cough, wheezing, choking, apnea, or near sudden infant death syndrome (SIDS) can all be symptoms attributable to GER. Recurrent bronchitis or pneumonia can occur from aspiration of the refluxate.<sup>70</sup> Esophageal stimulation via acidification of the esophageal mucosa causes vagally mediated laryngospasm and bronchospasm, which clinically presents as apnea or choking or mistakenly as asthma.<sup>71,72</sup> Esophageal inflammation, as seen with esophagitis, likely enhances this mechanism.<sup>73,74</sup> The effects of GER on premature infants with respiratory problems have been studied.<sup>75</sup> Most of these infants were intubated for varying periods owing to respiratory distress syndrome or bronchopulmonary dysplasia. In the former group, GER was responsible for deteriorating pulmonary status requiring intubation. In the latter, deterioration of pulmonary status plus failure to thrive and anorexia led to the diagnosis of GER. All improved with correction of the GER.<sup>76</sup>

Although uncommon, hemorrhage can be a presenting symptom of GER. Esophagitis, gastritis, and ulcer formation can lead to hematochezia or melena in a small percentage of infants or children.<sup>58</sup>

## DIAGNOSTIC EVALUATION

As noted in the previous section, the clinical history is an invaluable asset when evaluating for the presence of GERD and determining the need for antireflux therapy. Once the concern for GER as the etiologic cause of the patient’s complaints has been raised, diagnostic evaluation should be initiated. Upper gastrointestinal radiography is the most frequent initial study employed. Evidence for reflux is sometimes seen on the examination. However, the absence of reflux is an extremely poor indicator of GER as a cause of the patient’s symptoms. The contrast study is most useful for delineating the anatomy of the esophagus and esophagogastric junction. It also evaluates esophageal clearance and assesses esophageal and gastric motility. The contrast study can identify the presence of esophageal strictures, webs, or distal obstructions, such as duodenal obstruction, antral web, or malrotation, as the cause of the reflux symptoms.

Twenty-four-hour pH monitoring is the gold standard for establishing the diagnosis of GER, especially in infants and children whose history is unclear. It provides the diagnosis of GER in cases in which the clinical history cannot be obtained or is confusing, such as a patient presenting with respiratory symptoms only. The study is performed by placing an electrode 2 to 3 cm proximal to the gastroesophageal junction and measuring the pH in the distal esophagus. Although initially developed in adults, its use in children is now accepted and invaluable.<sup>77,78</sup>

The accuracy of the pH examination is dependent on the cessation of all antireflux medication. PPIs should be withheld for 7 days, and histamine receptor blockers are stopped 48 hours before the study. A reflux episode is considered to have occurred if the esophageal pH is recorded as less than 4. Ideally, the examination should occur over an uninterrupted 24-hour period. The pH is continuously monitored via the esophageal electrode while the patient’s position (upright and supine) and activities (awake, asleep, eating) are simultaneously recorded. The final score is calculated based on the percent of total time that the pH was less than 4, the total number of reflux episodes, the number of episodes lasting longer than 5 minutes, and the longest reflux episode.<sup>79,80</sup> A normal range of values has been established that is easily reproducible and reliable.<sup>81</sup>

The 24-hour pH monitoring study is indicated in the following specific circumstances:

1. Infants who have respiratory symptoms (apnea, ALTE spells)
2. Infants who are irritable, intractably crying, and anorexic
3. Children who have reactive airway disease (asthma) or unexplained or recurrent pneumonia
4. Children who are unresponsive to medical measures and in whom the role of GER in their symptoms is uncertain

The study also should be done in those children who again become symptomatic after fundoplication. Conversely, the study generally is not useful or necessary

for infants with uncomplicated regurgitation, children with esophagitis already found by endoscopy and biopsy, and children with dysphagia or heartburn thought to be caused by GER.

Three patterns of reflux have been described in symptomatic infants, as determined by extended esophageal pH monitoring: continuous, discontinuous, and mixed.<sup>82</sup> Those infants with the discontinuous type rarely required a surgical antireflux operation, whereas approximately half of those with the other two types did. One should keep in mind that medical treatment at the time of this study was much less effective than in the late 1990s. Nonetheless, this study indicates that pH monitoring can be useful in sorting out infants with GER who may or may not require an antireflux procedure.<sup>81,83</sup> Incidentally, all of the infants in this study, including the “normal controls,” experienced reflux frequently in the first 2 hours after being given apple juice.

It has been assumed that the retrograde flow of acid/pepsin material from the stomach into the esophagus is the basic pathologic event of reflux disease. It is becoming clear that the situation is not this straightforward. Attempts to correlate symptoms (other than spitting up and vomiting) to pH-probe-detected reflux episodes have been particularly problematic. For example, in infants with spells of choking or colic, a close association between pH-probe-detected acid reflux and these symptoms cannot be routinely demonstrated. Some spells coincide with reflux episodes, but many do not. Similar questions can be raised when looking at pH-probe data on the relation between acid reflux episodes and apnea/bradycardia spells of premature infants or between wheezing, coughing, dental erosion, sleep disturbance, and all the other myriad symptoms attributed to reflux.

By using one “old” diagnostic technique and one “new” one, some of the disparities between pH-probe observations and “events” may be better understood. This is based on the recent observation that some reflux of acid into the lower esophagus occurs while the intraesophageal pH is still less than 4 due to a traditional acid-reflux episode. This is called “acid reflux” (ARR) and will be missed by using only pH-monitoring techniques.<sup>84</sup> ARR is most likely to occur in patients with severe esophagitis, postprandially, and in the recumbent posture. It is now thought to be a common cause of prolonged acid contact. Detecting ARR provides a better estimation of the incompetence of the antireflux barrier than does traditional pH-probe evaluations.

Two methods may be used to evaluate ARR. The first is scintigraphy, which directly measures radiolabeled liquid gastric contents flowing into the esophagus, independent of the pH of the refluxate or the esophageal lumen. The second is multichannel intraluminal impedance (MII), a method that recognizes the flow of gastric contents into the esophagus by detecting decreases in impedance from high (the esophagus) to low (the stomach) values across electrode pairs placed throughout the esophagus and in the stomach. MII also can distinguish liquid from gas refluxate.<sup>85-87</sup>

Recent studies using MII suggest that measuring acid reflux (pH study) may not be the best method of evaluating GERD.<sup>88-91</sup> These studies indicate that the pH probe does not simultaneously detect the majority of reflux events as defined by impedance monitoring, presumably because the re-reflux boluses are not acidic. When MII and pH monitoring are used simultaneously, there are significant reflux episodes that are not identified with pH monitoring alone because the episodes are actually non-acid reflux episodes with a pH greater than 4.<sup>89</sup> These non-acid reflux episodes are less common in untreated GERD patients than in normal patients. MII has shown that GERD patients more commonly have liquid-type reflux events, whereas non-GERD patients generally have more gas-type reflux events.<sup>90</sup> Additionally, MII data suggest that treatment with PPIs does not decrease the amount of reflux but rather converts the reflux to non-acid or weakly acidic in nature.<sup>91</sup>

Although essential in adults, esophageal manometry is infrequently utilized in the pediatric population. When employed, the study measures the motility of the esophagus and the pressure at the LES via a multiple-port pressure transducer placed in the esophagus and traversing the LES. The clinical data accumulated in adult patients have revealed several important points that are likely applicable to infants and children with GERD. First, it has been shown that pharyngeal swallowing and primary peristaltic contractions are responsible for the majority of the esophageal clearance of refluxed gastric contents, rather than by secondary and tertiary peristalsis as previously believed.<sup>92</sup> Additionally, through the use of a concomitant 24-hour pH study and esophageal manometry, it has been shown that there is a direct relationship between worsening esophagitis secondary to GERD and deterioration of esophageal motility. Manometric evaluation has been particularly useful in documenting abnormal distal esophageal motility in infants after repair of EA/TEF.<sup>93</sup> It is hoped that, as technology continues to provide more appropriately sized instruments for sophisticated manometric studies in infants and children, the usefulness and feasibility of such studies will increase our knowledge of the physiology and abnormalities associated with GERD in this population.

Endoscopic evaluation of the esophagus and stomach is occasionally needed in the diagnosis of GERD in infants and children. Hematemesis, dysphagia, or irritability in infants, or dysphagia with or without heartburn in children, should prompt esophagogastroscopy to determine if esophagitis is present. Other complications, such as ulcer formation, esophageal stricture, and Barrett’s esophagus, can also be diagnosed during the endoscopic examination. Mucosal biopsy should be performed to stage the severity of esophagitis or to histologically exclude dysplasia or malignancy in Barrett’s esophagus.<sup>94,95</sup>

The relationship between delayed gastric emptying (DGE) and GERD in infants and children has been extensively studied and continues to be one of the more controversial aspects of antireflux surgery. The evaluation for DGE is undertaken using

radionuclide scanning via a technetium-99-labeled meal. When documented preoperatively, DGE has not been shown to significantly improve when an emptying procedure is performed at the time of an antireflux procedure.<sup>96</sup> In fact, one study evaluating patients with DGE undergoing fundoplication showed significantly improved gastric emptying for both solids and liquids after fundoplication alone.<sup>97</sup> Neurologically impaired children with GERD have been shown to have DGE more often than neurologically normal children. Conflicting data regarding the benefit and complication rates for these patients undergoing emptying procedures at the time of their fundoplication have been reported as well.<sup>98</sup> Based on these data, it is not recommended that an emptying procedure be performed for a patient with DGE and GERD unless a second operative intervention would place the patient at significant morbidity or mortality.

At our institution, the evaluation for GERD includes an upper gastrointestinal contrast study and 24-hour pH monitoring for most patients suspected of having GERD. The main exceptions are the neurologically impaired patient in the intensive care unit who needs a gastrostomy for feeding and for whom the intensivists request a fundoplication to protect the airway from aspiration. Esophagogastroscope and esophageal manometry are employed only when circumstances suggest that the information they will provide will dictate changes in the operative management. An example of this situation is the patient with symptoms of GER but a normal pH study. When esophagitis or other complications of GERD are found after esophagogastroscope or manometry, surgical intervention is usually recommended. Preoperative gastric emptying studies are not performed on a routine basis, primarily owing to the improvement that has been seen and reported in gastric emptying after fundoplication.<sup>96,97</sup> If symptoms of DGE persist after antireflux surgery, gastric emptying studies can be performed with a subsequent emptying procedure, if necessary. However, all patients requiring a second fundoplication undergo an emptying study to be sure their recurrent symptoms are not exacerbated by DGE.

## TREATMENT

Once GERD has been diagnosed, the question becomes: should medical or surgical treatment be applied?<sup>15</sup> This decision needs to be individualized based on the patient's age, anatomic information, disease severity, and social environment (which will affect compliance with a treatment regimen). In the majority of cases, nonoperative treatment is the initial therapy of choice.

## Medical Management

### *Position and Feeding*

Nonoperative therapy for GERD in infants and children has been based on postural changes and dietary modification for many years. It is important to know

the caloric needs of the patient so that a reduction in feeding volume in an attempt to limit reflux does not result in caloric deprivation. Postural and dietary modifications alone will result in clinical improvement in the vast majority of infants with GERD.<sup>99,100</sup> In older children, dietary alterations should include a diet low in fat and the elimination of chocolate, coffee, tea, carbonated drinks, and spicy foods.

The seated semi-upright position (approximately 45 degrees) for an infant with reflux has been recommended since the 1950s. In the 1960s, Carré showed that 60% of children with GERD treated in this way improved by approximately 2 years of age and an additional 30% improved by age 4 years.<sup>1,101</sup>

Failure of postural therapy may be related to social problems, chronic infections, or impaired gastric clearance. In older patients, postural treatment is impractical because of the virtual impossibility of maintaining the desired semi-sitting posture for sleep. Close attention to the details of postural therapy by the family members is most important to its success.<sup>102</sup>

### *Pharmacologic Therapy*

If symptoms persist despite a well-monitored program of postural therapy and dietary modifications, pharmacologic measures should be added. Medical therapy includes the administration of one or more drugs that increase esophageal peristalsis, increase LES pressure, increase gastric emptying, or lessen gastric acid production.

### *Prokinetic Agents*

Historically, prokinetic agents have been utilized in an attempt to increase LES pressure, enhance esophageal peristalsis, and accelerate gastric emptying. The use of cisapride and, more recently, metoclopramide, has been questioned with regard to their safety.<sup>103-105</sup> Both randomized controlled trials and meta-analyses have shown no clinically relevant improvement in children receiving cisapride or metoclopramide.<sup>103,104,106,107</sup> Therefore, the current recommendation regarding prokinetic agents in the management of GERD is that there is no beneficial effect and their use is not advantageous.

### *Acid Alteration*

Measures to reduce gastric acidity should be given to patients with complicated reflux, especially with esophagitis.<sup>108</sup> Alterations in gastric acid may be accomplished by neutralization with antacids, by competition with histamine-2 (H<sub>2</sub>)-receptor antagonists, or by PPIs. Because of the superiority of PPIs in controlling acid production, H<sub>2</sub>-receptor antagonists or antacids are being utilized less frequently.

PPIs inhibit the final step of gastric acid secretion by blocking proton production by bonding and deactivating H<sup>+</sup>,K<sup>+</sup>-ATPase (or proton pump) by traversing the parietal cell membrane and accumulating in the secretory canaliculi.<sup>109</sup> The PPI omeprazole has been

demonstrated to reduce gastric acid production to zero.<sup>110-112</sup> It is a very powerful medicine that affects gastric acid production for 72 hours after cessation of administration. A prospective study determined that, within the therapeutic dose range (0.7 to 3.5 mg/kg/day), omeprazole was both efficacious and safe for children.<sup>111</sup> In this study, omeprazole was found to be highly effective in severe (grade IV) esophagitis and patients refractory to other medical therapy. A dosage of 0.7 mg/kg/day healed 45% of patients, and 1.4 mg/kg/day healed another 30%. On a body weight basis, the dosages required in children are generally higher than those in adults.<sup>112</sup> For children unable to swallow the whole capsule, it is suggested to open the capsule and give the granular contents in a weakly acidic vehicle such as orange juice, yogurt, or cranberry juice. The granules are stable in acid but are degraded in a neutral or alkaline pH. Newer PPIs (lansoprazole, rabeprazole, pantoprazole, esomeprazole) hold promise as better medical therapeutic possibilities.<sup>113-116</sup>

## Operative Management

Operative management usually follows failed medical management for growth failure (failure to thrive or gain weight appropriately), most respiratory symptoms, and other symptoms such as pain and esophagitis. However, in selected circumstances, it may be best to proceed with fundoplication without a trial of medical therapy. These selective situations include the previously mentioned patient in an intensive care unit who requires gastrostomy and the neurologically impaired patient with a similar need for gastrostomy and concern for aspiration. This latter scenario is commonly seen in infants and children, and the decision for or against fundoplication at the time of gastrostomy should be individualized. For example, in a 2- or 3-year-old (or older) neurologically impaired patient who begins to have difficulty with oral intake and requires tube feedings but has no reflux symptoms

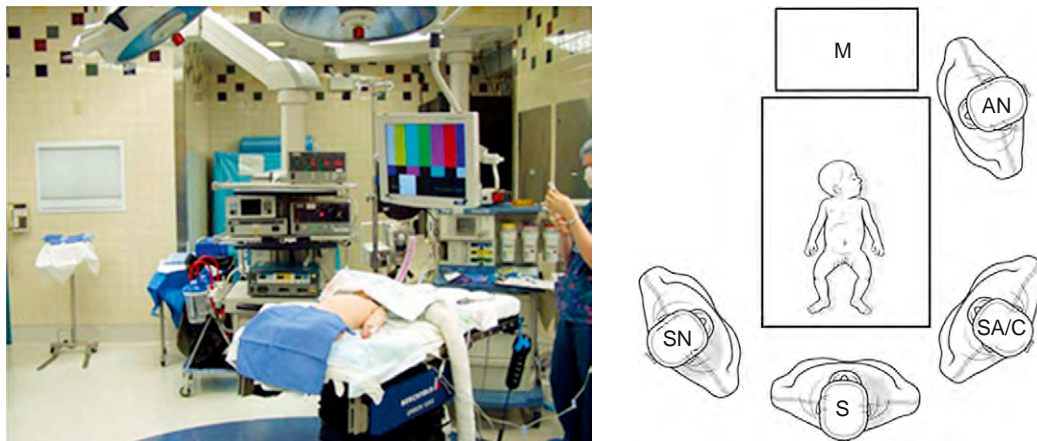

and a normal pH study, gastrostomy alone without fundoplication is very reasonable. On the other hand, a neurologically impaired infant who cannot swallow and requires tube feedings in the intensive care unit probably should have a fundoplication in addition to a gastrostomy.

Another scenario is the infant who presents with an ALTE spell and GER is documented but no other etiology is identified. This patient may be best served with a fundoplication as the initial therapy. In a review from our institution involving 81 infants presenting with ALTE, their symptoms resolved with fundoplication in 78.<sup>117</sup> The median follow-up in this study was 1738 days. Two required a second fundoplication when their symptoms recurred, and one needed a pyloromyotomy. Interestingly, 96.3% of these patients had been treated with antireflux medication and 87.7% were taking antireflux medications at the time of their ALTE. Therefore, medical management may not be effective in this population.

Barrett's esophagitis and esophageal stricture are the two other conditions in which initial operative therapy is recommended. The changes of Barrett's esophagus will usually resolve in adolescents after fundoplication, although lifelong postoperative endoscopic surveillance will be needed. Regarding a stricture, dilation can be performed at the time of fundoplication. Subsequent dilations may be needed in severe cases. Finally, children with a known hiatal hernia and symptomatic GER are not likely to respond to medical management. Initial fundoplication is a reasonable choice in these patients.

## Laparoscopic Nissen Fundoplication

The patient is placed at the end of the operating table so that the surgeon can stand at the foot of the bed and the assistant to his or her right. The scrub nurse stands to the surgeon's left (Fig. 29-2). For infants, the legs should be placed in a frog-leg position. For

**Figure 29-2.** For laparoscopic fundoplication, the patient is placed supine on the operating table. Infants and young children are positioned at the foot of the bed in a frog-leg position and the foot of the bed is dropped. The surgeon (S) and surgical assistant/camera holder (SA/C) stand next to the patient at the end of the bed. The scrub nurse (SN) is to the surgeon's left. A single monitor (M) is placed over the patient's head. AN, anesthesiologist. (From Holcomb GW III: Laparoscopic Nissen fundoplication. In Holcomb GW, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 15-20.)

**Figure 29-3.** There are a number of ways to orient the instruments when performing a laparoscopic fundoplication. With our technique, a 45-degree angled, 5-mm telescope is introduced after insertion of the 5-mm umbilical cannula. The liver retractor is introduced in the patient's right subcostal region (*solid arrow*). The two main working ports are in the left and right epigastrium. The main working port for the surgeon is the one in the patient's left epigastric region. It is through this incision that dissecting instruments, needle holder, and suture are introduced. The instrument utilized by the surgical assistant is in the patient's left subcostal region (*dotted arrow*). The stab incision technique can be utilized for both infants (**A**) and adolescents (**B**). (From Holcomb GW III: Laparoscopic Nissen fundoplication. In Holcomb GW, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 15-20.)

older children, the legs can be positioned in stirrups. Although a single monitor placed over the patient's head is usually sufficient, two monitors, placed to the right and the left of the patient's head, can be used as well. An orogastric tube is introduced by the anesthesiologist to decompress the stomach. The bladder is usually emptied using a Credé maneuver.

After prepping and draping, a 5-mm vertical incision is made in the center of the umbilicus and carried down through the umbilical fascia. A Step sheath (Covidien, Mansfield, MA) is gently introduced into the abdominal cavity, followed by introduction of a cannula with a blunt-tipped trocar through the sheath. By using this open technique, injury to the underlying viscera should be extremely rare. The sheath can be secured to the umbilical skin for stabilization should the surgeon desire. A pneumoperitoneum is created to a pressure of 12 to 15 mm Hg, and diagnostic

laparoscopy is performed with a 5-mm, 45-degree angled telescope. Four stab incisions are then placed in infants, and three stab incisions and a 5-mm port for the ultrasonic scalpel are utilized in children older than 5 years of age. The arrangement of these canulas is seen in Figure 29-3. A liver retractor is introduced through the lateral right port. The two main working sites are the instruments positioned on either side of the midline. The assistant's instrument is in the patient's left lateral abdomen.

We have standardized our technique and have utilized it for the past 8 years.<sup>118-123</sup> Initially, the superior short gastric vessels are ligated and divided. Cautery connected to a Maryland dissecting instrument is used in the younger patients. As previously mentioned, the ultrasonic scalpel is used in older children. The retroesophageal window is initially made from the patient's left side because it is quite easy

**Figure 29-4.** If an adequate length of intra-abdominal esophagus is present, then as little dissection as possible is performed to help prevent migration of the fundoplication wrap through an enlarged esophageal hiatus. The phrenoesophageal ligament is kept intact on both the patient's right side of the esophagus (**A**) and the patient's left side of the esophagus (**B**). Note creation of the retroesophageal window has been initiated (*arrows*). (From Holcomb GW III: Laparoscopic Nissen fundoplication. In Holcomb GW, Georgeson KE, Rothenberg SS [eds]: Atlas of Pediatric Laparoscopy and Thoracoscopy. Philadelphia, Elsevier, 2008, pp 15-20.)

**Figure 29-5.** Following closure of the esophageal hiatus with a 2-0 silk suture placed posterior to the esophagus, esophagocrural sutures are placed at the 7-, 11-, 1-, and 5-o'clock positions around the esophagus. These photographs show the right (A) and left (B) sides of the patient's esophagus. The purpose of these sutures is to secure the esophagus in the intra-abdominal position to reduce the incidence of postoperative reflux and also to obliterate the space between the esophagus and crura in an effort to prevent transmigration of the fundoplication wrap.

to accomplish after mobilization and ligation of the superior short gastric vessels. We do not mobilize the esophagus very much to help reduce postoperative transmigration of the fundoplication wrap. (This will be discussed later.) Once the left side of the patient's gastroesophageal junction has been identified, the stomach is flipped to the patient's left and attention is turned toward the right aspect of the esophagus and upper stomach. The gastrohepatic ligament is incised to expose the esophagus and stomach on the right side. Great care must be taken to always know the location of the left gastric artery. It is imperative that the fundoplication wrap is positioned above the left gastric artery rather than inferior to it. The opening in the retroesophageal window is then completed from the right side so that the fundus can be brought through it for the Nissen fundoplication. Again, as little esophageal mobilization as possible is performed at the gastroesophageal junction (Fig. 29-4). Essentially, this means that the phrenoesophageal membrane is incised minimally, if at all.

At this point, usually a single suture is placed posterior to the esophagus to close a small hiatal hernia that may have either been present initially or created during the dissection. This is usually accomplished with a 2-0 silk suture. After placement of this suture and tying it, a small bite of the esophagus at the 7-o'clock position is then taken with the same needle and tied to help obliterate the space between the posterior esophagus and the posterior crural closure. Next, esophagocrural sutures are then created with 3-0 silk at the 8-, 11-, 1-, and 5-o'clock positions to further obliterate the space between the esophagus and the crura to prevent transmigration of the fundoplication wrap (Fig. 29-5).<sup>121</sup> After placement of these crural sutures, the bougie is then introduced. A table describing the appropriate bougie size for neonates weighing less than 15 kg has been developed (Table 29-3).<sup>118</sup> The fundoplication is then performed using a standard Nissen technique. Usually, three 2-0 sutures are utilized to perform the fundoplication. The most superior suture also incorporates a small portion of the

anterior esophagus. The length of the fundoplication is measured. Usually a length of approximately 2 cm is desired.<sup>118</sup> For older children, 2.5 to 3.0 cm may be appropriate.

Bupivacaine is instilled in the incisions, and the umbilical fascia and skin are closed. Steri-strips are usually utilized for closure of the stab incisions.

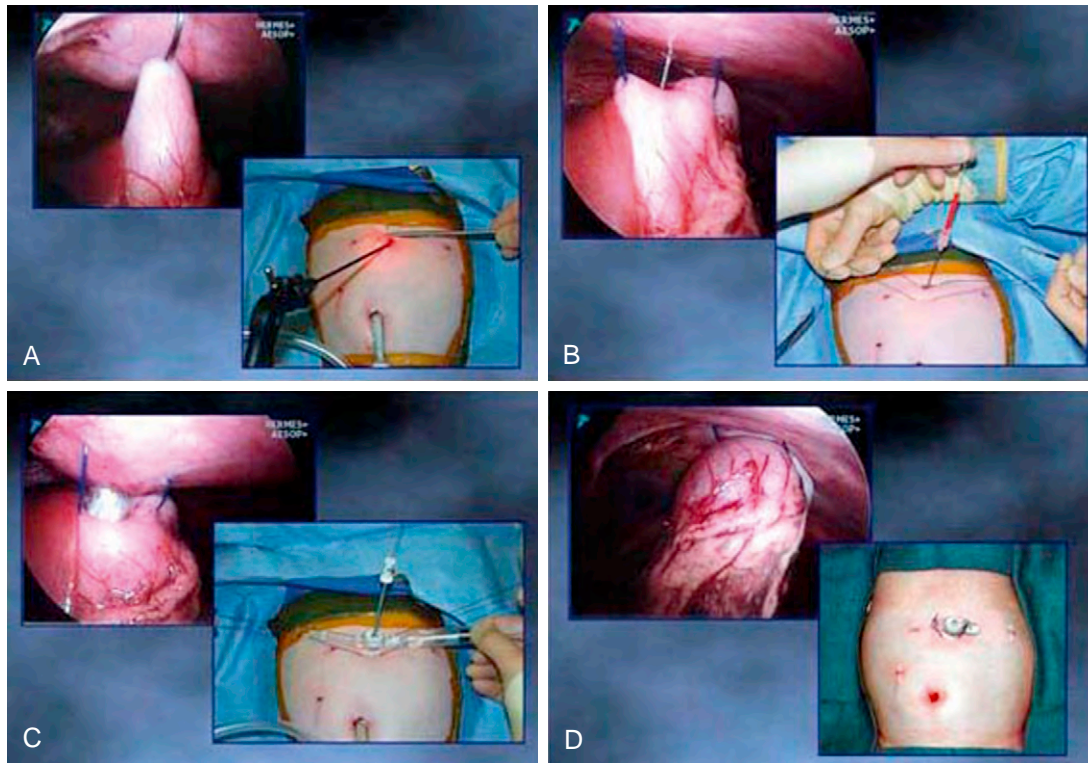

## Gastrostomy

If a gastrostomy is also needed, the stab incision or cannula site in the patient's left midepigastic area is the one utilized for exteriorization of the gastrostomy button. If a fundoplication has not been performed, then the same site is used for locating the button. In either event, this site is marked before insufflation so as not to distort its location when the abdomen is distended with CO<sub>2</sub>.

A red rubber catheter is introduced by the anesthesiologist into the stomach and the stomach is insufflated with 30 to 60 mL of air to prevent incorporating the back wall of the stomach with the suture utilized to secure the stomach to the anterior abdominal wall. The anterior wall of the stomach is grasped with a locking grasper and brought toward the anterior abdominal wall. The technique for laparoscopic gastrostomy is

<b>Table 29-3</b>

From Ostlie DJ, Miller KA, Holcomb GW III: Effective Nissen fundoplication length and bougie diameter size in young children undergoing laparoscopic Nissen fundoplication. *J Pediatr Surg* 37:1664-1666, 2002.

**Figure 29-6.** **A**, After approximation of the stomach to the anterior abdominal wall, two sutures of 2-0 or 0 PDS (depending on the patient's age) are placed extracorporeally through the abdominal wall, through the stomach, and out through the abdominal wall inferior to the gastrostomy. **B**, After placing the extracorporeal sutures, an 18-gauge needle is introduced through the left epigastric incision and into the stomach under direct visualization. Following a rush of air through the needle, a guide wire is inserted through the needle and the needle is removed. With the guide wire in place, the tract is serially dilated using the Cook Vascular Dilator Set (Cook, Inc., Bloomington IN). These dilators come in 8-Fr, 12-Fr, 16-Fr, and 20-Fr sizes. **C**, After dilating the tract and gastrostomy with the 20-Fr dilator, the 8-Fr dilator is placed through the Mic-Key gastrostomy button and is introduced over the guide wire and into the stomach. **D**, After placement of the button within the stomach, the balloon on the button is inflated, the guide wire and dilator are removed, and the extracorporeal sutures are tied over the button to secure it to the anterior abdominal wall. (From Holcomb GW III: Gastroesophageal reflux in infants and children. In Fischer JE [ed]: *Mastery of Surgery*, 5th ed. Philadelphia, Lippincott Williams & Wilkins, 2007, pp 650-651.)

seen in Figure 29-6. Two 2-0 PDS sutures (Ethicon, Inc., Somerville, NJ) are placed through the anterior abdominal wall cephalad to the grasper, through the stomach, and out through the anterior abdominal wall inferior to the instrument that has been used to grasp the stomach. Next, a needle followed by a guide wire is introduced through the abdominal wall and stomach in the center of the square formed by the two PDS sutures. Dilators from a Cook Vascular Dilator Set (Cook, Inc., Bloomington, IN) are used to serially dilate the anterior abdominal wall and gastrotomy. In infants, a 16-Fr dilator is usually the largest needed. In older children, the 20-Fr dilator may be required. The gastrostomy button is then placed over the guide wire and into the stomach. Under visualization, the balloon on the Mic-Key (Ballard Medical Products, Draper, UT) gastrostomy button is inflated. Attention must be paid to be sure that the button is, in fact, in the stomach and not external to the stomach. This can also be confirmed with the angled telescope by looking around each side of the stomach with the button in place. The PDS sutures are then secured over the button to prevent its dislodgement. Our protocol is to cut these sutures in 5 days. Others may cut them sooner. This technique was initially described by Georgeson

and Owings, and details about complications have been published.<sup>124,125</sup>

### Postoperative Care

Postoperatively, if a gastrostomy button was placed with the fundoplication (or if a button was placed primarily), feedings are usually started several hours later and advanced over the evening and the next morning. Most (90%) patients are ready for discharge the day after the operation. The parents will have been instructed on the use of the gastrostomy during the patient's 24-hour hospitalization and can advance the feedings as needed. The patient can also be seen in the clinic should further questions or issues arise.

If the patient did not need a gastrostomy, then liquids are allowed several hours after the procedure. It is very important to mention to the family that there is initial edema around the fundoplication. Therefore, for the first 3 weeks, the diet should be a mechanical soft diet that has the consistency of pudding, apple sauce, mashed potatoes, and so on. Essentially, meats and pizza should not be allowed because these food substances can become lodged above the fundoplication wrap. After 3 weeks, the edema usually resolves

**Table 29-4** Operative Results after Open Operations for Management of GERD

Study	No. Patients	% Reoperation	Herniation	Wrap Dehiscence	Other

and small portions of meats and pizza can be added to the diet.

Patients are seen 2 weeks, 3 months, 6 months, and 1 year after the operation. An upper gastrointestinal contrast study is performed at 1 year to evaluate for transmigration of the wrap or any other abnormalities.

## Outcomes

Our group has been interested in the efficacy of laparoscopic fundoplication for the past 10 years. A number of articles have been published from our institution detailing our thoughts about indications, complications, the operative technique, and ways to improve the results.<sup>117-123,126-130</sup> A number of other authors have been interested as well and have published their experience with laparoscopic fundoplication.<sup>131-136</sup>

In early 2002, in looking at our outcomes from January, 2000, through March, 2002, we believed that the need for repeat fundoplication was higher than desired.<sup>121</sup> In 130 patients undergoing laparoscopic Nissen fundoplication during that time, the incidence of repeat fundoplication was 12%. All patients who required a repeat operation had transmigration of the fundoplication wrap. During that time period, the esophagus was being extensively mobilized to try to create at least a 2-cm length of intra-abdominal esophagus. Moreover, there was no attempt to obliterate the space between the esophagus and the crura. These principles derived from prior training as well as literature reports in adults.<sup>20,21</sup> Although the operations proceeded nicely and no conversions were needed, this 12% incidence of re-do procedures seemed high. However, historical reports for the open operation have also documented a relatively high incidence of repeat fundoplications from 6% to 12% (Table 29-4).<sup>59,137-139</sup>

In an attempt to reduce the incidence of postoperative transmigration of the wrap, two modifications were made in the operative technique beginning in April, 2002. First, there was minimal mobilization of the esophagus. It was believed that the main reason for wrap transmigration was that the esophagus was being mobilized and a space was being created between the esophagus and crura to allow for the transmigration to occur. Therefore, the phrenoesophageal membrane was kept as intact as possible to try to obliterate this space. Second, to further obliterate this space, sutures were placed between the esophagus and crura. Initially, only two sutures were used, but eventually

four sutures have come to be placed for the purpose of further obliterating this space (see Fig. 29-5). No other modifications in the operative technique were made. In looking at the results from April, 2002, through December, 2004, the incidence of transmigration was reduced to 5%.<sup>121</sup> This was actually reduced even further when looking at the patients in whom four esophageal crural sutures were utilized rather than two or three.

In 2005, in conversations with Georgeson and colleagues at the University of Alabama-Birmingham, it was evident that similar observations had been made by the Alabama group. Therefore, it was decided to join together and perform a prospective, randomized trial looking at the operative technique.<sup>140</sup> Initially, it was believed that the efficacy of esophageal mobilization should be evaluated. The primary endpoint was transmigration of the wrap. A power analysis based on the difference between the 12% and 5% repeat fundoplication rate previously mentioned was made and the study was powered at 360 patients. The patients were randomized on the day of the surgery. One group was randomized to receive minimal esophageal mobilization with placement of four esophagocrural sutures. The other group was randomized to extensive esophageal mobilization to create a 2-cm length of intra-abdominal esophagus along with the four esophagocrural sutures. In addition, all patients would receive an upper gastrointestinal series at 1-year postoperatively to evaluate for transmigration of the fundoplication wrap. Other variables were also captured.

The two surgical groups have met twice yearly since 2005. At the midpoint of the study, 172 patients had been entered. The data were overwhelmingly in favor of minimal esophageal mobilization and placement of the four esophagocrural sutures. At the time of the interim analysis, almost all of the re-do operations had occurred in patients undergoing extensive esophageal mobilization and placement of the four esophagocrural sutures. Therefore, it was believed that ethically the study could not continue and was closed. The upper gastrointestinal studies for all the enrolled patients should be completed late in 2009. A final report will be available in 2010.

## Repeat Fundoplication

As mentioned previously, the goal of the initial fundoplication is to control symptomatic GER but also to prevent the need for a second operation.<sup>141</sup> In 2006,

**Figure 29-7.** In 5% to 10% of patients undergoing laparoscopic fundoplication, reoperation becomes necessary. **A**, In our experience, almost all reoperations are due to transmigration of the fundoplication wrap, which is seen on this upper gastrointestinal study. **B**, The intraoperative photograph shows a large esophageal hiatus (arrows) with transmigration of the fundoplication wrap and upper stomach into the lower mediastinum. Note the significant lack of adhesions after the initial laparoscopic fundoplication. (From Ostlie DJ, Holcomb GW III: Reiterative surgery for gastroesophageal reflux. *Semin Pediatr Surg* 16:252-258, 2007.)

our group looked at our experience with re-do funduplications.<sup>142</sup> Of 273 patients who underwent laparoscopic fundoplication by the senior surgeon (GWH) between January, 2000, and April, 2006, 21 required a re-do fundoplication (Fig. 29-7).<sup>142</sup> The repeat operative technique generally fell into two groups. In one group, it was performed laparoscopically without the use of mesh to reinforce the large hiatal closure that had developed after transmigration of the wrap. In the other group, Surgisis (Cook, Inc, Bloomington, IN) was used to reinforce the hiatal closure because it was believed that a great deal of tension was needed to close the large muscular defect (Fig. 29-8). Initially 4-ply Surgisis was used, but 8-ply Surgisis was employed when it became available. In the patients undergoing the second operation without Surgisis, three required a second re-do or third overall fundoplication. To date, no patient has required another repeat operation in which Surgisis was placed at the time of the initial repeat procedure.<sup>142</sup>

At the same time as our concept developed about reinforcing the hiatal closure with Surgisis, a multi-institution, prospective randomized trial was being performed in adult patients.<sup>143</sup> The investigators were looking at the efficacy of placing 4-ply Surgisis at the time of initial repair of a large paraesophageal hernia defect to help prevent recurrence. This trial also closed early because of the marked disparity in results favoring the use of Surgisis to help close the large diaphragmatic defect. The study included 71 patients in each arm. The primary outcome variable was recurrence of the paraesophageal hernia. The study closed at 108 total patients because, at the time of interim review, 12 patients (24%) had developed a recurrence in the arm in which Surgisis was not used and only 4 patients (9%) had a recurrent paraesophageal hernia in the Surgisis arm.

Laparoscopic fundoplication has evolved into the preferred technique for surgical management of GERD.

Although the Nissen operation is generally performed, similar good results have been noted with the Thal operation.<sup>144-147</sup> It is only through critical evaluation of one's experience that advances are made in improving the results. There is no doubt that patients have less discomfort and earlier discharge from the hospital after the laparoscopic operation.<sup>130</sup> Moreover, there is a faster return to regular activities as well. However, the operative technique continues to need ongoing evaluation with proper data collection and critical analysis to improve these results.

**Figure 29-8.** This intraoperative photograph shows the 8-ply Surgisis that has been wrapped around the esophagus and is overlapped anterior to the esophagus. The 8-ply Surgisis is secured to the esophagus medially and the diaphragm laterally with interrupted 3-0 silk sutures. It is employed to help reinforce the closure of the crura at the time of repeat fundoplication.

# LESIONS OF THE STOMACH

Curt S. Koontz, MD • Mark Wulkan, MD

The stomach forms from the foregut and is recognizable by the fifth week of gestation. It then elongates, descends, and dilates to form its familiar structure by the seventh week of gestation. The vascular supply to the stomach is very robust, and ischemia of the stomach is rare. The stomach is supplied by the right and left gastric arteries along the lesser curvature, the right and left gastroepiploic arteries along the greater curvature, and the short gastric vessels from the spleen. There is also contribution from the posterior gastric artery, which is a branch of the splenic artery, as well as the phrenic arteries.

In this chapter, we discuss common and unusual conditions of the stomach that are treated surgically. Some topics relevant to the stomach, such as gastroesophageal reflux and obesity, are covered elsewhere.

## HYPERTROPHIC PYLORIC STENOSIS

Hypertrophic pyloric stenosis (HPS) is one of the most common surgical conditions of the newborn.<sup>1-9</sup> It occurs at a rate of 1 to 4 per 1000 live births in white infants but is seen less in non-white children.<sup>1-4</sup> Males are affected more often with a 4:1 male-to-female ratio. Risk factors for HPS include family history, gender, younger maternal age, being a first-born infant, and maternal feeding patterns.<sup>4,9,10</sup> Premature infants are diagnosed with HPS later than term or post-term infants.<sup>4</sup>

### Etiology

The cause of HPS is unknown, but genetic and environmental factors appear to play a large role in the pathophysiology. Circumstantial evidence for a genetic predisposition includes race discrepancies, the increased frequency in males, and the birth order (first-born infants with a positive family history). Environmental factors associated with HPS include the method of feeding (breast vs. formula), seasonal variability, exposure to erythromycin, and transpyloric feeding in premature infants.<sup>5-7</sup> Additionally, there has been interest in several gastrointestinal peptides or growth factors that may facilitate pyloric hypertrophy.

Some of these include excessive substance P, decreased neurotrophins, deficient nitric oxide synthase, and gastrin hypersecretion.<sup>8,9</sup> Thus, the etiology of HPS is likely multifactorial with environmental influences.

### Diagnosis

The classic presentation of HPS is nonbilious, projectile vomiting in a full-term neonate who is between 2 and 8 weeks old. Initially, the emesis is infrequent and may appear to be reflux. However, over a short period of time, the emesis occurs with every feeding and becomes forceful (i.e., projectile). The contents of the emesis are usually the recent feedings, but signs of gastritis are not uncommon ("coffee-ground" emesis). On physical examination, the neonate usually appears well if the diagnosis is made early. However, depending on the duration of symptoms and degree of dehydration, the neonate may be gaunt and somnolent. Visible peristaltic waves may be present in the mid to left upper abdomen. To palpate the pyloric mass (i.e., "olive"), the neonate must be relaxed. Techniques for relaxing the patient include bending the neonate's knees and flexing the hips and using a pacifier with sugar water. These techniques should be attempted after the stomach has been decompressed with a 10-Fr to 12-Fr orogastric tube. After palpating the liver edge, the examiner's fingertips should slide underneath the liver in the midline. Slowly, the fingers are pulled back down, trying to trap the "olive." Palpating the pylorus requires patience and an optimal examination setting. The definitive diagnosis can be made in a considerable number of patients with this examination. However, if the diagnosis is unclear after a thorough physical examination, radiologic evaluation is warranted.

Ultrasonography has become the standard technique for diagnosing HPS and has supplanted the physical examination at most institutions. The diagnostic criteria for pyloric stenosis is a muscle thickness of greater than or equal to 4 mm and a length of greater than or equal to 16 mm (Fig. 30-1).<sup>10</sup> A thickness of more than 3 mm is considered positive if the neonate is younger than 30 days of age.<sup>11</sup> The study is dependent on the expertise of the ultrasound technician and radiologist.

**Figure 30-1.** Ultrasonography has become the standard imaging study for diagnosing pyloric stenosis and has supplanted physical examination at most institutions. The transverse (A) and longitudinal (B) views of hypertrophic pyloric stenosis are seen here. Muscle thickness greater than or equal to 4 mm on the transverse view or a length greater than or equal to 16 mm on the longitudinal view is diagnostic of pyloric stenosis. On this study, the pyloric wall thickness was 5 mm and the length (arrows) was 20 mm.

Availability of skilled personnel can also be a problem at night. There are reports of non-radiologists performing ultrasonography for diagnosing HPS, which would obviously reduce the need for the ultrasound technician.<sup>12,13</sup> If the ultrasound findings are equivocal, then an upper gastrointestinal series can be helpful in confirming the diagnosis (Fig. 30-2). It is, however, important to evacuate the contrast agent after the study to reduce the risk of aspiration and deleterious pulmonary complications.

**Figure 30-2.** At some hospitals outside of urban centers, ultrasound technicians and radiologists proficient in performing an ultrasound study for pyloric stenosis are not available. Also, in some instances, an ultrasound study can be equivocal. An upper gastrointestinal series can be helpful in making the diagnosis of pyloric stenosis or confirming an equivocal ultrasound study. In this upper gastrointestinal study, note the "string sign" indicating a markedly diminished pyloric channel (arrow) and subsequent gastric outlet obstruction. It is important to evacuate the contrast material after this study to reduce the risk of aspiration and pulmonary complications.

In the past, the diagnosis was often delayed and profound dehydration with metabolic derangements was common. Today, however, primary care physicians are more aware of the problem and the availability of ultrasonography facilitates an earlier diagnosis and treatment of HPS. The differential diagnosis for nonbilious vomiting, however, should be considered. This includes medical causes such as gastroesophageal reflux, gastroenteritis, increased intracranial pressure, and metabolic disorders. Anatomic causes would include an antral web, foregut duplication cyst, gastric tumors, or a tumor causing extrinsic gastric compression.

## Treatment

The mainstay of therapy is typically resuscitation followed by pyloromyotomy. There are reports of medical treatment with atropine and pyloric dilation, but these treatments require long periods of time and are often not effective.<sup>14-18</sup>

Once the diagnosis of HPS is made, feedings should be withheld. Gastric decompression is usually not necessary but occasionally may be required for extreme cases. If a barium study was performed, it is important to remove all of the contrast material from the stomach to prevent aspiration.

The hallmark metabolic derangement of hypochloremic, hypokalemic metabolic alkalosis is usually seen to some degree in most patients. Profound dehydration is rarely seen today, and correction is usually achieved in less than 24 hours after presentation. A basic metabolic panel should be ordered and the resuscitation should be directed toward correcting the abnormalities. Most surgeons use the serum carbon dioxide (<30 mmol/L), chloride (>100 mmol/L), and potassium (4.5-6.5 mmol/L) levels as markers of resuscitation. Initially, a 10- to 20-mL/kg bolus of normal saline should be given if the electrolyte values are abnormal. Then D5/½NS with 20 to 30 mEq/L of

potassium chloride is started at a rate of 1.25 to 2 times the maintenance rate. Electrolytes should be checked every 6 hours until they normalize and the alkalosis has resolved. Then the patient can safely undergo anesthesia and operation. It is important to appreciate that HPS is not a surgical emergency and resuscitation is of the utmost priority.

After general anesthesia has been induced, an abdominal examination should be performed to physically check for an “olive” if one was not detectable preoperatively. The pyloromyotomy may be performed by the standard open technique or by the minimally invasive approach. The anesthesiologist should pass and leave a suction catheter in the stomach for decompression and for instilling air after the pyloromyotomy to check for a leak.

### The Open Approach

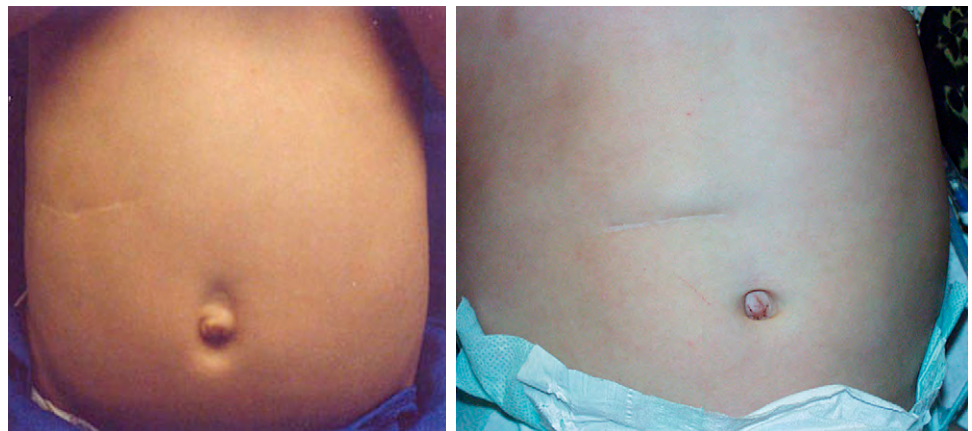

Several incisions have been described for the open approach. The typical right upper quadrant transverse incision seems to be used most commonly (Fig. 30-3). An alternate, more cosmetically pleasing incision involves an omega-shaped incision around the superior portion of the umbilicus followed by incising the linea alba cephalad. With either incision, the pylorus is exteriorized through the incision. A longitudinal serosal incision is made in the pylorus approximately 2 mm proximal to the junction of the duodenum and is carried onto the anterior gastric wall for approximately 5 mm. Blunt dissection is used to divide the firm pyloric fibers. This can be performed using the handle of a scalpel. Once a good edge of fibers has been developed, a pyloric spreader or hemostat can be used to spread the fibers until the pyloric submucosal layer is seen. The pyloromyotomy is then completed by ensuring that all fibers are divided throughout the entire length of the incision. This is confirmed by visualizing the circular muscle of the stomach proximally as well as a slight protrusion of the mucosa. The most common point of mucosal disruption is at the distal part of the incision at the duodenal-pyloric junction. Therefore, care must be exercised when dividing the fibers in this region. The pyloromyotomy can

be checked for completeness by rocking the superior and inferior edges of the myotomy back and forth to ensure independent movement. The mucosal integrity can be checked by instilling air through the previously placed suction catheter. If there are no leaks, the air should be suctioned. Minor bleeding is common and should be ignored because it will cease after the venous congestion is reduced when the pylorus is returned to the abdominal cavity. The abdominal incision is then closed in layers.

### The Laparoscopic Operation

Neonatal laparoscopy has grown in popularity with the refinement in technique and smaller instruments. The first reported laparoscopic pyloromyotomy in the English language was in 1991 (the authors had reported the first case in the French literature in 1990).<sup>19</sup> Since then, this procedure has been accepted by most pediatric surgeons. Critics of the procedure argue that laparoscopic pyloromyotomy exposes the patient to undue risks compared with the open technique. However, recent randomized prospective trials have not shown any difference in complication rates.<sup>20,21</sup> Operative times can vary depending on the laparoscopic experience of the surgeon. The minimally invasive approach is similar to laparoscopic appendectomy in terms of acceptance and has become the standard technique for pyloromyotomy in many centers.

The technique involves entering the abdomen through an umbilical incision. A Veress needle is placed at the base of the umbilicus between the umbilical arteries. It is paramount to ensure proper placement of the Veress needle before insufflation. This can be done by several simple methods, including the “blind man’s cane” sweep and the water drop test. Alternatively, an open approach can be used to introduce the umbilical cannula. The abdomen is then insufflated to a pressure of 10 mm Hg and a 3- or 5-mm port is introduced for the telescope and camera. Two stab incisions are made. One incision is in the right paramedian side of the abdomen at the level of the umbilicus, and the other is in the left paramedian side of the abdomen just superior to the umbilicus.

**Figure 30-3.** These two children underwent open pyloromyotomy through a right upper quadrant transverse incision. Over time, the cosmetic appearance of their incision is not as attractive as that seen after the laparoscopic operation.

Local anesthesia is used at all incisions. An atraumatic bowel grasper is placed through the left incision, and an arthrotomy knife is introduced through the right incision (Fig. 30-4). The duodenum is grasped firmly just distal to the pylorus, and the pylorus is maneuvered

**Figure 30-4.** For laparoscopic pyloromyotomy, a 3- or 5-mm cannula is introduced through the umbilicus and insufflation achieved to a pressure of 10 mm Hg. Through a stab incision in the right upper abdomen, an atraumatic bowel grasper is introduced for grasping and stabilizing the duodenum. The arthrotomy knife and pyloric spreader are introduced through the stab incision in the patient's left upper abdomen.

into view. Occasionally, a transabdominal stay suture wrapping around the falciform ligament is helpful to elevate the liver away from the pylorus. A pyloromyotomy is then made with the knife in a similar manner as the open technique (Fig. 30-5). The closed arthrotomy knife can be used to separate the muscle fibers similar to the scalpel handle. A laparoscopic pyloric spreader or a box-type grasper can be used to complete the myotomy. Completeness of the myotomy and mucosal integrity is checked in a similar manner as the open technique. Omentum can be placed over the myotomy to help with hemostasis. The pneumoperitoneum is evacuated after the instruments are removed. The umbilicus is closed with absorbable suture, and the stab incisions are closed with skin adhesive.

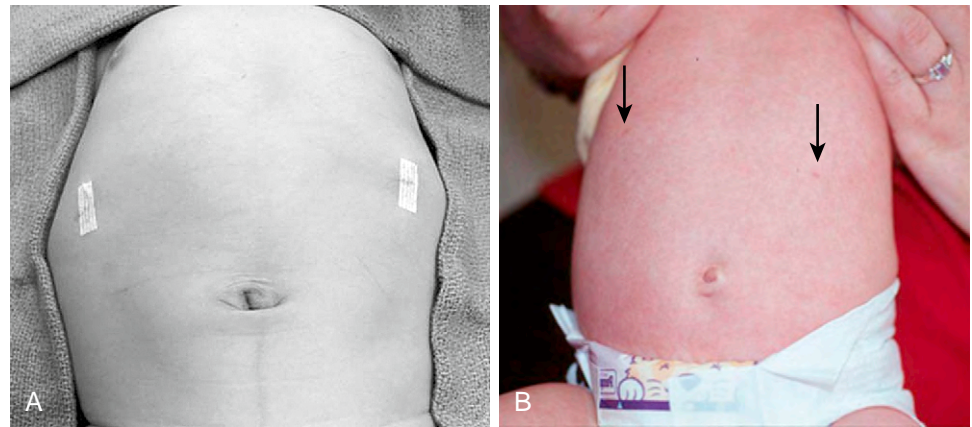

### Postoperative Care

Postoperative care is similar for both surgical techniques, assuming the mucosal integrity is intact. Complicated feeding regimens have been advocated in the past. However, recent studies support the use of ad libitum feeds in the early postoperative period. This results in a faster time to full feeds and quicker discharge.<sup>22,23</sup> If postoperative emesis is encountered, it is suggested to "feed through it." At our institution, we limit the feedings to a maximum of 3 oz every 3 hours. There are data to suggest that the degree and duration of metabolic derangement affects postoperative feeding. Patients who required more complicated resuscitation tend to take longer to reach full feeds and discharge.<sup>24</sup>

Pain is usually controlled with acetaminophen. Intravenous fluids are discontinued when the patient tolerates a 2-oz feeding twice. The infant can be

**Figure 30-5.** Technique of laparoscopic pyloromyotomy. **A**, With the duodenum stabilized, a seromuscular incision is made in the hypertrophied pylorus with the arthrotomy knife. **B**, Next, the knife is returned to its sheath and the sheath is used to further bluntly divide the hypertrophied fibers. **C**, Then a pyloric spreader can be introduced to completely divide the hypertrophied muscle. **D**, After pyloromyotomy, omentum can be placed over the myotomy to help with hemostasis.

**Figure 30-6.** The cosmetic advantage of the laparoscopic approach cannot be overemphasized. **A**, Incisions after a laparoscopic pyloromyotomy. **B**, Incisions (arrows) 3 weeks after the operation. Often after 6 months the incisions cannot be easily seen.

discharged when tolerating full feeds, which is usually on the first postoperative day.

### Complications

The major complications of pyloromyotomy include mucosal perforation, wound infection, incisional hernia, prolonged postoperative emesis, incomplete myotomy, and duodenal injury. There have been retrospective studies that do not show any difference in complication rates between the laparoscopic and open techniques.

Mucosal perforation occurs in 1% to 2% of cases.<sup>20,21</sup> If the disruption occurs at the duodenopyloric junction, a simple interrupted absorbable suture can be placed to close the defect and a patch of omentum can be used to bolster the repair. This can be accomplished laparoscopically depending on the experience of the surgeon. Otherwise, the laparoscopic case should be converted to open. If the perforation is large or in the middle of the myotomy, then the myotomy should be closed with absorbable suture. A new myotomy can then be made 90 to 180 degrees from the original incision. Repairing this injury would be difficult to perform laparoscopically. Feedings should be held for 24 hours and then restarted. A water-soluble contrast study can be performed if desired.

Duodenal injuries also can occur with either the laparoscopic or open approach. In a 25-year retrospective review of 901 open pyloromyotomies performed between 1969 and 1994, there were 39 duodenal perforations that were recognized intraoperatively and repaired. There were no unrecognized duodenal perforations that developed after the operation.<sup>25</sup>

Wound infections also occur in 1% to 2% of cases.<sup>20,21</sup> There are no data to support the use of prophylactic perioperative antibiotics because a pyloromyotomy is considered a clean procedure. Local wound care is usually sufficient to treat these infections.

Incisional hernias and wound dehiscence occurs in approximately 1% of cases.<sup>20</sup> Most hernia defects require repair at some point. Laparoscopically, port site hernias usually involve omentum protruding

through the incision. This can sometimes be managed at the bedside by cleansing the area with povidone-iodine (Betadine), ligating and trimming the extracorporeal omentum, elevating the abdominal wall to get the omentum back into the peritoneal cavity, and using fine absorbable suture to close the skin.

Postoperative emesis is common, occurring in up to 80% of patients at some point. Prolonged emesis is less common and ranges in incidence from 2% to 26%. Most commonly, this is due to gastroesophageal reflux (24%-31%) but can be secondary to incomplete myotomy (0-6%). It has been suggested that the laparoscopic approach may be a risk factor for inadequate myotomy, but this is likely related to surgical experience with this technique.<sup>21</sup>

### Outcome

In the past, the mortality from pyloric stenosis was considerable and approached 50%. Today, however, mortality is nearly zero with improvement in neonatal resuscitation and anesthesia as well as surgical techniques. Morbidity is also significantly lower than in the past, with an overall complication rate between 1% and 2%. Additionally, with more pyloromyotomies being performed laparoscopically, the cosmetic advantage of the minimally invasive techniques cannot be overemphasized (Fig. 30-6).

## PYLORIC ATRESIA

Pyloric atresia is a rare disease (1:100,000 live births) and presents as symptoms of gastric outlet obstruction. The disease is difficult to characterize because it is so rare. However, several generalizations can be made from looking at larger series. Pyloric atresia may be associated with epidermolysis bullosa and other gastrointestinal anomalies, such as duplications.<sup>26-33</sup> Pyloric atresia is diagnosed with a "single bubble" on the abdominal radiograph (Fig. 30-7). The diagnosis may be confirmed with a contrast study. Pyloric atresia may occur as a web, a cord, or

**Figure 30-7.** **A**, In contrast to duodenal atresia in which a “double bubble” sign is the pathognomonic finding on the abdominal radiograph, pyloric atresia is diagnosed with a “single bubble” on the abdominal film. **B**, A cross-sectional histologic view of an infant with pyloric atresia. Note the obliterated lumen and the enlarged muscular layer.

a gap between the antrum of the stomach and the first portion of the duodenum. Repair is performed after resuscitation. These infants may have similar electrolyte abnormalities to infants with hypertrophic pyloric stenosis. Repair is usually with a Billroth type I (gastroduodenostomy) anastomosis. Morbidity and mortality are usually related to the associated anomalies.

## GASTRIC PERFORATION

The causes of gastric perforation are spontaneous perforation of the newborn, iatrogenic perforation from instrumentation, peptic ulcer disease, and trauma. Gastric perforation usually presents as abdominal distention and signs of sepsis or shock related to the perforation. The diagnosis is suspected when a large amount of extraluminal gas is seen on an abdominal radiograph.

Neonatal gastric perforations most commonly occur in premature infants. About half of neonatal perforations are spontaneous, and the other half are iatrogenic from instrumentation.<sup>34</sup> Prematurity is associated with an increased mortality.<sup>35</sup> The perforations are usually managed with laparotomy or laparoscopy. The perforation can usually be closed primarily with or without an omental patch.

Gastric perforation due to peptic ulcer disease in infants and children is very rare. Typically, perforation occurs at the site of a prepyloric ulcer. Again, this may be repaired primarily via laparotomy or laparoscopy with or without an omental patch.<sup>36</sup>

## PEPTIC ULCER DISEASE

Peptic ulcer disease and its complications are rarely seen in children. However, there have been reports of neonatal and pediatric perforated ulcers as well as

gastric outlet obstruction in children due to peptic ulcer disease.<sup>36-38</sup> Peptic ulcer disease appears to be associated with *Helicobacter pylori* in the majority of pediatric cases. Treatment is primarily directed at acid reduction and eradication of *H. pylori*. Triple therapy with a proton pump inhibitor, amoxicillin, and clarithromycin is typically used initially. For strains that are resistant to clarithromycin, metronidazole is substituted.<sup>39</sup> Operative treatment is usually reserved for complications of peptic ulcer disease, such as perforation or gastric outlet obstruction (Fig. 30-8).

**Figure 30-8.** A 10-year-old presented with abdominal pain and vomiting. She was found to have a prepyloric ulcer (arrow) on the upper gastrointestinal study. In addition, there was evidence of gastric outlet obstruction. She underwent antrectomy and Billroth I reconstruction.

If ulcer perforation is suspected, it is reasonable to start with exploratory laparoscopy because there are reports of successful laparoscopic treatment in children.<sup>37</sup> A gastric resection operation is not usually needed since the development of effective proton pump inhibitors.

## GASTRIC DUPLICATIONS

Gastric duplications are rare anomalies that generally occur along the greater curvature (Fig. 30-9). If the lesion is near the pylorus, the presentation may be very similar to hypertrophic pyloric stenosis. The diagnosis can be differentiated from pyloric stenosis by ultrasonography. The lesion rarely communicates with the lumen. If it does, the patient may present with hematemesis or melena. Gastric duplications represent approximately 4% of all gastrointestinal duplications. Ectopic gastric mucosa is common in other duplications throughout the gastrointestinal tract. These are not considered gastric duplications. Approximately half are discovered in the neonatal period and are seen when the neonate presents with vomiting, poor feeding, and an epigastric mass.<sup>40</sup>

Treatment of gastric duplications is complete resection of the cyst. There have been gastric duplications associated with pancreatic ductal abnormalities.<sup>41</sup> In this case, care must be taken during the dissection not to injure normal pancreas, although it may be necessary to resect an accessory pancreas.

## MICROGASTRIA

Congenital microgastria is a rare disorder that usually occurs in conjunction with other congenital anomalies or, more rarely, alone (Fig. 30-10). Associated

**Figure 30-9.** This intraoperative view shows a gastric duplication (asterisk) emanating from the greater curvature of the stomach. This lesion was able to be removed without compromising the native stomach.

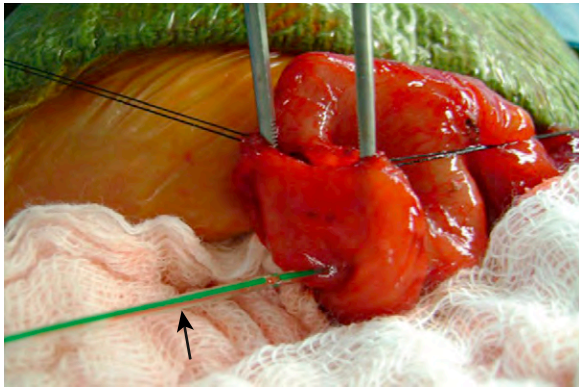

**Figure 30-10.** This neonate was born with congenital microgastria. Note the dilated esophagus and the extremely small stomach (arrow). There is also malrotation. The patient underwent creation of a Hunt-Lawrence pouch and was doing well at 1-year follow-up.

anomalies include the VACTERL association (Vertebral anomalies, Anorectal atresia, Cardiac anomalies, TracheoEsophageal fistula and esophageal atresia, Renal and Limb anomalies), tracheoesophageal cleft, malrotation, and asplenia. There are currently only three reported cases of isolated microgastria.<sup>42,43</sup> Microgastria is usually temporized with jejunal feedings. Operative intervention consists of jejunal feeding tubes and Hunt-Lawrence gastric augmentation. There are a few patients who have been reported with successful follow-up after a Hunt-Lawrence pouch.<sup>42,44,45</sup>

## ANTRAL WEB

The first modern description of an antral web was in 1969.<sup>46</sup> Early case reports in children described incomplete gastric outlet obstruction due to an antral web.<sup>47-50</sup> The etiology is unknown and is generally thought to be congenital or the result of an inflammatory process. In adults there has been a case report that strongly suggested peptic ulcer disease can lead to antral web.<sup>51</sup> The patient presents with a typical gastric outlet obstruction. In the infant, antral web may be confused with hypertrophic pyloric stenosis. The patient with antral web may have a normal abdominal sonogram. However, an upper gastrointestinal series will show the lesion. The abdominal examination may be normal.

Treatment of an antral web consists of resuscitation (see earlier section on pyloric stenosis) and operative correction (Fig. 30-11). The procedure can be completed with laparotomy or laparoscopically. This is a diagnosis that may be amenable to endoluminal treatment.

**Figure 30-11.** This neonate developed nonbilious emesis shortly after birth and was thought to have an antral web. At laparotomy, the antral web is visualized. The forceps are proximal to the web and the feeding tube (arrow) has been placed through the web. After resection of the web, the patient recovered uneventfully and has not developed any further problems.

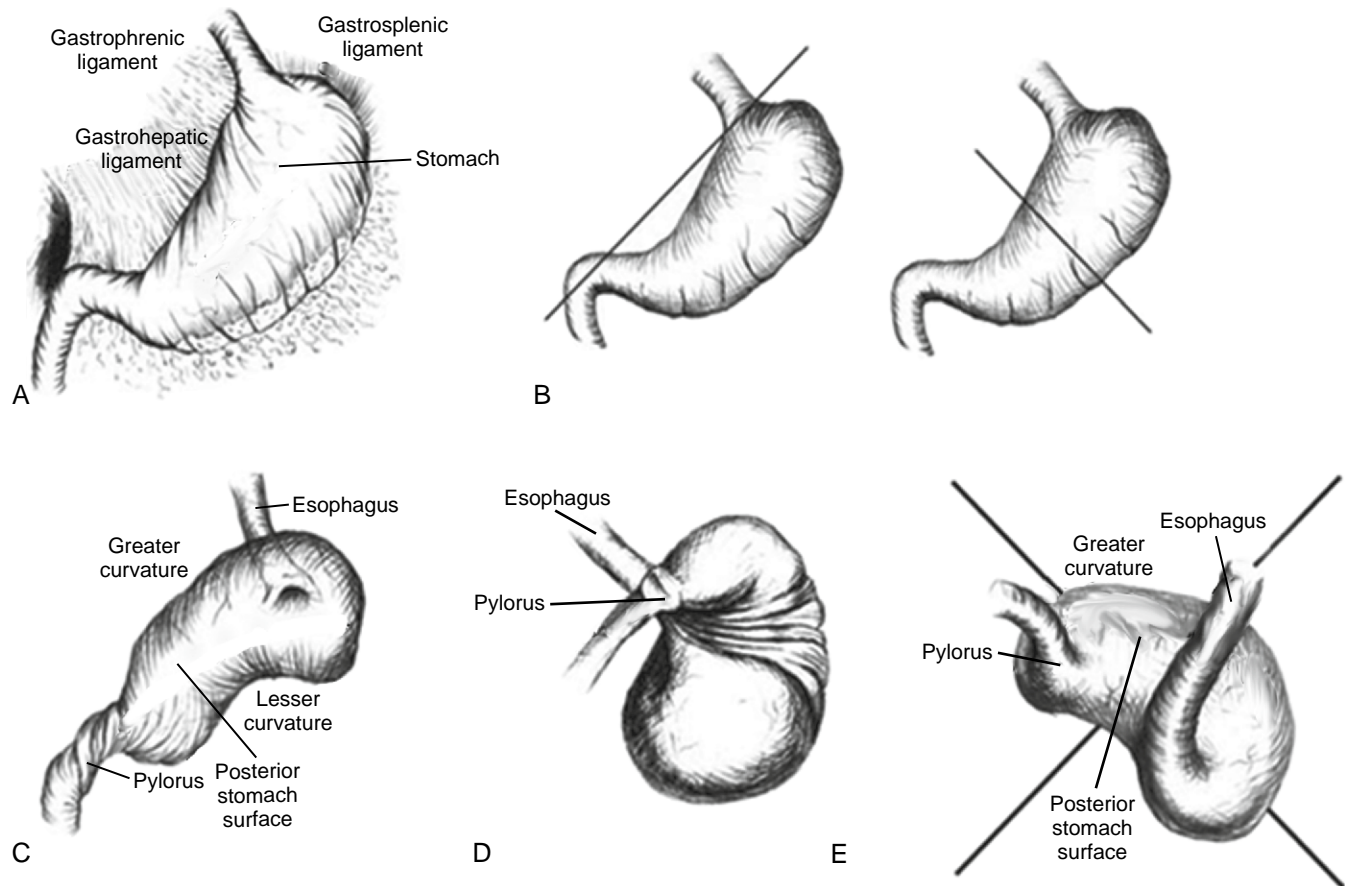

## GASTRIC VOLVULUS

Gastric volvulus can occur from primary or secondary causes. Primary gastric volvulus is thought to be due to laxity of the gastric ligaments. Secondary disease

may occur due to a paraesophageal hernia or other diaphragmatic hernia. The presenting symptoms can be intermittent or complete gastric obstruction, ischemia, pain, and/or bleeding. The most common signs and symptoms of gastric volvulus in children include acute abdominal pain, intractable retching, and the inability to pass a nasogastric tube into the stomach lumen.<sup>52,53</sup>

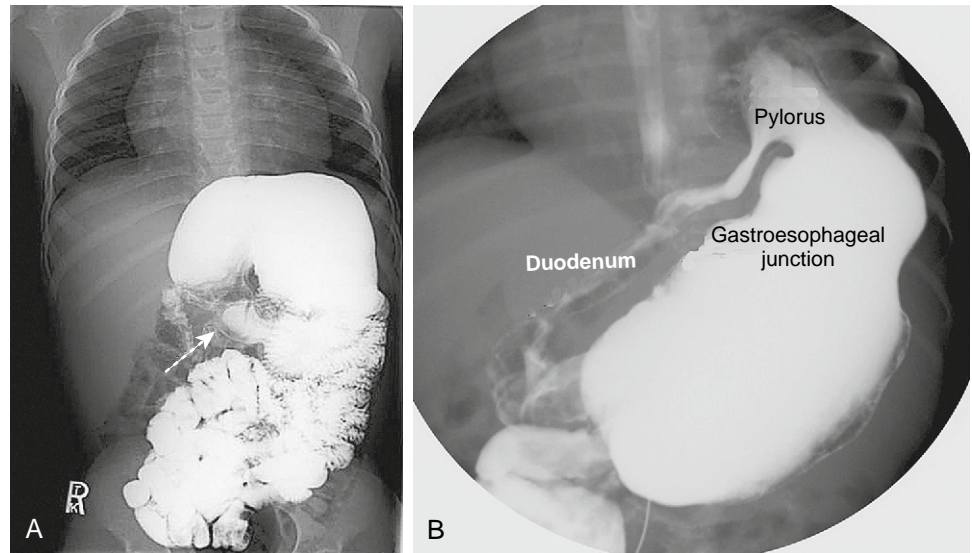

The average age at presentation is 2.5 years. Equal numbers of males and females are affected.<sup>52</sup> Gastric volvulus is classified into categories based on the axis of gastric rotation. Mesenteroaxial gastric volvulus is rotation about the gastric short axis, transecting the greater and lesser curvatures. Organoaxial gastric volvulus is rotation around the long axis of the stomach (Figs. 30-12 and 30-13).

Treatment consists of patient resuscitation, nasogastric decompression, and surgical correction. The volvulus is reduced. Any diaphragmatic defects are repaired in secondary gastric volvulus. A gastropexy is then performed. This has traditionally been accomplished with a gastrostomy tube or button. However, there have been several recent reports of successful laparoscopic gastropexy in which the anterior stomach, along the greater curvature, is sutured to the abdominal wall.<sup>54</sup>

**Figure 30-12.** These drawings depict the development of a gastric volvulus. **A**, Normal anatomy. **B**, The axis of rotation for an organoaxial volvulus is seen on the left and a mesoaxial volvulus is on the right. **C**, Demonstration of an organoaxial volvulus. **D**, Demonstration of a mesoaxial volvulus. **E**, Combined mesoaxial and organoaxial volvulus. (Reprinted with permission from Cribbs RK, Gow KW, Wulkan ML: Gastric volvulus in infants and children. *Pediatrics* 122:e752-e762, 2008.)

**Figure 30-13.** These two contrast studies depict a gastric volvulus. **A**, This contrast study depicts an organoaxial volvulus in which the stomach has rotated on its long axis. Note the relatively normal position of the pylorus (*arrow*). **B**, This contrast study shows a mesoaxial volvulus. In this study, the pylorus is in the left upper abdomen due to rotation around the short axis of the stomach. In both studies, the gastroesophageal junction is in a relatively normal position.

## FOREIGN BODIES AND BEZOAR

Foreign bodies in the stomach can be generally ignored. If the foreign body passed through the esophagus, it will likely pass out the rectum. Even razor blades and other sharp objects usually safely pass. The exception would be button batteries, which have a high incidence of leakage and should be removed if they have not passed through the pylorus. Otherwise, watchful waiting is a reasonable strategy. Occasionally larger coins, such as quarters, can remain in the stomach and cause intermittent gastric outlet obstruction. It is also reasonable to remove the object in this circumstance. Most gastric foreign bodies are removed endoscopically with a snare, grasper, or bag. The surgeon should consider using an overtube to extract large sharp objects that may injure the esophagus upon retrieval.

Gastric bezoars are relatively uncommon causes of gastric outlet obstruction and chronic abdominal pain in children. Phytobezoars are made up of vegetable matter. Trichobezoars are made up of hair that is swallowed. This is referred to as the Rapunzel syndrome.<sup>55</sup> The hair usually fills the stomach and extends into the duodenum. However, it can extend to the ileum. Attempts at gastroscopic removal are usually futile, except in cases of small bezoars. The bezoar has been typically removed through a gastrotomy at laparotomy. However, there are recent reports of laparoscopic removal.<sup>56,57</sup> At our institution, we recently removed a large gastric trichobezoar laparoscopically with the aid of an endoscopic bag (Fig. 30-14).

**Figure 30-14.** A young girl presented with gastric outlet obstruction and was found to have a trichobezoar. The preoperative radiograph shows the outline of the bezoar in the stomach. **Inset**, The bezoar after removal.

# DUODENAL AND INTESTINAL ATRESIA AND STENOSIS

Pablo Aguayo, MD • Daniel J. Ostlie, MD

**C**ongenital intestinal obstruction occurs in approximately 1:2000 live births and is one of the most common causes of admission to a neonatal surgical unit, accounting for up to one third of all admissions.<sup>1</sup> Morphologically, congenital defects related to continuity of the intestine can be divided into either stenosis or atresia. Together, they constitute one of the most common causes of neonatal intestinal obstruction.<sup>2-4</sup>

## PYLORIC ATRESIA

Pyloric atresia is a rare congenital anomaly that occurs in approximately 1:100,000 live births and constitutes less than 1% of all gastrointestinal atresias.<sup>5,6</sup> Although usually occurring as an isolated lesion, an associated congenital anomaly rate of 30% to 44% has been reported. Epidermolysis bullosa is the most common associated lesion, but associations with aplasia cutis congenita and multiple intestinal atresias have also been found.<sup>7-12</sup> Familial occurrence has also been reported, with a suggestion of autosomal recessive transmission.<sup>11</sup>

Three anatomic variants of pyloric atresia have been described. In type I, there is a mucosal membrane or web. In type II, the pyloric channel is a solid cord (Fig. 31-1). In type III, there is a gap between the stomach and the duodenum.<sup>6</sup> Clinically, neonates with pyloric atresia present with nonbilious vomiting. There is a single stomach bubble in 98%, polyhydramnios in 63%, and epigastric distention in 68%.<sup>13</sup> The diagnosis is made with the appearance on plain abdominal radiographs of a solitary gas-filled bubble representing the distended stomach with no distal air in the gastrointestinal tract (see Fig. 31-1). A long, stretched-out beak at the pylorus is regarded as a pathognomonic sign of complete pyloric obstruction.<sup>14</sup> The differential diagnosis includes proximal duodenal atresia, malrotation with midgut volvulus,

gastric volvulus, pyloric duplication, retrograde duodenogastric intussusception, and aberrant pancreatic tissue plugging the pylorus.<sup>15-17</sup>

The operative management of pyloric atresia depends on the anatomic type. The recommended treatment for a pyloric web (type I) is excision with Heinecke-Mikulicz pyloroplasty. For solid pyloric atresia (types II or III), a Finney or Heinecke-Mikulicz pyloroplasty is performed if the atresia is short. A Billroth I gastroduodenostomy may be needed if the solid core or gap is long.<sup>13,18</sup> Reports of successful treatment of solid segment atresias with gastroduodenal mucosal advancement have also been described.<sup>19</sup> Gastrojejunostomy should be avoided because there is a 60% failure rate and a reported mortality rate of 55%.<sup>20</sup>

Long-term outcomes in cases of isolated pyloric atresia are excellent. However, cases of pyloric atresia associated with epidermolysis bullosa are usually fatal, with death occurring from septicemia, electrolyte imbalances, protein loss, and failure to thrive secondary to the exudative skin lesions. Reported cases of long-term survival of neonates with epidermolysis bullosa and surgically treated pyloric atresia exist.<sup>21</sup> Therefore, aggressive surgical intervention for these patients should not be withheld.

## DUODENAL ATRESIA AND STENOSIS

Congenital duodenal atresia and stenosis is a frequent cause of intestinal obstruction, occurring in 1 per 5000 to 10,000 live births and affecting boys more commonly than girls.<sup>22</sup> More than 50% of affected patients have associated congenital anomalies, with trisomy 21 occurring in approximately 30% of patients.<sup>23,24</sup> At present, either laparoscopic or open duodenoduodenostomy, with or without tapering duodenoplasty, has become standard with early postoperative survival rates of greater than 90%.<sup>24-31</sup>

**Figure 31-1.** A, Abdominal radiograph of a newborn with pyloric atresia. The diagnosis is made by the large single gastric bubble with no distal intestinal air. B, Laparoscopic view of the stomach in this infant with pyloric atresia. The entire length of the pylorus was a solid core and required resection with a Billroth I reconstruction. The infant has recovered uneventfully.

## Etiology

Congenital duodenal obstruction can present due to an intrinsic or extrinsic gastrointestinal lesion.<sup>32</sup> The most common cause of duodenal obstruction is atresia.<sup>24</sup> This intrinsic lesion is most commonly believed to be caused by a failure of recanalization of the fetal duodenum, resulting in complete obstruction. Early in the 4th week of gestation, the duodenum begins to develop from the distal foregut and the proximal midgut. During the 5th and 6th weeks of gestation, the duodenal lumen temporarily obliterates owing to proliferation of its epithelial cells. Vacuolation due to degeneration of the epithelial cells during the 11th week of gestation then leads to recanalization of the duodenum.<sup>33</sup> An embryologic insult during this period can lead to an intrinsic web, atresia, or stenosis. The extrinsic form of duodenal obstruction is due to defects in the development of neighboring structures such as the pancreas, a preduodenal portal vein, or secondary to malrotation and Ladd's bands.<sup>34,35</sup>

Although annular pancreas is an uncommon etiology for duodenal obstruction, it warrants special mention because this form of obstruction is likely due to failure of duodenal development rather than a true constricting lesion. Thus, the presence of an annular

pancreas is simply a visible indicator for an underlying stenosis or atresia.<sup>27,36</sup> Between the fourth and eighth weeks of gestation, the pancreatic buds merge. In annular pancreas, the tip of the ventral pancreas becomes fixed to the duodenal wall forming a non-distensible, ring-like or annular portion of pancreatic tissue surrounding the descending part of the duodenum.<sup>33</sup> In annular pancreas associated with duodenal obstruction, the distal biliary tree is often abnormal and may open proximal or distal to the atresia or stenosis.<sup>37,38</sup> Other reported biliary abnormalities associated with duodenal obstruction include biliary atresia, gallbladder agenesis, stenosis of the common bile duct, and choledochal cyst.<sup>39-44</sup>

## Classification

Anatomically, duodenal obstructions are classified as either atresias or stenoses. An incomplete obstruction due to a fenestrated web or diaphragm is considered a stenosis. Most stenoses involve the third and/or fourth part of the duodenum. Atresias, or complete obstruction, are further classified into three morphologic types (Fig. 31-2). Type I atresias account for more than 90% of all duodenal obstructions and contain a

**Figure 31-2.** Duodenal atresia (and stenosis) is depicted. In type I, either a membrane (B) or web (C) causes the intrinsic duodenal obstruction. There is no fibrous cord and the duodenum remains in continuity. Type II is characterized by complete obliteration of a segment of the duodenum with the proximal and distal portions attached via a fibrous cord. Type III is associated with complete separation of the dilated proximal duodenum from the collapsed distal duodenum.

**Figure 31-3.** Illustration of the “windsock” deformity, a variant of type I duodenal atresia. Note the actual position of the origin of the web in relation to the extent of proximal duodenal dilation and the distal collapsed duodenum.

luminal diaphragm that includes mucosal and submucosal layers. A diaphragm that has ballooned distally (“windsock”) is a type I atresia.<sup>45,46</sup> The “windsock” deformity is of particular concern because a portion of the dilated duodenum may actually be distal to the actual obstruction (Fig. 31-3). Type II atresias are characterized by a dilated proximal and collapsed distal segment connected by a fibrous cord. Type III atresias have an obvious gap separating the proximal and distal duodenal segments.<sup>47</sup>

More than 50% of affected patients with duodenal atresia have associated congenital anomalies.<sup>48</sup> Approximately 30% are associated with trisomy 21, 30% with isolated cardiac defects, and 25% with other gastrointestinal anomalies.<sup>49,50</sup> Approximately 45% of patients are premature, and about one third exhibit growth retardation.<sup>23,24</sup>

## Pathology

The obstruction can be classified as either preampullary or postampullary with approximately 85% of obstructions located distal to the ampulla of Vater.<sup>51</sup> With complete or almost complete obstruction, the stomach and proximal duodenum become significantly dilated. The pylorus is usually both distended and hypertrophic. As expected, the bowel distal to the obstruction is collapsed. The exception is a “windsock” deformity, where the distal bowel is dilated to a variable length depending on the length of the “windsock” (see Fig. 31-3). In most cases of duodenal obstruction, the gastrointestinal tract can be decompressed proximally, with perforation rarely occurring.<sup>52</sup> With complete obstruction of the duodenum, the incidence of polyhydramnios ranges from 32% to 81%.<sup>1,52-55</sup> Growth retardation is also common, presumably from nutritional deprivation from the swallowed amniotic fluid.

## Diagnosis

There are multiple benefits to the antenatal diagnosis of duodenal obstruction including parent counseling and further investigations to exclude associated congenital abnormalities. The diagnosis can often be suggested by prenatal ultrasonography. Sonographic evaluation in fetuses of mothers with a history of polyhydramnios

can detect two fluid-filled structures consistent with a double bubble in up to 44% of cases.<sup>56-58</sup> Although most cases of duodenal atresia are detected at between 7 and 8 months of gestation, one report described duodenal obstruction before the 20th week of gestation.<sup>59</sup> Despite duodenal obstruction usually occurring by week 12, the reason for failure of early prenatal detection is not entirely clear. The prevailing thought is that immature gastric emptying may contribute to low gastric pressures failing to dilate the proximal duodenum until later in gestation. Both circular and longitudinal muscle layers are present in the stomach by week 8 of gestation, but pressure amplitudes at 25 weeks are only 60% of term gastric pressures.<sup>60,61</sup>

Clinically, the presentation of the neonate with duodenal obstruction varies depending on whether the obstruction is complete or incomplete, and on the location of the ampulla of Vater in relation to the obstruction. The classic presentation is that of bilious emesis within the first hours of life in an otherwise stable neonate. In about 10% of cases, however, the atresia is preampullary and the emesis is nonbilious.<sup>35</sup> Abdominal distention may or may not be present. In neonates with duodenal atresia, the abdomen is scaphoid. Aspiration via a nasogastric tube of more than 20 mL of gastric contents in a newborn suggests intestinal obstruction as normal aspirate is less than 5 mL.<sup>62</sup> For patients with stenosis, the diagnosis is often delayed until the neonate has started on enteral feeds and feeding intolerance develops with emesis and gastric distention. A delay in diagnosis can result in dehydration and acid-base disorders.

**Figure 31-4.** Classic “double bubble” sign. This abdominal radiograph in a newborn shows a markedly distended stomach and duodenal bulb without evidence of distal intestinal air.

**Figure 31-5.** Variations in biliary ductal anatomy seen in infants with duodenal atresia.

In antenatally suspected cases of duodenal obstruction, as well as in neonates with a clinical presentation consistent with a proximal bowel obstruction, an upright abdominal radiograph is usually sufficient to confirm the diagnosis of duodenal atresia. The diagnostic radiographic presentation of duodenal atresia is that of a “double bubble” sign with no distal bowel gas (Fig. 31-4). The proximal left-sided bubble represents the air- and fluid-filled stomach, whereas the dilated proximal duodenum represents the second bubble to the right of midline.<sup>63</sup> In almost all cases of duodenal atresia, the distal bowel is gasless. The presence of distal gas, however, does not

necessarily exclude the diagnosis of atresia because there are reports of bifid common bile ducts with an insertion both proximal and distal to the atretic segment allowing the air to bypass the atresia.<sup>64</sup> In neonates whose stomach has been decompressed by either nasogastric aspiration or vomiting, 40 to 60 mL of instilled air into the stomach will reproduce the “double bubble.”<sup>47</sup> Rarely, the biliary tree is air filled, and a variety of pancreatic and biliary anomalies have been demonstrated (Fig. 31-5).<sup>64</sup> At our institution, neonates who present with bilious emesis and a decompressed stomach on plain abdominal films receive a limited upper gastrointestinal contrast study to exclude malrotation and volvulus. With duodenal stenosis, a “double bubble” sign is usually not present and the diagnosis is usually made with a contrast study (Fig. 31-6).

**Figure 31-6.** An upper gastrointestinal contrast study is shown illustrating a duodenal web. Contrast medium outlines the markedly dilated proximal duodenum (D) with a collapsed distal segment. Note the absence of contrast agent at the location of the tiny web (arrow). P, pylorus.

## Management

After the diagnosis is made, appropriate resuscitation is required with correction of fluid balance and electrolyte abnormalities in addition to gastric decompression. At our institution, all neonates diagnosed with duodenal obstruction receive a complete metabolic profile, complete blood cell count, coagulation studies, an abdominal and spinal ultrasound evaluation, and two-dimensional echocardiography before any surgical intervention. Emergent surgery is only performed in cases in which malrotation with concurrent volvulus cannot be excluded.

Prior to the mid 1970s, duodenojejunostomy was the preferred technique for correcting duodenal atresia or stenosis.<sup>24,65,66</sup> The various techniques utilized since then include side-to-side duodenoduodenostomy, diamond-shaped duodenoduodenostomy, partial web resection with Heineke-Mikulicz-type duodenoplasty, and tapering duodenoplasty.<sup>65-67</sup> The long side-to-side duodenoduodenostomy, although effective, is associated with a high incidence of anastomotic dysfunction and prolonged obstruction.<sup>50</sup> Blind-loop syndrome appears to be more common in patients treated with duodenojejunostomy.<sup>68</sup> Gastrojejunostomy should not be performed because it is associated with a high incidence of marginal ulceration and bleeding.<sup>47</sup>

**Figure 31-7.** A and B, The technique of duodenoduodenostomy. A diamond-shaped anastomosis is created via the proximal transversely oriented and distal vertically oriented duodenotomies.

Today, the procedure of choice is either laparoscopic or open duodenoduodenostomy.<sup>29-31,50</sup> Originally, a side-to-side anastomosis was performed. Currently, a proximal transverse to distal longitudinal, or diamond-shaped, anastomosis is preferred.<sup>24,65,66,69,70</sup> For the open approach, a right upper quadrant supraumbilical transverse incision is made. After mobilizing the ascending and transverse colons to the left, the duodenal obstruction is readily exposed. Malrotation should be evaluated at this point because it can occur in association with congenital duodenal obstruction in up to 30% of patients.<sup>1</sup> A sufficient length of duodenum distal to the atresia is mobilized to allow for a tension-free anastomosis. A transverse duodenotomy is made in the anterior wall of the distal portion of the dilated proximal duodenum, and a duodenotomy of similar length is made in a vertical orientation on the antimesenteric border of the distal duodenum. The anastomosis is then fashioned by approximating the end of each incision to the appropriate midportion of the other incision (Fig. 31-7).<sup>71</sup> Tapering duodenoplasty is usually not necessary as the proximal duodenal dilation frequently resolves after relief of the obstruction. Muscular continuity of the duodenal wall suggests a

“windsock” deformity of diaphragm and calls for extra vigilance in the operative correction, because dilated and collapsed bowel, both distal to the “windsock,” have been anastomosed in error.<sup>45,72</sup>

The laparoscopic approach was first described by Rothenberg.<sup>29</sup> The standard laparoscopic approach begins with the patient supine, and the abdomen is insufflated through the umbilicus. Two other instruments are inserted: one in the infant’s right lower quadrant and one in the right midepigastriac region. A liver retractor can be placed in the right or left upper quadrant if necessary. Alternatively, the liver can be elevated by placing a transabdominal wall suture around the falciform ligament and tying it outside the abdomen (Fig. 31-8). The duodenum is mobilized, and the location of obstruction is identified. By using the same principles that have been described for the open approach, a standard diamond-shaped anastomosis is created. Although some surgeons will perform the laparoscopic anastomosis with interrupted sutures, this can be technically demanding because of the significant number of sutures required. We recently reported our results using Nitinol U-clips (Medtronic, Minneapolis, MN) to create the duodenoduodenostomy with no leaks and more rapid initiation of feeds when compared with the traditional open approach (Fig. 31-9).<sup>30,31</sup> The main advantage of using U-clips is a reduction in the time to complete the anastomosis.

Early postoperative mortality for duodenal atresia repair has been reported to be as low as 3% to 5%, with the majority of deaths occurring secondary to complications related to associated congenital abnormalities.<sup>73</sup> Long-term survival approaches 90%.<sup>24,74-76</sup> Long-term complications have been noted after repair and include delayed gastric emptying, severe gastroesophageal reflux, bleeding peptic ulcer, megaduodenum, duodenogastric reflux, gastritis, blind-loop syndrome, and intestinal obstruction related to adhesions.<sup>50</sup>

**Figure 31-8.** Two approaches to placement of the instruments for a laparoscopic duodenal atresia repair. A, The two right-sided instruments are the primary working sites for the surgeon. The liver retractor (arrow) has been placed in the left midepigastriac region. The falciform ligament has been elevated by a suture placed under it and tied over the red rubber catheter, which is used as a bolster. The suture (dotted arrow) exteriorized in the infant’s left upper abdomen was placed in the dilated proximal duodenum so that it could be easily manipulated. B, This is a similar configuration except the instrument elevating the liver (arrow) is placed in the infant’s right upper abdomen rather than the left upper abdomen. The suture that was placed through the proximal dilated duodenum in A was not needed in this particular case.

**Figure 31-9.** A, Laparoscopic view of a completed duodenoduodenostomy using the Nitinol U-clips. B, A postoperative contrast study at 5 days showed no evidence of obstruction or leak at the anastomosis. The U-clips (arrow) can be seen marking the anastomosis.

## JEJUNOILEAL ATRESIA AND STENOSIS

### Etiology

Jejunioleal atresia occurs in approximately 1 in 5000 live births. It occurs equally in males and females, and about one in three infants is premature.<sup>73</sup> Although the majority of cases are thought to occur sporadically, familial cases of intestinal atresias have been reported.<sup>77</sup> It is generally accepted that jejunioleal atresia occurs as a result of an intrauterine ischemic insult to the midgut affecting single or multiple segments of the already developed intestine.<sup>33,73,78-84</sup> Intrauterine vascular disruption can lead to ischemic necrosis of the bowel with subsequent resorption of the affected segment or segments (Fig. 31-10).

The hypothesis that most cases of jejunioleal atresia occur secondary to vascular disruption during fetal life has been derived from experimental as well as clinical evidence. Isolated mesenteric vascular insults and interference with the segmental blood supply to the small intestine were created in fetal dogs and resulted in different degrees and patterns of intraluminal obstruction, reproducing the spectrum of stenosis and atresia found in humans.<sup>81-83,85-88</sup> Moreover, the presence of bile, lanugo hair, and squamous epithelial cells from swallowed amniotic fluid distal to an atresia, as well as evidence of intrauterine fetal intussusception, midgut volvulus, thromboembolic occlusions, transmesenteric internal hernias, and incarceration or snaring of bowel in an omphalocele or gastroschisis have contributed to wide acceptance of this hypothesis.<sup>79,88-93</sup>

The presence of associated extra-abdominal organ abnormalities in jejunioleal atresia is low (<10%), owing to its occurrence later in fetal life and the localized nature of the vascular compromise.<sup>94,95</sup> In rare instances, jejunioleal atresia has been found to be associated with Hirschsprung's disease, cystic fibrosis, malrotation, Down syndrome, anorectal and vertebral anomalies, neural tube defects, congenital heart disease, and other gastrointestinal atresias.<sup>73,94-96</sup> Methylene blue, previously used for amniocentesis in twin

pregnancies, has been implicated in causing small bowel atresia.<sup>97</sup>

Although jejunioleal atresias are usually not hereditary, there is a well-documented autosomal recessive

**Figure 31-10.** Proposed mechanism of vascular compromise and subsequent development of jejunioleal atresia.

pattern of inheritance of multiple atresias first documented in Montreal and later identified elsewhere.<sup>98</sup> In these cases of inherited jejunoileal atresia, rotation was normal, mesenteric defects were never observed, and lanugo hairs and squamous cells were not identified distal to the most proximal atresia, suggesting an early intrauterine event. This disorder is uniformly lethal even with successful bowel resection. No correlations have been found between jejunoileal atresia and parental or maternal disease. However, the use of maternal vasoconstrictive medications as well as maternal cigarette smoking in the first trimester of pregnancy has been shown to increase the risk of small bowel atresia.<sup>99</sup> Chromosomal abnormalities are seen in less than 1% of the patients.<sup>100</sup>

## Pathology

Following the Grosfeld classification, the defects of jejunoileal atresia are separated into four groups based on the type of atresia, with an additional consideration for type III(b) ("apple peel" or "Christmas tree" appearance) (Fig. 31-11E).<sup>4</sup> This classification has significant prognostic and therapeutic value because it emphasizes

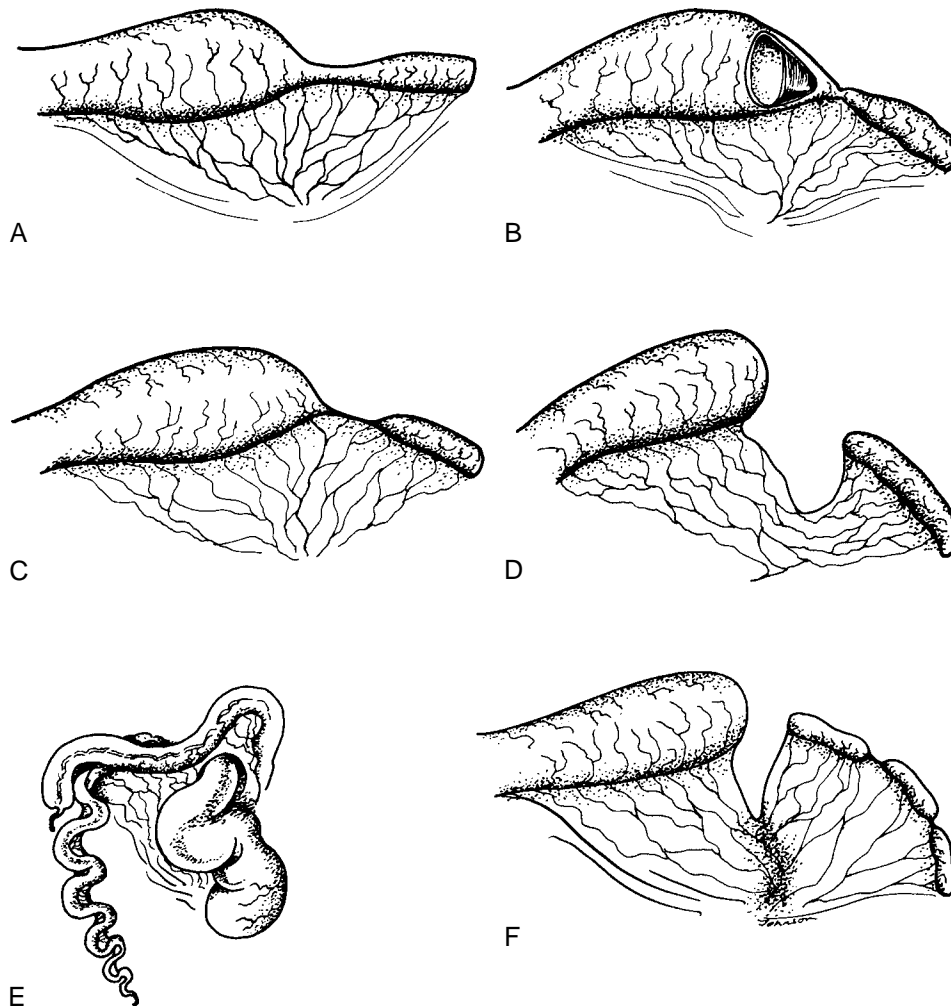

the importance of associated loss of intestinal length, abnormal collateral intestinal blood supply, and concomitant atresia or stenosis.<sup>101</sup> Regarding classification, the most proximal atresia determines whether the atresia is classified as jejunal or ileal atresia. Multiple atresias are found in up to 30% of patients.<sup>73,102</sup>

## Stenosis

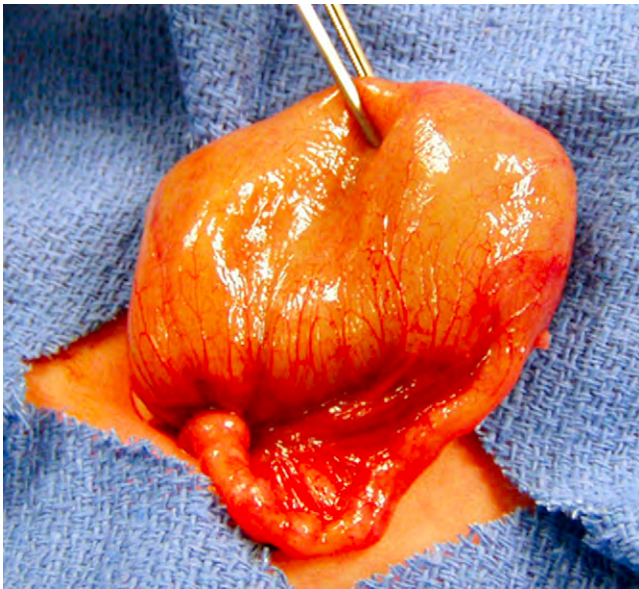

*Stenosis* is defined as a localized narrowing of the intestinal lumen without disruption in the intestinal wall or a defect in the mesentery (see Fig. 31-11A). At the stenotic site, a short, narrow, somewhat rigid segment of intestine with a small lumen is found. Often the muscularis is irregular and the submucosa is thickened. Stenosis may also take the form of a type I atresia with a fenestrated web. Patients with jejunoileal stenosis usually have a normal length of small intestine.

## Type I Atresia

In type I atresia, the intestinal obstruction occurs secondary to a membrane or web formed by both mucosa and submucosa while the muscularis and

**Figure 31-11.** The classification for jejunoileal atresia and stenosis. A, Stenosis. B, Type I. C, Type II. D, Type III(a). E, Type III(b). F, Type IV.

**Figure 31-12.** In this infant with abdominal distention and evidence of a congenital bowel obstruction, a type I jejunal atresia was found. Note the mesentery is intact and the small, distal jejunum is connected to the very dilated, proximal jejunum.

serosa remain intact (see Figs. 31-11B and 31-12). On gross inspection, the bowel and its mesentery appear to be in continuity. However, the proximal bowel is dilated while the distal bowel is collapsed. With the increased intraluminal pressure in the proximal bowel, bulging of the web into the distal intestine can create a windsock effect. As with stenosis, there is no foreshortening of the bowel in type I atresias.

### Type II Atresia

The clinical findings of a type II atresia are a largely dilated, blind-ending proximal bowel loop connected by a fibrous cord to the collapsed distal bowel with an intact mesentery (see Fig. 31-11C). Increased intraluminal pressure in the dilated and hypertrophied proximal bowel may lead to focal proximal small bowel ischemia. The distal collapsed bowel commences as a blind end, which sometimes assumes a bulbous appearance owing to the remains of an intussusception. Again, the total small bowel length is usually normal.

### Type III(a) Atresia

In type III(a) atresia, the atresia ends blindly with no fibrous connecting cord to the distal intestine. A V-shaped mesenteric defect of varying size is present between the two ends of intestine (see Figs. 31-11D and 31-13). The dilated, blind-ending proximal bowel is often aperistaltic and frequently undergoes torsion or becomes overdilated, with subsequent necrosis and perforation occurring as a secondary event.<sup>103</sup> In this scenario, the total length of the small bowel is variable (but usually less than normal), owing to intrauterine resorption of the affected bowel.

**Figure 31-13.** In this infant with congenital small bowel obstruction, a type III(a) jejunal atresia was found. Note the atresia ends blindly without a connection to the distal intestine. Moreover, there is a V-shaped mesenteric defect between the two segments of intestine.

### Type III(b) Atresia

Type III(b) atresia (“apple peel,” “Christmas tree,” or “maypole” deformity) consists of a proximal jejunal atresia, absence of the superior mesenteric artery beyond the origin of the middle colic branch, agenesis of the dorsal mesentery, a significant loss of intestinal length, and a large mesenteric defect (see Fig. 31-11E). The decompressed distal small bowel lies free in the abdomen and assumes a helical configuration around a single perfusing vessel arising from the ileocolic or right colic arcades (Fig. 31-14). Occasionally, additional type I or type II atresias are found distally. Also,

**Figure 31-14.** The operative findings in a neonate with type III(b) intestinal atresia are seen. Note the classic “apple core” or “Christmas tree” deformity associated with a type III(b) atresia and the wide mesenteric gap between the proximal dilated bowel and distal decompressed ileum. Also, the colon and distal small bowel are perfused through a single artery running through the coils of the bowel.

the vascularity of the distal bowel is often impaired. This type of atresia has been found in families with a pattern suggestive of an autosomal recessive mode of inheritance. It also has been encountered in siblings with identical lesions and in twins.<sup>84,103-107</sup>

The occurrence of intestinal atresia in other siblings, the association of multiple atresias (15%), and the discordance in a set of apparently monozygotic twins may point to more complex genetic transmission with an overall recurrence rate of 18%.<sup>104,108-110</sup> Infants with this anomaly are often premature. Up to 50% may have malrotation. Short bowel syndrome is present in nearly 75% of cases. Accordingly, there is increased morbidity (63%) and mortality (54%) in this population.<sup>104,111</sup> Type III(b) atresias are most likely the consequence of a proximal superior mesenteric arterial occlusion with extensive infarction of the proximal segment of the midgut. Also, it can develop from a midgut volvulus.<sup>79,104,105,112</sup> Primary failure of development of the distal superior mesenteric artery has also been suggested as an etiologic factor. However, this is unlikely because meconium is usually found in the bowel distal to the atresia. This finding indicates that the atresia develops after bile secretion begins, which occurs around week 12 of intrauterine life. The superior mesenteric artery develops much earlier than 12 weeks.<sup>113</sup>

#### Type IV Atresia

Multiple-segment atresias or a combination of types I to III are classified as type IV (see Fig. 31-11F). Twenty to 35 percent of infants affected with jejunoileal atresia present with multiple atresias.<sup>73,102</sup> A familial form of multiple intestinal atresia involving the stomach, duodenum, and both the small and large bowel has been described.<sup>98,114</sup> It is associated with prematurity and shortened bowel length. To date, it has been uniformly fatal. It is associated with type I and II atresias, with type II predominating. An autosomal recessive mode of transmission has been suggested for this familial form of hereditary multiple intestinal atresia because it is unlikely that an isolated prenatal vascular accident would be responsible for such extensive involvement of the gastrointestinal tract. In addition, infants affected with this familial form are found to have long segments of completely occluded small or large intestine without a recognizable lumen.<sup>114-116</sup> Another pathognomonic feature seen in familial multiple intestinal atresia is the sieve-like appearance of the intestine on histologic examination in which multiple lumens are surrounded by epithelial cells and muscularis mucosa.<sup>102</sup>

The majority of cases of multiple-segment atresias are sporadic with no other family history of gastrointestinal defects. They are likely a result of multiple vascular insults to the mesentery, intrauterine inflammatory processes, or a malformation of the gastrointestinal tract occurring during embryonic development.<sup>102,117</sup> Embolic material from a nonviable fetus to a living monozygotic twin through placental vascular connections could also account for single or multiple intestinal atresias.<sup>118</sup> Associated defects, particularly

abnormalities of the central nervous system, have been noted in approximately 25% of patients without familial multiple intestinal atresia.<sup>102</sup> Multiple atresias have also been seen in association with severe immunodeficiency.<sup>119</sup>

#### Pathophysiology

The vascular and subsequent ischemic insult not only causes morphologic abnormalities but also adversely influences the structure and subsequent function of the remaining proximal and distal bowel.<sup>78-81,84,120</sup> The blind-ended proximal bowel is dilated and hypertrophied with histologically normal villi, but without effective peristaltic activity. A deficiency of mucosal enzymes and muscular adenosine triphosphatase has also been found. At the level of the atresia, the ganglia of the enteric nervous system are atrophic with minimal acetylcholinesterase activity. These changes are most likely secondary to local ischemia.<sup>84,121</sup> Obstruction alone can elicit similar, but less severe, morphologic and functional abnormalities.<sup>122</sup>

Immunohistochemical stains of human intestinal tissue have revealed discrepancies of neural components both proximal and distal to the atretic intestinal segment. Quantification of the density of the myenteric plexus during the antenatal period has shown a decreased density proximal to the atresia despite an increase in the number of glial cells when compared with gestational age-matched controls.<sup>88</sup> Thus, these results cannot be ascribed solely to distention and obstruction proximal to the atresia. Similarly, staining for neurons and ganglion cells in the myenteric plexus was significantly decreased in the proximal and distal segments, suggesting a perturbation in the maturation of different components of the enteric nervous system.<sup>88</sup>

Experimental studies showing that the intestinal atresia results from ischemic necrosis of the intestine also imply that there is a precarious blood supply to the proximally dilated bowel. This has been confirmed with postmortem injection of barium sulfate into the mesenteric vessels.<sup>79,81,113</sup> However, it has also been postulated that the intestine is not ischemic at birth but rather becomes so only with swallowing air. Distention and increased intraluminal pressure or torsion can then occur. The good results obtained with tapering procedures without resection of the bulbous portion would support the contention that the blood and nerve supply to the bowel adjacent to the atresia is normal.<sup>79</sup> However, this ischemic insult may interfere with mucosal and neural function. Defective peristalsis is commonly noticed in the atretic area, thus supporting resection of the dilated bulbous proximal end for better function. Because the proximal end of the distal atretic bowel has been subjected to a similar insult, a small portion of it should be resected at the time of surgical correction as well.

Insufficient bowel length, excessive removal of residual bowel, or ischemic insult to the remaining bowel can lead to short gut syndrome with long-term sequelae for growth and development. Postoperative complications or the inappropriate use of hyperosmolar feeding or medication can predispose to these complications as well.

## Clinical Manifestations

Prompt recognition of intestinal obstruction in the neonate is paramount due to the possibility of midgut volvulus or an internal hernia with subsequent ischemia. Although ultrasonography is more reliable at detecting duodenal atresia, in recent years it has become useful in diagnosing jejunoileal atresia as well. The ultrasonographic findings include dilated loops of bowel and polyhydramnios. Polyhydramnios may not be present early in gestation or with very distal obstructions. Although these findings may be suggestive of atresia, they are not pathognomonic and other diagnoses must be entertained. However, abnormal findings should elicit a search for familial gastrointestinal abnormalities as well as referral for prenatal evaluation. The vast majority of patients with jejunoileal atresia will not be diagnosed prenatally.

Type III(b) and multiple intestinal atresias also have a familial tendency. A 3.4% incidence of anomalies in siblings has been reported in a large survey of children with jejunoileal atresias as well as an 18% recurrence rate in siblings of patients with multiple intestinal atresias.<sup>104,111</sup>

In neonates with atresia or stenosis, the presenting symptoms are consistent with bowel obstruction, including bilious emesis and abdominal distention. Although the meconium may appear normal, it is more common to see gray plugs of mucus passed via the rectum.<sup>123</sup> Occasionally, if the distal bowel in type III(b) atresia is ischemic, blood may be passed through the rectum.

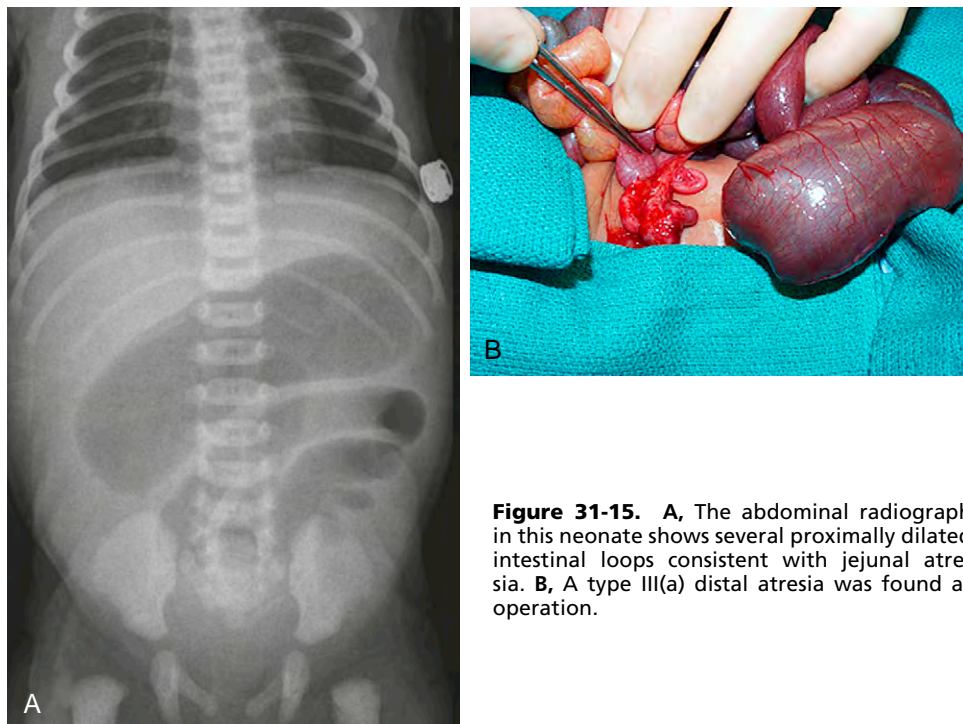

Intestinal stenosis is more likely to create diagnostic difficulty when compared with intestinal atresia.

Intermittent partial obstruction or malabsorption may improve without treatment.<sup>89,124,125</sup> Clinical investigations may initially be normal. However, these infants usually develop failure to thrive and ultimately progress to complete intestinal obstruction and require exploration.

## Diagnosis

The diagnosis of jejunoileal atresia can usually be made by radiographic examination of the abdomen with only swallowed air as contrast.<sup>124,125</sup> Swallowed air reaches the proximal bowel by 1 hour and the distal small bowel by 3 hours in a normal vigorous infant in whom its passage is blocked, but this pattern may be delayed in premature or sick infants with poor sucking.<sup>126,127</sup> Jejunal atresia patients have a few gas-filled and fluid-filled loops of small bowel, but the remainder of the abdomen is gasless (Fig. 31-15). When the atresia is associated with cystic fibrosis, fewer air-fluid levels are evident, and the typical ground-glass appearance of inspissated meconium is present. A limited-contrast meal may be useful if intestinal stenosis is suspected.

Because haustral markings are rarely seen in neonates, distal ileal atresia may be difficult to differentiate from colonic atresia (Fig. 31-16). A contrast enema reveals an unused appearance to the colon. Reliance on intraoperative injection of saline into the large bowel to confirm distal bowel patency may fail to identify an associated colonic or rectal atresia.<sup>128,129</sup> If the small bowel atresia occurred late in gestation, the bowel distal to the atresia may have a more normal caliber. Occasionally, air and meconium can accumulate proximal to an atresia, mimicking the radiologic appearance

**Figure 31-15.** A, The abdominal radiograph in this neonate shows several proximally dilated intestinal loops consistent with jejunal atresia. B, A type III(a) distal atresia was found at operation.

**Figure 31-16.** The diagnosis of colonic atresia can be difficult on the plain abdominal radiograph. This radiograph shows multiple dilated intestinal loops and appears similar to the findings shown in Figure 31-15. At operation, the infant was found to have atresia of the transverse colon (see Fig. 31-19).

of meconium ileus. Additionally, total colonic aganglionosis may be difficult to differentiate from atresia.

Ten percent of infants with jejunoileal atresia present with meconium peritonitis.<sup>4,125</sup> The intestinal perforation usually occurs proximal to the obstruction at the bulbous blind end. The radiologic appearance of a meconium pseudocyst containing a large air-fluid level is related to the late intrauterine perforation of bowel. Intraluminal calcification of meconium or intramural dystrophic calcification in the form of diffuse punctate or rounded aggregations has been reported with intestinal stenosis or atresia.<sup>130</sup> Meconium calcification in patients with hereditary familial multiple intestinal atresia produces a “string of pearls,” which is pathognomonic of this condition.<sup>98,116</sup>

The clinical and radiologic picture of jejunoileal stenosis is determined by the level and degree of stenosis. The diagnosis may be delayed for years.<sup>111,124</sup> Morphologic and functional changes in the proximal obstructed intestine vary depending on the degree of obstruction.

## Differential Diagnosis

Diseases that mimic jejunoileal atresia include colonic atresia, midgut volvulus, meconium ileus, duplication cysts, internal hernias, ileus due to sepsis, birth trauma, maternal medications, prematurity, and hypothyroidism.<sup>4,85,124,131,132</sup> Special investigations, including an upper gastrointestinal contrast study, contrast enema, rectal biopsy, and a  $\Delta F508$  gene deletion assay or

sweat test to exclude associated cystic fibrosis, may be needed.<sup>131,133</sup>

## Management

Delay in diagnosis may lead to impairment of intestinal viability (50%), frank necrosis and perforation (10% to 20%), fluid and electrolyte abnormalities, and sepsis.<sup>103,123,124</sup> Preoperative management involves insertion of a nasogastric or orogastric tube to decompress the stomach and fluid resuscitation to correct electrolyte abnormalities and hypovolemia. Antibiotics should be initiated if there is any concern for perforation or infection.

## Surgical Considerations

The surgical management of intestinal atresias is based on the location of the lesion, anatomic findings, associated conditions noted at operation, and the length of the remaining intestine.<sup>73</sup> Resection of the dilated and hypertrophied proximal bowel, with primary end-to-end anastomosis with or without tapering of the proximal bowel, is the most common surgical technique.<sup>4,79-81,85,103</sup>

As recently as the 1950s, the surgical mortality for neonates with intestinal atresia was 80% to 90%.<sup>85,124</sup> The poor prognosis early in the 20th century was mostly related to late presentation and dysmotility of the proximal dilated portion of the bowel, which led to complications related to chronic obstruction and inanition. The current survival rate is greater than 90%.<sup>73</sup> Understanding that the proximal bowel is dysfunctional, improvements in the anastomotic technique and suture material, and the development of total parenteral nutrition are the primary reasons for this significantly improved survival in recent years. Only infants with severe associated congenital abnormalities or short bowel syndrome should not have a good prognosis.

## Operative Considerations

The repair of small intestinal atresia can be undertaken via several approaches. One option is to evaluate using a laparoscopic approach, with subsequent resection and anastomosis performed in an extracorporeal fashion. Although this approach seems attractive, it can be difficult to identify the atresia due to the markedly dilated small intestine and the small working space of the neonate’s abdominal cavity. Because of these limitations, we have begun to explore the abdomen through the umbilicus. With this approach, the umbilical skin is incised and the fascia is opened vertically in the midline to the extent allowed by the umbilical skin incision. A Lonestar (CooperSurgical, Inc., Trumbull, CT) retractor can be inserted to obtain exposure and allow for evisceration of the bowel (Fig. 31-17). The traditional transverse supraumbilical or infraumbilical incision is also appropriate. Regardless of the approach, access to the entire intestine and peritoneal cavity is necessary. If perforation has

**Figure 31-17.** The operative approach through the umbilical ring allows for complete evaluation of the intestine and repair of an atresia. Shown here is the technique using the Lonestar retractor to maintain exposure during repair of a type IIIa jejunal atresia.

occurred, it should be controlled and the abdomen irrigated with normal saline. Careful inspection of the entire bowel is performed and the site and type of obstruction should be noted as well as any other abnormalities. In addition, the length of bowel should be assessed. The most distal limb of the atretic bowel should then be cannulated with a red rubber catheter and irrigated with warm saline to evaluate for distal obstruction. Continuity of the colon can be established preoperatively by a contrast enema or with a prepositioned transrectal catheter placed before prepping.<sup>134</sup> Failure to adequately evaluate for distal obstruction or stenosis can lead to postoperative complications such as an anastomotic leak. If present, malrotation should be corrected with a Ladd procedure. Because the length of functional bowel has important prognostic significance and determines the most appropriate method of repair, this length of functional bowel should be carefully measured along the antimesenteric border.

Delayed intestinal function in the blind proximal atretic segment as well as functional obstruction after performance of a side-to-side anastomosis without resection of the dilated proximal atretic bowel has been discussed.<sup>84,132</sup> In addition, it has been reported that the inciting ischemic event that led to the atresia may lead to a deficiency in mucosal enzymes for a distance of 10 to 20 cm proximal to the atresia.<sup>135</sup> Therefore, if the length of functional bowel is adequate, the bulbous hypertrophied proximal bowel should be resected to approximately normal-caliber bowel.<sup>79,103</sup> Ultimately, the goal is to restore bowel continuity while maintaining both intestinal function and length.<sup>84</sup> In high jejunal atresias, this proximal bowel resection may extend into the second portion of the duodenum, requiring de-rotation of the duodenum and mobilization of the right colon to the left. Intestinal imbrication has also been shown to be an effective method to reduce the caliber of the distended bowel while maintaining mucosal absorptive surface.<sup>136</sup> Distally, a short segment (4 to 5 cm) of the bowel is removed obliquely, leaving the mesenteric side longer than the antimesenteric aspect. An incision along the antimesenteric

**Figure 31-18.** The intestinal anastomosis in the infant seen in Figure 31-17 is shown. At the time of repair, there can be a significant size discrepancy between the proximal and distal bowel. The proximal bowel has been resected to a point that will allow for a more appropriately sized intestinal anastomosis.

border to create a “fish mouth” may be needed to create an adequate distal enterotomy for the anastomosis (Fig. 31-18).<sup>80,84,134</sup>

Although there are multiple techniques for the anastomosis, a one-layer modification of the end-to-back technique using 5-0 or 6-0 monofilament absorbable sutures has been shown to be safe and effective.<sup>100,103</sup> Once the anastomosis is completed, the suture line is tested for leaks and reinforcing sutures are placed as needed. The mesenteric defect is repaired with careful attention to avoid rotation or kinking of the anastomosis or injury to the blood supply. A temporary enterostomy should be performed in cases of perforation with significant contamination or meconium peritonitis or if there is a question of bowel viability.<sup>73</sup> However, neither decompressive gastrostomy nor transanastomotic stents are usually needed.<sup>137,138</sup>

Similar techniques are used for stenosis and jejunoileal membranes. Procedures such as transverse enteroplasty, excision of the membrane, and bypassing

techniques are not recommended, primarily because they fail to remove the abnormal segments of bowel and may produce blind-loop syndromes.

## Prognostic Factors

The normal small bowel length in term neonates is approximately 250 cm. In preterm infants, it ranges from 160 to 240 cm. With the development of total parenteral nutrition, special enteral diets, and pharmacologic management of short gut syndrome, previous estimates that a small bowel length of 100 cm or more is necessary to sustain oral intake and survival may no longer be applicable.<sup>81</sup> Regardless, preservation of bowel length at the expense of a poorly functioning anastomosis should be avoided.

If proximal resection will lead to significant, or unacceptable, bowel loss, tapering or plication of the dilated bowel is a useful technique.<sup>72,135-140</sup> Tapering enteroplasty as proximal as the second portion of the duodenum can be accomplished by resecting an antimesenteric strip of the dilated proximal bowel.<sup>141</sup> During tapering duodenojejunojejunoplasty, particularly with type III atresias, the duodenum is de-rotated and the cecum moved to the left to avoid kinking of the anastomosis.<sup>142</sup> The tapering can be safely performed up to 35 cm.<sup>140</sup> The tapered bowel may be anastomosed to the distal bowel or exteriorized as a stoma.

Plication or infolding along the antimesenteric border is preferred by some surgeons because it conserves mucosal surface area and may facilitate the return of bowel function.<sup>140</sup> Plication also reduces the risk of leak from the antimesenteric suture line that can occur with a tapering enteroplasty. More than 50% of the bowel circumference can be imbricated into the intestinal lumen over an extended length without causing obstruction. However, breakdown of the suture line results in a functional obstruction.<sup>73</sup> The plication may be less likely to disrupt if a longitudinal antimesenteric seromuscular strip is resected before the plication.<sup>143,144</sup>

A primary anastomosis may be contraindicated in cases of peritonitis, volvulus with vascular compromise, meconium ileus, and type III(b) atresia.<sup>145,146</sup> Under these circumstances, exteriorization of both ends of the atresia may be needed.

Atresia encountered in gastroschisis may be single or multiple and may be located in either the small or large bowel.<sup>91</sup> In a series from our institution, 12.6% of 199 patients with gastroschisis had an associated atresia.<sup>147</sup> The most common location for the atresia was jejunoileal, and most were type III(a). Our current management algorithm for patients with gastroschisis and atresia is to first assess the extent of reactive change of the intestine (peel). If there is minimal intestinal peel, a primary anastomosis may be considered. This is rare and should be considered only in the most optimal situations. In most instances, the atresia should be left undisturbed at the initial operation. After fascial closure is accomplished, management should include nasogastric decompression and total parenteral nutritional

support with subsequent repair of the atresia 4 to 6 weeks later.<sup>147</sup>

Although isolated type I atresias are usually managed by primary resection and anastomosis, multiple diaphragms have been successfully perforated and dilated by passing a bougie along the entire length of the small intestine.<sup>80,111</sup>

With type III(b) atresia, restricting bands along the free edge of the distal coiled and narrow mesentery should be divided to optimize the blood supply. The bowel should be returned to the abdomen with careful inspection of the mesentery to prevent torsion of the single marginal artery and vein.<sup>148</sup> In cases of questionable intestinal viability, improved long-term results have been achieved with resection and tapering of the dilated proximal bowel with limited resection of the distal bowel.<sup>149,150</sup>

Bowel length conservation methods, such as multiple anastomoses for multiple atresias, may result in increased morbidity.<sup>81,123</sup> An absorbable silicone (Silastic) catheter stent can be used with multiple primary anastomoses and serves as a conduit for radiologic evidence of anastomotic integrity, luminal patency, and enteral feeding.<sup>151</sup> If multiple atresias are grouped closely together and there is adequate bowel length, a single resection and anastomosis can be performed.<sup>134</sup>

There is no place for bowel lengthening procedures at the initial operation. However, such procedures may ultimately obviate the need for prolonged total parenteral nutrition in patients with short gut syndrome associated with intestinal atresias.

## Postoperative Care

Parenteral nutrition is mandatory and should begin as soon as possible. It should continue until the infant is tolerating full enteral feeding.

The return of bowel function varies. Generally, a more proximally located anastomosis takes longer to function. Enteral feedings can be initiated when the gastric aspirate is clear, output is minimal, and the infant is producing stools. At our institution, enteral feeding is usually started through the nasogastric feeding tube at a rate of 20 mL/kg/day of breast milk or formula in a continuous fashion. The feeds are increased by 20 to 30 mL/kg/day. Oral intake is started when the infant is alert, able to suck, and tolerating at least 8 mL of tube feeds per hour.

Any clinical findings suggestive of an anastomotic leak require immediate re-exploration. At operation, it is important to once again confirm patency of the distal bowel.

Transient gastrointestinal dysfunction is frequently observed in infants with jejunal and ileal atresia, and its etiology is multifactorial.<sup>4,89,103,152</sup> Lactose intolerance, malabsorption (owing to stasis with bacterial overgrowth), and diarrhea may be significant in infants who have undergone repair of type III(b) atresia or in those with short bowel syndrome after surgery for multiple atresias. Regular monitoring for clinical signs of intestinal overload or intolerance is required. Water-loss stools, increasing frequency of

stooling, hematochezia, fecal-reducing substances, or a decreased stool pH warrant biochemical evaluation of the stool for disaccharide or monosaccharide intolerance.<sup>153</sup> Unintentional injury to the mucosa can be caused by sugars, high-osmolality feeds, oral medications, and bacterial or viral infections. Pharmacologic control of altered gastrointestinal function may hasten adaptation. Loperamide decreases intestinal peristaltic activity, and cholestyramine is effective in binding bile salts.<sup>152,154</sup> Cholestyramine should not be used unless water-loss stools are evident. Vitamin B<sub>12</sub> and folic acid should be given regularly to the patient without a terminal ileum to prevent megaloblastic anemia.

Functional outcome ultimately depends on the following factors: (1) the location of the atresia (the ileum adapts to a greater degree than the jejunum), (2) the maturity of the intestine (the small intestine in a premature infant still has time for maturation and growth), and (3) the length of the small intestine, which can be difficult to determine accurately after birth.<sup>155</sup> The ileocecal valve is critically important because it allows for more rapid intestinal adaptation when the residual small bowel length is short.

## COLONIC ATRESIA

Colonic atresia is a rare cause of intestinal obstruction and comprises 1.8% to 15% of all gastrointestinal atresias.<sup>156,157</sup> The reported incidence of colonic atresia varies greatly from 1:5000 to 1:60,000 live births.<sup>158-161</sup> The accepted incidence is approximately 1 in 20,000 live births. Although it is most commonly reported as an isolated anomaly, approximately one third of infants have associated congenital lesions.<sup>158,159,162</sup> There are various classifications of colonic atresia, but the one most commonly used divides colonic atresia into three types. Type I consists of mucosal atresia with an intact bowel wall and mesentery. In type II the atretic ends are separated by a fibrous cord. In type III the atretic ends are separated by a V-shaped mesenteric gap (Fig. 31-19).<sup>4,101,131</sup> In the ascending and transverse colon, type III colonic atresias predominate. Types I and II are seen more commonly distal to the splenic flexure.<sup>158,163</sup> Type III lesions are the most commonly occurring lesions overall.

The rate of associated anomalies with colonic atresias is much smaller when compared with other atresias. Colonic atresias have been found in approximately 2.5% of neonates with gastroschisis.<sup>147</sup> There are fewer than 25 published cases of colonic atresia and Hirschsprung's disease.<sup>147,162,164</sup> Complex urologic abnormalities, multiple small intestinal atresias, an unfixed mesentery, and skeletal anomalies have also been reported to occur with colonic atresia.<sup>158,163,165,166</sup> Similar to small bowel atresias, a vascular insult to the fetal intestine continues to be the accepted cause for all types of colonic atresia.<sup>167,168</sup>

Prenatal diagnosis is of great importance in the management of colonic atresia. On prenatal ultrasonography, the colon has a relatively characteristic appearance. The presence of an obstruction can usually

**Figure 31-19.** A type III colonic atresia was found at operation in this infant with intestinal obstruction. Note the cecum and appendix and the very dilated right colon. Also, note the extremely small distal colon (arrow). A colostomy was performed as the initial procedure in this infant.

be determined when the diameter of the colon is larger than expected for gestational age.<sup>169</sup>

The characteristic clinical features of colonic atresia are abdominal distention, bilious emesis, and failure to pass meconium. On plain radiographs, air-fluid levels are usually appreciated as well as dilated intestinal loops of large bowel often associated with a “ground-glass” appearance of meconium mixed with air.<sup>122</sup> Occasionally, the dilation can be so massive that it mimics pneumoperitoneum (Fig. 31-20). The diagnosis is made with a contrast enema showing a small-diameter distal colon that comes to an abrupt halt at the level of the obstruction (Fig. 31-21).

The diagnosis of colonic atresia is an indication for urgent surgical management because the risk for perforation is higher than is seen in small intestinal atresias. The operative approach depends on the clinical status of the patient, the level of the atresia, any associated small intestinal atresias, and the patency of the bowel distal to the atresia. It is important to exclude other intestinal atresias and stenoses at the time of operation because they occur with some frequency.<sup>49,61,62,170</sup> A diagnosis of associated Hirschsprung's disease, although rare, must be made by frozen section analysis of rectal biopsy specimens during the initial surgery because unrecognized Hirschsprung's disease can lead to anastomotic leak or functional obstruction.

A staged surgical approach consisting of colostomy with mucous fistula is generally preferred. Because

**Figure 31-20.** A, Abdominal radiograph of colonic atresia showing huge air-filled proximal colon mimicking a pneumoperitoneum. B, Right colonic atresia with rectal stenosis (*arrow*) is seen on this retrograde contrast study.

**Figure 31-21.** The contrast enema (*right*) in a patient with a distal intestinal obstruction (*left*) shows a small colon and failure of the contrast agent to move proximally past the mid-transverse colon.

the proximal and distal ends adjacent to the atresia are abnormal in both innervation and vascularity, resection of the bulbous proximal colon as well as a portion of the distal microcolon is suggested.<sup>171-175</sup> Primary resection with anastomosis has a higher incidence of complications, usually due to undiagnosed distal pathology.<sup>160,175</sup>

In the absence of other serious co-morbidities, the prognosis in colonic atresia is excellent. If diagnosed

early, the overall mortality is less than 10%.<sup>162</sup> A delay in diagnosis beyond 72 hours, however, may result in a mortality of greater than 60%.<sup>164,166</sup> This high mortality is due, in part, to the formation of a closed loop obstruction between an intact ileocecal valve and the atresia, leading to massive colonic distention and perforation.

# MALROTATION

Danny C. Little, MD • Samuel D. Smith, MD

Normal rotation of the human intestine requires transformation from a simple, straight alimentary tube into the mature fixed and folded configuration present at birth. Through precise embryologic events, the duodenojejunal junction becomes fixed in the left upper abdomen while the cecum is anchored in the right lower quadrant. The midgut, defined as the portion of the intestine supplied by the superior mesenteric artery, is thus suspended from a wide mesenteric base. In children with malrotation, the bowel is not fixed adequately and is thus held by a precariously narrow-based mesentery. Rotational anomalies create a spectrum of anatomic conditions with critical importance to the pediatric surgeon. Clinical disorders may arise when intestinal rotation either fails to occur or is incomplete. Rotational anomalies may be isolated or occur as an intrinsic component of gastroschisis, omphalocele, or congenital diaphragmatic hernia. Additionally, malrotation may present as an incidental, subtle finding discovered during the radiographic evaluation of another diagnosis or with septic shock from a catastrophic midgut volvulus.

The earliest descriptions of intestinal development were from Mall in 1898 and later expanded upon by Frazer and Robbins in 1915.<sup>1,2</sup> Eight years later, Dott translated these preliminary embryologic observations into problems encountered clinically.<sup>3</sup> In his 1932 landmark surgical paper, Ladd described the evaluation and surgical treatment of malrotation.<sup>4</sup> He described a relatively simple solution to a complicated problem. In his 1941 textbook entitled *Abdominal Surgery of Infancy and Childhood*, Ladd warned that unfamiliarity with this lesion would quickly lead to surgical confusion.<sup>5</sup> Over 200 postmortem studies had been reported previous to Ladd's paper, yet he was the first to emphasize the importance of placing the duodenum along the right abdominal wall, widening the mesenteric base, and moving the cecum to the left upper abdomen. With the exception of the laparoscopic approach, the original Ladd procedure has remained relatively unchanged.

## EMBRYOLOGY

The development of the midgut begins with the differentiation of the primitive intestinal tract into the foregut, midgut, and hindgut at the fourth week of gestation.<sup>6</sup> The mature alimentary tract and all associated digestive organs are formed from this primitive tube. The most accepted model of midgut maturation involves four distinct stages: (1) herniation, (2) rotation, (3) retraction, and (4) fixation. Normal fixation of the duodenum and colon is illustrated in [Figure 32-1](#). The intestinal loop can be divided into the cephalic (duodenojejunal) limb and the caudal (cecocolic) limb, which rotate separately but in parallel. The superior mesenteric artery serves as the fulcrum with the omphalomesenteric duct at the apex. Because of disproportional growth and elongation of the midgut during the fourth gestational week, the intestinal loop herniates into the extraembryonic coelom. Next, the bowel enters a critical period of rotation when the prearterial and postarterial limbs make three separate 90-degree turns, all in the counterclockwise direction around the superior mesenteric artery. The first 90-degree rotation occurs outside the abdomen. The second 90-degree rotation commences during the return of the intestine into the abdominal cavity during the 10th gestational week. The duodenojejunal junction now passes posterior to the superior mesenteric artery. The last rotation occurs in the abdomen. The primitive intestine has thus completed a 270-degree counterclockwise rotation, allowing the duodenojejunal limb to be positioned to the left of the superior mesenteric artery while the cecocolic limb is on the right. Fixation of the ascending and descending colon now occurs. Disruption of any of these vital steps leads to the spectrum of malrotation encountered clinically.

Alternatively, Kluth has proposed another model of intestinal rotation based on rat embryo studies.<sup>6</sup> In this model, the rapid growth and subsequent duodenal lengthening forces the tip of the duodenojejunal loop to grow under the mesenteric root. Simultaneously,

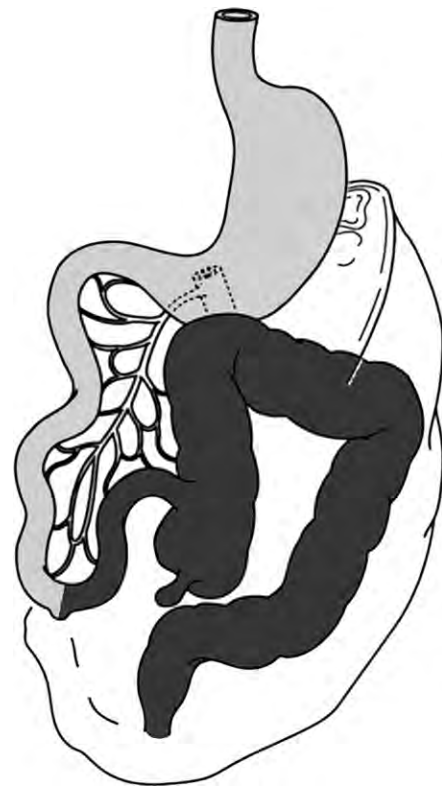

**Figure 32-1.** Normal intestinal anatomy results in fixation of the duodenojejunal junction in the left upper quadrant and the cecum in the right lower quadrant. This allows a wide breadth to the mesentery of the small bowel.

the distal midgut is also growing, forcing the cecum from a caudal to cranial position. In this hypothesis, cecal and colonic positioning is a passive process with final location of the midgut being based on a process of differential growth rather than active rotation.

The most common forms of rotational disorders include nonrotation (Fig. 32-2), incomplete rotation (Fig. 32-3), and reversed rotation. Right and left mesocolic hernias can also occur. In nonrotation, there is failure of the normal intestinal 270-degree counterclockwise rotation around the superior mesenteric artery. Thus, the duodenojejunal limb lies in the right hemi-abdomen with the cecocolic limb in the left hemi-abdomen. Midgut volvulus due to a narrow mesenteric pedicle and extrinsic duodenal obstruction secondary to abnormally positioned cecal attachments are significant risks. In cases of incomplete rotation, normal rotation has been arrested at or near 180 degrees. The cecum will usually reside in the right upper abdomen. Obstructing peritoneal bands are present. With reversed rotation, an errant 90-degree clockwise rotation occurs, which leaves a tortuous transverse colon to the right of the superior mesenteric artery, passing through a retroduodenal tunnel dorsal to the artery and in the small bowel mesentery.<sup>7,8</sup> The duodenum will assume an anterior position. Reverse rotation with volvulus may occur with obstruction of the transverse colon. Paraduodenal hernias are rare and result from failure of the right or left mesocolon to fuse to the posterior body wall. A potential space is created.

**Figure 32-2.** Illustration of nonrotation. The prearterial midgut (*lightly shaded*) is found on the right side of the abdomen, while the postarterial midgut (*darkly shaded*) remains on the left. Neither segment has undergone appropriate rotation. Volvulus is a risk.

Subsequently, the small intestine may become sequestered and potentially obstructed. A significant delay in diagnosis is often encountered.

## PRESENTATION

The incidence of malrotation has been estimated at 1 in 6000 live births. An increased incidence of 0.2% has been found in barium swallow studies,<sup>9</sup> whereas autopsy studies estimate that the true incidence may be as high as 1% of the total population.<sup>10</sup> Associated anomalies are common (Table 32-1).<sup>11</sup> Rotational disorders are also known to coexist with heterotaxia but rarely with situs inversus.<sup>12</sup> Intestinal malrotation occurs along a wide spectrum of anatomic variants and clinical presentations, including midgut volvulus and chronic duodenal obstruction. In-utero volvulus may lead to intestinal atresia.

Classic malrotation with midgut volvulus is often discovered in a previously healthy term neonate. Up to 75% of patients present during the first month of life. Another 15% will present within the first year.<sup>13-15</sup> Volvulus, intestinal gangrene, and mortality have been noted regardless of the patient's age or chronicity of symptoms.<sup>16</sup> Bilious vomiting remains the cardinal sign of neonatal intestinal obstruction, and malrotation must be the presumed diagnosis until

**Figure 32-3.** Illustration of incomplete rotation. Both the prearterial (*lightly shaded*) and postarterial (*darkly shaded*) segments have undergone partial, yet not complete, rotation. Ladd's bands are seen attaching the cecum to the right posterior abdominal wall. The duodenum becomes compressed and possibly obstructed. Volvulus is a risk.

proven otherwise. Delays in diagnosis can be devastating. Other signs in the neonate include abdominal pain and distention. The inconsolable infant may rapidly deteriorate as metabolic acidosis quickly advances to hypovolemic shock. Late signs include abdominal wall erythema and hematemesis or melena from progressive mucosal ischemia. Laboratory investigation may reveal leukocytosis or leukopenia, hyperkalemia, and thrombocytopenia. Mesenteric vascular compromise rapidly leads to peritonitis, sepsis, shock, and death.

Many other cases will present less dramatically. Failure to thrive, gastroesophageal reflux, early satiety,

**Table 32-1** Incidence of Associated Anomalies (by percent) with Malrotation

Intestinal atresia	5-26%
Imperforate anus	0-9%
Cardiac anomalies	7-13%
Duodenal web	1-2%
Meckel's diverticulum	1-4%
Hernia	0-7%
Trisomy 21	3-10%

Rare: esophageal atresia, biliary atresia, mesenteric cyst, craniocynostosis, Hirschsprung's disease, intestinal duplication.

and mild abdominal discomfort are routinely reported. Partial volvulus leads to mesenteric venous and lymphatic obstruction and subsequently impairs nutrient absorption. The diagnosis becomes more challenging with the older child or teenager because the symptoms are often very vague and seemingly unrelated to the abdomen.<sup>17</sup>

The discordant incidence of malrotation between clinical cases and autopsy studies suggests that many patients are asymptomatic but "anatomically at risk" for midgut volvulus. Although most cases will present in the neonatal period or infancy, presentation in children or adults is not uncommon.<sup>18</sup> Anomalies of intestinal rotation may be discovered incidentally in the teenager or adult during investigation for upper abdominal complaints. Yet, it is important to remember that these patients possess a narrow small bowel mesentery and thus remain susceptible to midgut volvulus.

## DIAGNOSIS

Radiologic studies play a critical role in establishing a diagnosis of intestinal malrotation. Initial evaluation will usually begin with a plain anteroposterior abdominal flat plate combined with a lateral decubitus or upright view (Fig. 32-4). Variable, nonspecific findings are common. However, gastric and/or duodenal distention ("double bubble" sign) may be observed. Additionally, bowel wall thickening and edema may be present secondary to vascular compromise. A gasless

**Figure 32-4.** Upright abdominal film in an infant demonstrating proximal small bowel dilatation. This infant had a midgut volvulus.

**Figure 32-5.** Lateral image on upper gastrointestinal series in an infant with malrotation and midgut volvulus showing the "corkscrew" appearance of the obstructed duodenum.

abdomen is particularly worrisome because the compromised bowel may be filled with fluid alone. Of particular importance is the presence of rectal gas in the newborn, which essentially excludes duodenal atresia (but not duodenal stenosis or web). If the diagnosis remains in doubt, an emergent upper gastrointestinal contrast study is needed to document the position of the ligament of Treitz. Delineation of the duodenojejunal junction remains the most important diagnostic tool with high sensitivity and is preferred over barium enema.<sup>19</sup> The duodenum should be seen traveling across the spine to the left. Additionally, the lateral film will show the duodenum obtaining a retroperitoneal, posterior position. Abnormal findings include positioning of the duodenojejunal flexure to the right of the spine, obstruction of the duodenum, and the "coil spring," "corkscrew," or "beak" appearance of the obstructed proximal jejunum (Figs. 32-5 and 32-6). In some settings, color Doppler ultrasound imaging is favored and may reveal a dilated duodenum with inversion of the superior mesenteric artery and vein (the whirlpool sign) in cases of acute volvulus.<sup>20,21-23</sup> Moreover, with ultrasonography, it is now possible to diagnose intestinal volvulus in utero.

The patient with suspected or confirmed midgut volvulus should be aggressively resuscitated, given intravenous broad-spectrum antibiotics, and taken to the operating room for immediate exploration. Delaying surgery for confirmatory testing should be discouraged when the diagnosis is likely based on clinical grounds. Prompt diagnosis and exploration is paramount to limit the complications and mortality of massive bowel resection. Clinicians should counsel the family preoperatively, but an intraoperative discussion is also advisable in certain cases.

## MANAGEMENT

Management of children with radiographically proven symptomatic malrotation is relatively straightforward. A discussion of the open and laparoscopic techniques is presented later. Malrotation is an integral part of abdominal wall defects and congenital diaphragmatic hernia. Operative correction of these defects creates intra-abdominal adhesions. These patients are considered to be protected from volvulus. Therefore, Ladd's procedure is not generally required.

The dilemma arises when an abnormality is discovered on imaging, and the child is labeled as a "malrotation variant." To exclude malrotation, the duodenojejunal flexure must be located to the left of the spine at the level of the duodenal bulb. Defined as the ligament of Treitz, this flexure may be in an equivocal position. Symptoms are generally mild and could easily be attributed to several diagnoses. Volvulus or internal hernia is usually not seen with malrotation variants. These children are usually referred, leaving the surgeon with the dilemma to decide whether the symptoms are truly related to the radiographic findings. Given the higher rate of persistence of symptoms after operation and an overall increase in postoperative complications in general, close observation or repeated contrast study has been suggested in these equivocal cases.<sup>24,25</sup>

**Figure 32-6.** Lateral image on upper gastrointestinal series in infant with malrotation and midgut volvulus showing the "beak" (arrow) appearance of the obstructed duodenum. Note that a small amount of contrast agent has progressed through the volvulus.

**Table 32-2** Six Key Elements in Operative Correction of Malrotation

1. Entry into abdominal cavity and evisceration (open)
2. Counterclockwise detorsion of the bowel (acute cases)
3. Division of Ladd's cecal bands
4. Broadening of the small intestine mesentery
5. Incidental appendectomy
6. Placement of small bowel along the right lateral gutter and colon along the left lateral gutter

## Open Surgical Technique

There has been little change from Ladd's original description of the operative technique for correction of malrotation with or without acute volvulus. Preoperative discussion with the family is crucial. The six essential/critical steps are summarized in Table 32-2. Prolonged resuscitation efforts are not warranted. Preincision broad-spectrum antibiotics should be administered in cases of suspected volvulus. The surgeon's primary goal is to prevent the catastrophic loss of portions of the entire midgut. Entry into the abdomen through a right upper quadrant transverse approach is preferred, although a midline incision is also reasonable. In suspected cases of acute volvulus, time to detorsion is critical. Chylous ascites secondary to lymphatic obstruction and rupture of mesenteric lacteals is often encountered. When turbid fluid is seen, contamination should be suspected and peritoneal cultures taken. The bowel and mesentery should be eviscerated. One will commonly encounter two or three complete clockwise revolutions. The bowel will be often discolored and congested, although frankly gangrenous or perforated bowel is not uncommon. The bowel wall is fragile, and manipulation should be delicate. Care with counterclockwise detorsion is needed to prevent serosal or full-thickness injury (Fig. 32-7). The bowel may remain dusky. After detorsion, release of inflammatory mediators and lactic acid is common and may require aggressive fluid resuscitation and the temporary use of vasoactives. Once detorsion has been accomplished, **warm soaked lap pads** are placed on the bowel, and the surgeon should patiently observe for reperfusion. Twenty or 30 minutes of intraoperative rewarming may be required. If perfusion remains in question, the surgeon has several options, including (1) assessment of the antimesenteric vascular integrity with the use of a Doppler probe and (2) intravenous administration of fluorescein with Wood's lamp evaluation.

After a period of observation, a limited segment of intestine may remain gangrenous and resection should proceed. However, when longer segments are of questionable viability, the principles of intestinal salvage and preservation should be remembered. Resection of clearly necrotic bowel should be performed while leaving bowel of uncertain perfusion in the abdomen (clip and drop) to be re-evaluated at a second-look operation 24 to 48 hours later. At the second exploration, recovery of questionable bowel or demarcation of

necrotic bowel requiring resection is usually obvious. Unfortunately, an occasional patient will have complete infarction of the midgut. Closure of the abdomen, without bowel resection and comfort care, may be considered after intraoperative family discussion. The development of intestinal and multiple-viscera transplantation makes this approach less clear.

Assuming bowel viability has been confirmed, the breadth of the mesentery must be widened. This is accomplished through a series of maneuvers, including excision of cecal peritoneal bands traversing the duodenum (Ladd's bands) and Kocherization of the duodenum. The dissection then continues to the base of the superior mesenteric artery and vein by incising the anterior mesenteric leaflet. When properly opened, the mesentery is maximally broadened and the possibility of postoperative volvulus is reduced, although not completely eliminated.

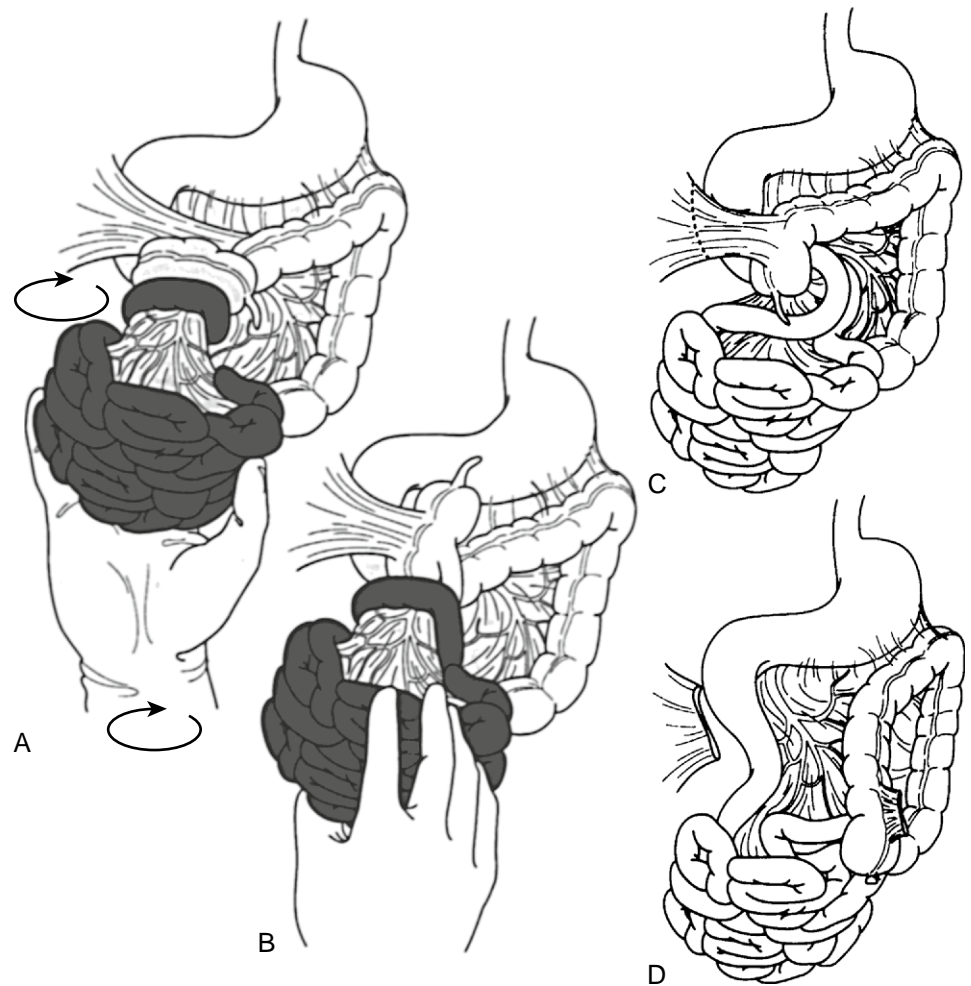

Most surgeons will complete the procedure with an appendectomy. Owing to the subsequent malposition of the cecum in the left upper quadrant, failure to remove the appendix could lead to diagnostic uncertainty and delay if appendicitis developed. Standard or inversion appendectomy is equally acceptable. Finally, as the surgeon prepares for closure, the duodenum and small intestine are positioned toward the right abdomen with the colon in the left abdomen. A final check to rule out mesenteric torsion is advisable. Suture fixation of the bowel to the lateral abdominal wall is not recommended.<sup>26,27</sup>

In patients without evidence of volvulus or obstruction, a nasogastric tube is not required. Bowel function generally returns in 1 to 5 days. However, older patients with chronic obstruction are likely to have a prolonged ileus, and thus nasogastric drainage and parenteral support should be considered. Antibiotics are not required. Feedings can be advanced per the surgeon's discretion. Patients with extended or subtotal small bowel resection pose a special problem. Total parenteral nutrition is essential to sustain these patients until adaptation and compensatory growth of the residual bowel can occur.<sup>28</sup> Small bowel or multiple-viscera transplantation should be considered. Postoperative intussusception has been noted in 3.1% of all patients who underwent a Ladd procedure, compared with 0.05% following other laparotomies.<sup>29</sup> The incidence of recurrent volvulus is low. Finally, up to 10% of patients may develop an adhesive small bowel obstruction requiring laparotomy after the procedure.<sup>26,27,30</sup>

## Laparoscopic Approach

The laparoscopic treatment for intestinal rotation anomalies in neonates, infants, and children with or without midgut volvulus has been proposed by several authors since van der Zee's original report in 1995.<sup>31</sup> The previously published reports have been single-institution case reports or small case series. Clinical outcomes for the laparoscopic technique have been favorable.

The patient is placed supine in the reversed Trendelenburg position, on a shortened operating room

**Figure 32-7.** Open correction of malrotation. **A** and **B**, Initial appearance of the malrotated bowel during exploration. The surgeon first will perform counterclockwise detorsion of the midgut. **C**, Next, Ladd's bands from the cecum to the right abdominal wall are divided. **D**, Last is the critical step of broadening the small bowel mesentery. An appendectomy is also performed.

table, if available. The surgeon will stand at the child's feet with the assistant positioned to the surgeon's left. Alternatively, the surgeon may stand at the patient's right with the assistant and camera holder to the left. The stomach and bladder are decompressed. The child's arms are tucked. A four-port technique provides adequate visualization with cannulas placed at the umbilicus, right and left mid abdomen, and sub-xiphoid region (for the liver retractor, if required). Gentle insufflation with carbon dioxide to a pressure of 8 to 12 mm Hg with flow at 2 to 5 L/min is generally well tolerated.<sup>31-33</sup> Muscle relaxation will allow an optimal working space. Full abdominal exploration may reveal internal hernias, which are associated with malrotation. The surgeon's first goal is to determine if malrotation is actually present and thus confirm preoperative imaging (Figs. 32-8 and 32-9). Tilting the table 30 degrees may help identify the ligament of Treitz and the ileocecal junction. Findings are variable but may include a high and medial cecal position and an elongated, tortuous duodenum. Although there are no specific guidelines established to predict whether a future volvulus will occur, a mesenteric

base extending more than half the diameter of the abdomen is generally sufficient to prevent volvulus.<sup>34</sup>

Owing to the necessity of rapid detorsion, the laparoscopic approach for acute volvulus is controversial. In these acute cases, a clockwise volvulus is easily recognized. The expeditious dissection may progress by identifying the second portion of the duodenum and excising restricting peritoneal bands. Next the surgeon may proceed with reduction of the volvulus (if present), mobilization of the duodenum and jejunum, and incision of the anterior mesenteric leaflet. The friable, ischemic bowel may be injured by the laparoscopic instruments. In older children with long-standing duodenal obstruction, the proximal bowel may be molded into a cocoon-like deformity (Fig. 32-10).<sup>33</sup> Lastly, the appendix is brought out through the umbilicus for an extracorporeal appendectomy (Fig. 32-11). Alternatively, an intracorporeal appendectomy may be performed through the 5-mm ports using bipolar cautery and endoloops, or the surgeon may proceed with a standard stapled intracorporeal appendectomy if a 12-mm umbilical cannula has been placed. The ports are removed under direct visualization, and the

**Figure 32-8.** An upper gastrointestinal study was performed in this infant who presented with vomiting. **A** and **B**, The radiologic interpretation was that the duodenum was entirely on the patient's right side and the ligament of Treitz was at the level of pylorus. Also, the ligament of Treitz did not cross the midline. There was no evidence of obstruction. This patient underwent diagnostic laparoscopy and was found to have normal anatomy with correct positioning of the ligament of Treitz and the cecum (see Fig. 32-9).

incisions are closed in layers with absorbable suture. Postoperative management is similar to that for the open approach. Most children may begin clear liquids on the day of surgery. Discharge on day 1 or 2 is expected.<sup>33</sup>

Although each procedure will present its own challenges, several recommendations may expedite the procedure, decrease the conversion rate, and reduce surgeon frustration. For elective cases, decreasing stool burden with a gentle bowel preparation will improve visualization. Furthermore, it is important to position the working sites as far away as possible from the congenital bands, which increases the intra-abdominal working space. Direct handling of the bowel increases the risk of serosal tears so gentle manipulation is important. The majority of the dissection may be accomplished by grasping the congenital bands or appendix.

Since van der Zee's initial report, other authors have described variations in technique and have published their positive results.<sup>35-38</sup> Successful laparoscopic management of a 15-day-old with acute midgut volvulus has been described.<sup>39</sup> The authors carefully reduced the acute volvulus, divided the Ladd's bands, incised

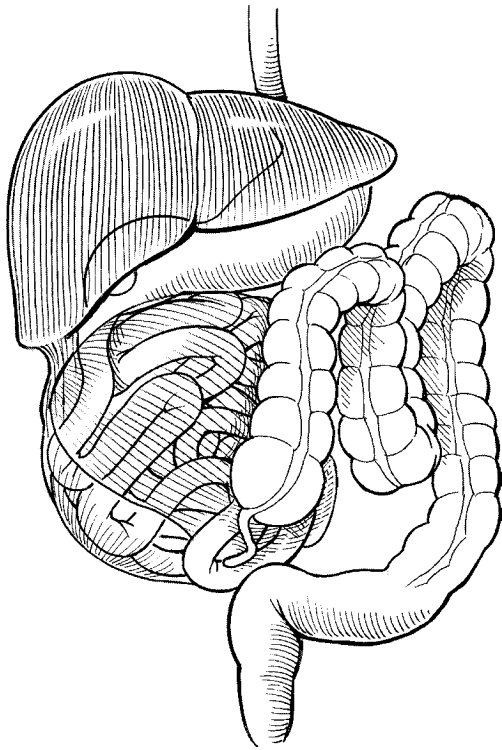

the anterior mesentery, and performed an appendectomy. However, the majority of patients undergoing laparoscopic repair of intestinal malrotation have been elective cases without volvulus.<sup>36,37,40</sup> Operative times have been reported to average 111 to 120 minutes.<sup>36,40</sup> In one report, the time to a regular diet was 2 days (median) and resolution of symptoms was found in 5 of 7 patients at 15 months.<sup>36</sup>

In another series, 12 neonates and infants, weighing 3 to 7 kg, underwent a three-port laparoscopic Ladd's procedure.<sup>35</sup> Presentation included intermittent upper intestinal obstruction, and the diagnosis was eventually confirmed by contrast study. Three 3.5-mm ports were placed in the infraumbilical ring and in the right and left abdomen. Operative time was equivalent to published open results, ranging from 35 to 120 minutes (mean, 58 minutes). Feedings were started on postoperative day 1 or 2, and the patients were discharged at a mean of 2 days. All symptoms had resolved on postoperative evaluation.

In a review of 21 adults undergoing both an open and laparoscopic Ladd procedure, comparative results were favorable for the laparoscopic group for resumption of oral intake (1.8 days vs. 2.7 days), shorter

**Figure 32-9.** At times, the upper gastrointestinal study can be equivocal for possible malrotation (see Fig. 32-8). In such patients, diagnostic laparoscopy is a useful technique to ascertain whether the patient actually has malrotation. **A**, In such patients, the position of the ligament of Treitz (*arrow*) to the patient's left of midline is important. **B**, In addition, the location of the cecum in the right lower quadrant also helps verify that the patient does not have malrotation.

**Figure 32-10.** In older children with long-standing partial obstruction or internal herniation, the Ladd bands may cause the bowel to form into a cocoon-like deformity. (From Moir CR: Laparoscopic Ladd procedure. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: *Atlas of Pediatric Laparoscopy and Thoracoscopy*. Philadelphia, Elsevier, 2008, pp 55-60.)

hospitalization (4 days vs. 6.1 days), and decreased requirements for intravenous narcotics on postoperative day 1 (4.9 mg vs. 48.5 mg).<sup>41</sup> Operative times, however, averaged 51 minutes longer for the laparoscopic patients (194 minutes vs. 143 minutes). Conversion to an open operation occurred in 25% of the patients undergoing a laparoscopic procedure. No patients required a second operation.

One additional value of laparoscopy is found in cases of malrotation variants when the ligament

of Treitz is in an equivocal position on preoperative imaging (see Fig. 32-8). Radiographic terms such as “wandering duodenum,” “low ligament of Treitz,” and “abnormal rotation” are frequently encountered in the radiologist’s vernacular. Such “soft” radiologic findings place the responsibility of excluding malrotation directly on the surgeon. In equivocal cases, laparoscopy may be used to determine the position and fixation of the cecum and the overall breadth of the mesenteric pedicle (see Fig. 32-9). Additionally, when performing open exploration based on these preoperative descriptives, a surgeon may find relatively normal rotation that is not suggestive of malrotation or prone to volvulus. The laparoscopic approach allows excellent visualization of the width and fixation of the mesentery and the presence of Ladd’s bands. Questionable cases are thus stratified regarding whether operative correction is required.<sup>42</sup> If the mesentery is noted to be narrow, the patient will be prone to volvulus and requires operative correction. The procedure may continue with laparoscopic correction, or the surgeon may wish to convert to an open procedure at this point.

The formation of intra-abdominal adhesions has generally been viewed as necessary to prevent postoperative volvulus. Through open exploration and direct manipulation of the bowel, adhesions are created. Concerns have been raised that adhesion formation may be limited with laparoscopy, as is seen in other laparoscopic procedures. Initial reports have not validated these concerns.

Laparoscopic correction of malrotation is an accepted procedure but still remains a technical challenge. In patients with acute volvulus, the working space will be limited owing to bowel edema and chylous ascites. Although many cases can be accomplished with these minimally invasive techniques, conversion to an open procedure should be considered if significant progress has not been made after 60 minutes. As a collection, the available literature supports consideration of laparoscopy. Further prospective studies with large sample sizes, possible randomization, and long-term follow-up should be conducted to confirm the advantages and disadvantages of the laparoscopic approach.

**Figure 32-11.** When performing a laparoscopic Ladd procedure, an extracorporeal appendectomy eliminates the need for a large port for the endoscopic stapler. The appendix is grasped with one of the intracorporeal instruments and brought into view through the umbilicofascial defect, where it is grasped and exteriorized. (From Moir CR: Laparoscopic Ladd procedure. In Holcomb GW III, Georgeson KE, Rothenberg SS [eds]: *Atlas of Pediatric Laparoscopy and Thoracoscopy*. Philadelphia, Elsevier, 2008, pp 55-60.)

## THE OLDER PATIENT

Malrotation is occasionally diagnosed in the teenager or adult, yet the symptoms are often vague, including vomiting, diarrhea, early satiety, bloating, dyspepsia, and ulcer disease.<sup>43-46</sup> After a lengthy period of medical evaluation, some of these patients are labeled with functional or psychiatric disorders.<sup>10,44,45</sup> The diagnosis may require multiple imaging modalities, including barium studies, computed tomography, magnetic resonance imaging, and angiography. Furthermore, preoperative imaging may also delineate vascular and/or hepatobiliary anatomic irregularities that are associated with rotational disorders.<sup>47</sup> In the acute symptomatic patient, only emergent laparotomy can provide the correct diagnosis in a timely fashion. Given that adult surgeons may have little experience with this disorder, it is common for pediatric surgeons to be asked for intraoperative consultations.

Outcomes in patients younger than 16 years old have been compared with those of patients older than 16.<sup>48</sup> When compared with younger patients, the older patients experienced longer delays in diagnosis, endured a higher percentage of postoperative complications, and required a higher percentage of reoperation. No patients in the adult group were diagnosed correctly at the time of initial presentation.

The question arises whether an incidental discovery of malrotation in the older child or adult should be repaired at all. A candid discussion on the risk-benefit ratio with these older patients is important. The principle of “watchful waiting” has been suggested.<sup>49</sup> Currently, there are no diagnostic modalities that can assess an individual’s future risk for midgut volvulus. Up to 20% of adult patients undergoing operative repair of malrotation will have an acute volvulus or bowel ischemia, both potentially life-threatening presentations.<sup>50</sup> Furthermore, even in patients who are believed to be asymptomatic, preoperative symptoms attributable to malrotation have retrospectively been noted, and postoperative improvement has been seen.<sup>37,48,51</sup>

As noted by Ladd in 1932, malrotation is a “condition rare enough that it is likely to escape the mind, and it is common enough to be important.”<sup>74</sup> This advice is especially true in older patients. The subtle presentation may lead to unnecessary or ineffective treatment. A high index of suspicion is required to prevent a delay in diagnosis, counsel patients effectively, and improve outcomes. Operative correction in the symptomatic and asymptomatic older patient is currently recommended.<sup>45,48,52,53</sup>

# MECONIUM DISEASE

Michael G. Caty, MD • Mauricio A. Escobar, MD

**I**ntestinal obstruction in the neonate is one of the most common diagnoses requiring admission to the neonatal intensive care unit, accounting for as many as one third of all admissions.<sup>1</sup> Failure to pass meconium within the first 24 to 48 hours of life, feeding intolerance, abdominal distention, and bilious emesis are hallmarks of intestinal obstruction in the newborn period and evoke a differential diagnosis of obstruction based on anatomic, metabolic, and functional considerations. Strictly speaking, the term *meconium disease* refers to meconium ileus and meconium plug syndrome. These conditions are considered here separately from functional or anatomic causes of neonatal intestinal obstruction such as Hirschsprung's disease, intestinal atresia, and anorectal malformations.

## MECONIUM ILEUS

Meconium ileus is one of the most common causes of intestinal obstruction in the newborn, accounting for 9% to 33% of neonatal intestinal obstructions.<sup>2</sup> It is characterized by extremely viscid, protein-rich, inspissated meconium causing an intraluminal obturator-type obstruction of the distal ileum. It is the earliest clinical manifestation of cystic fibrosis (CF), occurring in approximately 16% of patients with that disease.<sup>3</sup> Although meconium ileus may occur with rare conditions such as pancreatic aplasia and total colonic aganglionosis, it is considered pathognomonic for CF<sup>4,5</sup> and may be an early indication of a more severe phenotype of CF. This has been suggested due to significantly lower pulmonary function found in children with a history of meconium ileus compared with age- and sex-matched children with CF who did not have meconium ileus.<sup>6</sup>

Due to abnormalities of exocrine mucus secretion and pancreatic enzyme deficiency, the meconium in meconium ileus differs from normal meconium in that it has less water content (meconium ileus, 65%; normal, 75%), lower sucrase and lactase levels, increased albumin, and decreased pancreatic enzymes.<sup>7-9</sup> Additionally,

concentrations of sodium, potassium, magnesium, and heavy metals in meconium are reduced in CF patients. Concentrations of protein nitrogen are increased and composed of abnormal mucoproteins, and concentrations of carbohydrate are reduced.<sup>10-12</sup> Thus, more viscous intestinal mucus in the absence of degrading enzymes results in thick, dehydrated meconium that obstructs the intestine.<sup>13</sup> An understanding of CF guides the clinical management of patients with meconium ileus.

## Cystic Fibrosis

The association of inspissated meconium in a newborn with pathologic changes of the pancreas was first described in 1905.<sup>14</sup> In 1936, the term *cystic fibrosis* was first used to describe the combination of pancreatic insufficiency and chronic pulmonary disease in childhood.<sup>15</sup> Two years later, the coexistence of meconium ileus and CF was described and the histologic lesions in the pancreas were noted to be identical in both conditions.<sup>16</sup> Inspissation of meconium, caused by abnormal intestinal mucus, was first suggested in 1946.<sup>17</sup> Chemical analysis of inspissated meconium from infants with meconium ileus was carried out as early as 1952.<sup>18</sup> In 1953, the abnormally viscid nature of meconium in meconium ileus was attributed to abnormal mucus secreted by the intestine of patients with CF.<sup>19</sup>

## Incidence

CF is the most common potentially lethal genetic defect affecting whites, with approximately 1200 infants with CF born each year. Approximately 30,000 children and young adults live with CF in the United States.<sup>4</sup> It is an inherited autosomal recessive disease with a 4% to 5% carrier rate and occurs in 1:3000 to 1:2000 live births yearly. The incidences of CF in non-white populations are 1 in 15,000 African-American births (much lower in native Africans), 1 in 31,000 in Asian-American births, 1 in 10,500 Native American Aleut (Eskimo) births, and 1:13,500 in Hispanic-white births.

## Genetics

In 1989, the CF locus was localized through linkage analysis to human chromosome 7q31.<sup>20,21</sup> Mutations in the cystic fibrosis transmembrane (conductance) regulator gene (*CFTR*) result in CF.<sup>22,23</sup> The cell membrane protein coded by *CFTR* is a 3',5'-cyclic adenosine monophosphate (cAMP)-induced chloride channel, which also regulates the flow of other ions across the apical surface of epithelial cells. The alteration in *CFTR* results in an abnormal electrolyte content in the environment external to the apical surface of epithelial membranes. This leads to desiccation and reduced clearance of secretions from tubular structures lined by affected epithelia.

The most common mutation of the *CFTR* gene, the  $\Delta F508$  mutation, is a 3-base pair deletion that results in the removal of a phenylalanine residue at amino acid position 508 of the *CFTR*. Over 1000 *CFTR* mutations have been reported to the CF Genetic Consortium. The  $\Delta F508$  mutation is responsible for approximately 70% of abnormal CF genes.<sup>20,21,23</sup> Genetically, families with meconium ileus have a significantly higher occurrence rate than the expected 25% for an autosomal recessive genetic disorder.<sup>15,24</sup> In one series, for the few CF patients for whom genetic analysis was available, 79% with the  $\Delta F508$  mutation presented with abdominal complaints including meconium ileus rather than pulmonary complaints.<sup>4</sup> However, there is no evidence of distinct allelic frequencies or haplotypic variants in CF patients with meconium ileus compared with those without<sup>25</sup> or in those CF patients with significant liver disease.<sup>26,27</sup>

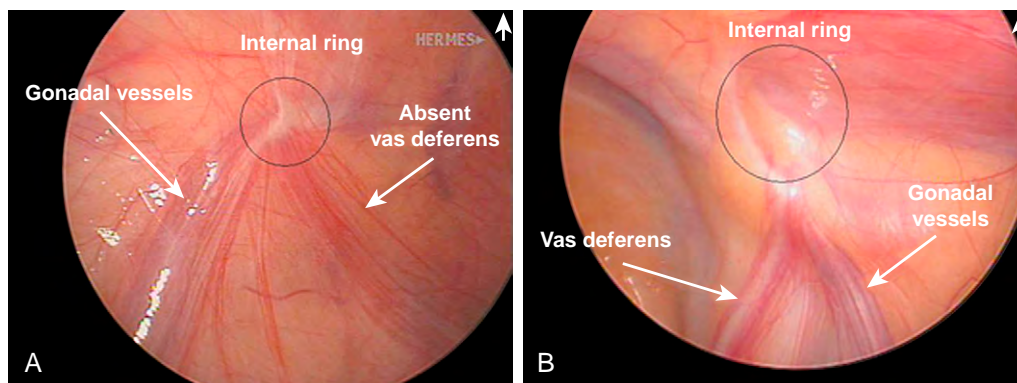

## Gastrointestinal Pathophysiology

Cystic fibrosis is characterized by mucoviscidosis of exocrine secretions throughout the body resulting from abnormal transport of chloride ions across the apical membranes of epithelial cells.<sup>28-30</sup> The clinical result is chronic obstruction and infection of the respiratory tract, insufficiency of the exocrine pancreas, and elevated sweat chloride levels.<sup>31</sup> Other variants can have minimal other manifestations, such

as patients with chronic sinusitis or men with congenital bilateral absence of the vas deferens (CBAVD) (Fig. 33-1).<sup>32-34</sup> In patients with CBAVD, the *CFTR* genotype usually includes at least one mild mutation not typical of CF patients. The mild-mutation allele is frequently associated with a severe mutation on the other allele, such as the  $\Delta F508$  mutation.<sup>6,35</sup> CBAVD has been described in a patient with  $\Delta F508$  and G551D mutations,<sup>36</sup> both of which are categorized as severe. The allele G551D is the third most common CF-associated mutation.<sup>7,37</sup>

Development of both the pancreas and intestinal tract in fetuses with CF is abnormal. In patients with CF, abnormal pancreatic secretions obstruct the ductal system leading to autodigestion of the acinar cells, fatty replacement of pancreatic parenchyma, and fibrosis. Although the process begins in utero, it occurs variably over time. Pancreatic insufficiency is prevalent in young infants with CF and has a significant impact on growth and nutrition.<sup>26</sup>

Investigations have also suggested that pancreatic insufficiency plays a central role in the pathogenesis of meconium ileus. Congenital stenosis of the pancreatic ducts is associated with meconium-induced bowel obstruction. This is further supported by the fact that two thirds of infants found to have CF by neonatal screening are pancreatic insufficient at birth. However, approximately 10% of patients with CF are pancreatic sufficient and will tend to have a milder course. Pancreatic lesions are also variable at birth and are more severe in children with CF older than 1 year of age. This suggests that pancreatic insufficiency is not the leading cause of abnormal meconium in meconium ileus. In fact, histologic data have shown that a prevalence of intestinal glandular abnormalities contributed more significantly to the production of the abnormal meconium. In CF, intestinal disease is characterized by a glandular abnormality in which hyperviscous mucus is produced. The lack of concordance between meconium ileus and the severity of pancreatic disease and preponderance of intestinal glandular lesions implies that intraluminal intestinal factors contribute more to the development of meconium ileus than absence of pancreatic secretions.<sup>17-19,38-42</sup>

**Figure 33-1.** Congenital bilateral absence of the vas deferens (CBAVD). **A**, Laparoscopic view of a patient's left internal ring. **B**, Compare with a laparoscopic view of a similar-aged patient's right internal ring with a normal vas deferens. (From Escobar MA, Lau ST, Glick PL: Congenital bilateral absence of the vas deferens. *J Pediatr Surg* 43:1222-1223, 2008.)

Abnormal intestinal motility may also contribute to the development of meconium ileus. Some patients with CF have prolonged small intestinal transit times.<sup>43,44</sup> Non-CF diseases associated with abnormal gut motility, such as Hirschsprung's disease and chronic intestinal pseudo-obstruction, have been associated with meconium ileus-like disease, signifying that decreased peristalsis may allow for increased reabsorption of water and the development of abnormal meconium.<sup>45-47</sup> Moreover, the *CFTR* ion channel defect results in an exocrine secretion abnormally rich in sodium and chloride, leading to further dehydration of intraluminal contents and their impaired clearance.<sup>9</sup>

## Prenatal Diagnosis and Screening

The antenatal diagnosis of meconium ileus can be made in two different groups, a high-risk group and a low-risk group. In the low-risk group the diagnosis is suspected when the sonographic appearances of meconium ileus are found on routine prenatal ultrasonography when there is no previous family history of CF. All pregnancies subsequent to the birth of a CF-affected child are considered high risk, and parents of a child with CF are considered to be obligate carriers of a CF mutation.

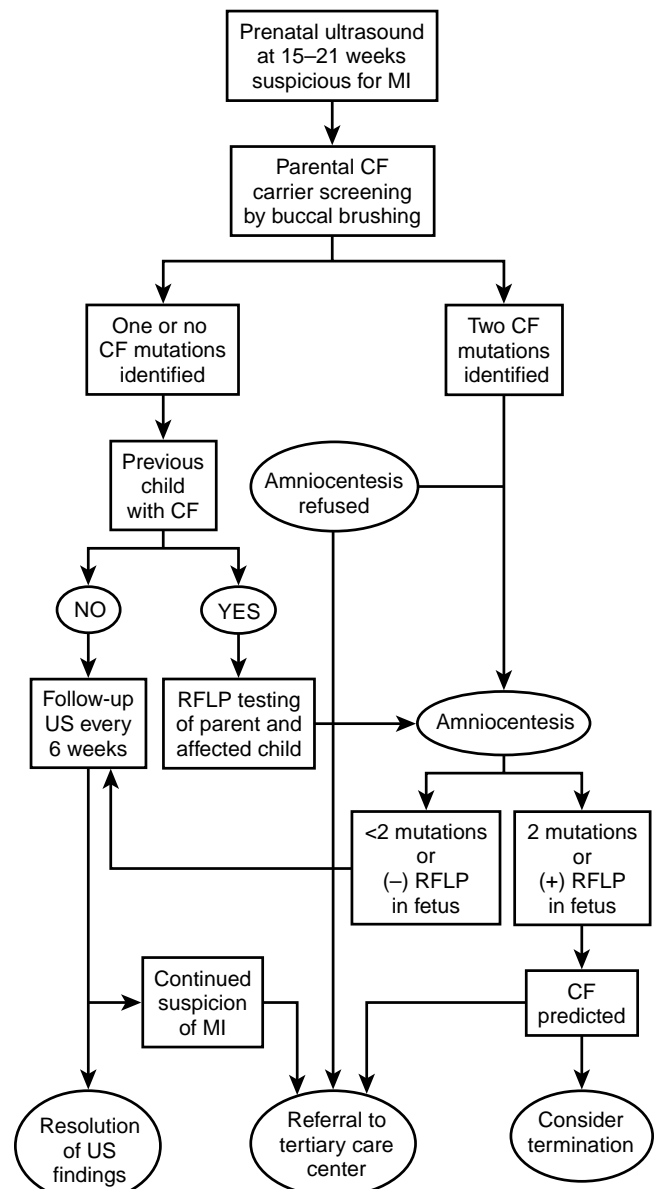

Pediatric surgeons are often asked to provide prenatal consultations to parents of fetuses suspected of bowel obstruction. Meconium ileus must be considered in the differential diagnosis, particularly in the high-risk fetus. An algorithm has been established that may be useful in counseling and management of the fetus suspected of having meconium ileus (Fig. 33-2).<sup>48-50</sup> The obvious advantage of establishing a prenatal diagnosis is that it allows clinicians to prepare for the medical and psychological needs of the parents, fetus, and newborn before, during, and after delivery. In a pregnancy in which CF is suspected, sonographic examinations should be performed on a monthly basis until delivery. This evaluation allows the early detection of potential complications as they occur and prepares the physicians for special or urgent medical or surgical needs upon delivery.

## Ultrasound Evaluation

Sonographic characteristics associated with meconium ileus include a hyperechoic, intra-abdominal mass ( inspissated meconium) (Fig. 33-3), dilated bowel, and nonvisualization of the gallbladder. Normal fetal meconium, when visualized in the second and third trimesters, is usually hypoechoic or isoechoic to adjacent abdominal structures.<sup>51-56</sup> The sensitivity of intra-abdominal echogenic masses in the detection of meconium ileus is reported to be between 30% and 70%. As a sonographic marker of meconium ileus, this finding is plagued by difficulties, including the subjective assessment of echogenicity and the lengthy associated differential diagnosis. In addition to meconium ileus,<sup>51-54,57,58</sup> hyperechoic bowel has been reported with Down syndrome,<sup>59,60</sup> intrauterine

growth retardation,<sup>51,53,54,59-61</sup> prematurity,<sup>62</sup> in-utero cytomegalovirus infection,<sup>63</sup> intestinal atresia, abruptio placentae, and fetal demise.<sup>61</sup> The importance of hyperechoic fetal bowel is related to gestational age at detection, ascites, calcification, volume of amniotic fluid, and the presence of other fetal anomalies.<sup>56</sup> Furthermore, the prenatal diagnosis of meconium ileus using the sonographic feature of hyperechoic bowel must take into account the a priori risk of the parents. The positive predictive value of hyperechoic masses in a high-risk fetus is estimated to be 52%, whereas it is only 6.4% in the low-risk fetus.<sup>51</sup>

Reviews of pregnancies with a 1 in 4 risk of CF show a 25% to 60% association between hyperechoic

**Figure 33-2.** Suggested algorithm for antenatal management of suspected meconium ileus (MI) and cystic fibrosis (CF). US, ultrasonography; RFLP, restriction fragment length polymorphism. **Figure 33-3.** Ultrasound image of a 22-week gestation demonstrating a 2 × 3-cm intraluminal (distal ileum) mass (arrows) consistent with meconium inspissation (meconium ileus). (From Irish MS, Ragi JM, Karamanoukian H, et al: Prenatal diagnosis of the fetus with cystic fibrosis and meconium ileus. *Pediatr Surg Int* 12:434-436, 1997.)

bowel and CF.<sup>58,62</sup> However, this association is less prevalent in the general population. In a review of 12,776 fetal ultrasound examinations performed after 14 weeks' gestation, hyperechoic bowel was noted in only 30 fetuses (0.2%)<sup>51</sup> and CF was found in 13.3%. Whereas an echogenic bowel wall noted in the third trimester is often thought to be diagnostic, it is crucial to note that hyperechoic bowel has been found to be a normal variant in both the second and third trimesters.<sup>55,56,64</sup>

The finding of dilated bowel on prenatal ultrasonography, in association with CF, has been reported less frequently than that of hyperechoic bowel. In meconium ileus, bowel dilation is caused by obstruction from meconium but mimics findings in midgut volvulus, congenital bands, intestinal atresia, intestinal duplication, internal hernia, meconium plug syndrome, and Hirschsprung's disease.<sup>65</sup> The correlation of dilated fetal bowel and meconium ileus suggests that dilated fetal bowel warrants parental testing for CF and continued sonographic surveillance of the fetus.

Inability to visualize the gallbladder on fetal ultrasonography has also been associated with CF.<sup>66</sup> Combined with other sonographic features, nonvisualization of the gallbladder can be useful in the prenatal detection of the disease. However, caution should be exercised in the interpretation of an absent gallbladder because the differential diagnosis also includes biliary atresia, omphalocele, and diaphragmatic hernia.

Sonographic characteristics of fetal bowel obstruction are neither sensitive nor specific for meconium ileus, but the interpretation of these findings must include consideration of the risk of the fetus having CF. Certainly findings suggesting meconium ileus in the high-risk fetus indicate a high probability of CF.<sup>66</sup> In the low-risk fetus, suspicious ultrasound findings warrant

consideration of prenatal screening by DNA testing or, at the very least, serial follow-up examinations.

The utility of prenatal screening for CF in fetuses with intestinal obstruction was recently examined by prospectively reviewing patients with meconium ileus, meconium plug syndrome, meconium peritonitis, jejunoileal atresia, and volvulus. Prenatal sonographic signs were correlated with postnatal findings of CF and the type of bowel obstruction. Immuno-reactive trypsin measurement, genetic studies, and sweat tests were performed to evaluate for CF. Of the 80 patients reviewed, 30 (37.5%) had a prenatal diagnosis of an intestinal anomaly. The overall incidence of CF with a prenatal diagnosis of an intestinal anomaly was 13%, or 333 times the estimated risk of CF in the general population. A hyperechoic pattern with dilated bowel was associated with higher specificity for CF (100%), followed by hyperechoic bowel with ascites (75%). These authors suggest that prenatal screening for CF is indicated in all pregnancies with ultrasound patterns of specific intestinal disorders, and all neonates with any type of neonatal intestinal obstruction should be screened for CF.<sup>67</sup> Neonatal screening has also been noted to lead to better preservation of lung function in the long term, prevents severe malnutrition, and improves long-term growth in CF patients.<sup>68</sup>

## Clinical Presentation

Meconium ileus is categorized as either simple or complicated. Thickened meconium begins to form in utero. As it obstructs the mid-ileum, proximal small bowel dilatation and bowel wall thickening occur. Approximately one half of these neonates present with a simple uncomplicated obstruction.<sup>4</sup> The remaining patients present with complications of meconium ileus, including volvulus, gangrene, atresia, and perforation, which may result in meconium peritonitis and giant cystic meconium peritonitis.<sup>18,40,69-76</sup>

### Simple Meconium Ileus

In simple meconium ileus, the terminal ileum is filled with firm concretions, is small in diameter, and molds around the inspissated lumps of meconium. Proximally, the ileum becomes dilated and filled with thick sticky meconium with gas and fluid found within the small bowel proximal to this area.<sup>4</sup> Newborns with uncomplicated meconium ileus can appear healthy immediately after birth. However, within 1 to 2 days, they develop abdominal distention and bilious vomiting. Normal meconium will not be passed. Dilated loops of bowel become visible on examination and have a "doughy" character that indents on palpation.<sup>77</sup> The rectum and anus are often narrow, a finding that may be misinterpreted as anal stenosis.<sup>78</sup> The presentation of the patient with meconium ileus is similar to that of many types of neonatal small bowel obstructions. Therefore, the clinician should simultaneously consider and evaluate for malrotation, small intestinal atresia, colonic atresia, and meconium plug syndrome.

The history, physical examination, and contrast enema help make the distinction between these conditions.

### Complicated Meconium Ileus

Complicated meconium ileus may present dramatically and immediately after birth. In others, symptoms will develop within 24 hours of birth. Signs of peritonitis (abdominal distention, tenderness, abdominal wall erythema), as well as clinical evidence of sepsis, may be present on the initial neonatal examination as a result of in-utero perforation or bowel compromise. Abdominal distention can be so severe as to cause immediate respiratory distress. A palpable mass suggests pseudocyst formation, which results from in-utero bowel perforation.<sup>77,78</sup> Often the neonate is in extremis and needs urgent resuscitation and surgical exploration.

Historically, segmental volvulus was reported to be the most common complication of meconium ileus.<sup>71,72</sup> Prenatal volvulus of the meconium-distended segment of ileum may lead to occlusion of the mesenteric blood flow and subsequent ischemic necrosis, intestinal atresia with an associated mesenteric defect, or perforation. When prenatal perforation occurs, most of the sterile meconium is reabsorbed, with trace amounts becoming calcified. Atretic segments are common in meconium ileus, and the affected bowel may appear viable with no evidence of perforation or gangrene. Twelve to 17 percent of neonates born with jejunoileal atresia have CF.<sup>4,79,80</sup> These observations indicate that all neonates with jejunoileal atresia and abnormal meconium presentation (e.g., meconium ileus, meconium plug syndrome, giant cystic meconium peritonitis) should undergo a sweat chloride test.<sup>4</sup>

The incidence of CF in neonates with meconium peritonitis is reported to be 15% to 40%. Four types of meconium peritonitis have been recognized, including adhesive meconium peritonitis, giant cystic meconium peritonitis or pseudocyst, meconium ascites, and infected meconium peritonitis.<sup>81</sup> Each form of meconium peritonitis shares a common etiology, namely, bowel perforation. The differences in clinical presentation are secondary to the timing of perforation and whether the perforation seals spontaneously. The site of perforation is usually closed by birth. However, mortality is increased in cases in which the perforation remains patent.<sup>82</sup> Initially, meconium peritonitis is a nonbacterial, chemical and foreign body peritonitis occurring during intrauterine or early neonatal life.<sup>83</sup> As meconium escapes from the obstructed bowel, a sterile chemical peritonitis ensues. After delivery, however, bacterial superinfection may occur with colonization of the gastrointestinal tract. It is important to note that meconium peritonitis may also occur without meconium ileus and is not pathognomonic for CF.<sup>4,76</sup>

### Radiographic Features

Uncomplicated meconium ileus is characterized by a pattern of unevenly dilated loops of bowel with the variable presence of air-fluid levels on abdominal

**Figure 33-4.** This abdominal radiograph in a neonate with meconium ileus shows the typical ground-glass appearance in the right lower abdomen. Also note the different-sized loops of distended small bowel.

radiography.<sup>73,84,85</sup> The absence of air-fluid levels is due to the increased viscosity of the meconium not allowing an air interface with the fluid. As swallowed air mixes with the tenacious meconium, bubbles of gas develop. This ground-glass appearance (Fig. 33-4) depends on the viscosity of the meconium and is not a constant feature.<sup>73,84</sup> Although each of these features alone is not diagnostic of meconium ileus, collectively with a family history of CF, they strongly suggest the diagnosis.<sup>86</sup>

Radiographic findings in complicated meconium ileus vary with the complication. Prenatal ultrasound findings include ascites, intra-abdominal cystic masses, dilated bowel, and calcifications.<sup>87</sup> Neonatal radiographic findings may include peritoneal calcifications, free air, and/or air-fluid levels (related to atresia).<sup>4</sup> Air-fluid levels may be few or absent, misleading the clinician to make an incorrect diagnosis of uncomplicated meconium ileus. Speckled calcification on abdominal plain films is highly suggestive of intrauterine intestinal perforation and meconium peritonitis. A large dense mass with a rim of calcification implies a pseudocyst (Fig. 33-5). When present, these calcium deposits are linear, coursing from the parietal peritoneum to the serosal surface of the visceral organs.<sup>88</sup> Interestingly, one third of cases of complicated meconium ileus have no radiologic findings suggesting a complication of meconium ileus.<sup>89</sup>

A contrast enema should be performed when there is evidence of a low intestinal obstruction in the newborn. We advocate a hyperosmolar, water-soluble contrast enema for both diagnosis and treatment. In

**Figure 33-5.** This neonate presented with evidence of meconium peritonitis. A mass effect in the left abdomen with a rim of calcification (arrows) implies in-utero perforation and a pseudocyst.

meconium ileus, the contrast enema reveals a small-caliber colon, a “microcolon of disuse,” which often contains small, inspissated “rabbit pellets” of meconium (Fig. 33-6). If contrast medium cannot be refluxed into the dilated small bowel, operative exploration is required for diagnosis and therapy.

## Diagnostic Testing

The diagnosis of CF is established with a sweat test at several weeks of life. A concentration of 60 mmol/L in 100 mg of sweat is diagnostic of CF with 40 to 60 mmol/L being intermediate (but more likely to be diagnostic in infants) and less than 40 mmol/L being normal. To ensure an adequate sweat sample, the test is typically performed at several weeks of life.<sup>90</sup> Neonatal CF screening programs using the Guthrie blood spot test for raised concentrations of immunoreactive trypsinogen are available in many countries but must be confirmed in a two-stage approach incorporating *CFTR* mutation analysis.<sup>91,92</sup> Genetic testing for *CFTR* mutations is available, but commercial assays test for a limited number of mutations. Most regional laboratories will provide the results for the four or five most common mutations for the relevant ethnic group or geographic region in their area using the amplification refractory mutation system (ARMS) technique.<sup>91</sup> Stool analyses for albumin, trypsin, and chymotrypsin are available, and abnormal values coupled with operative findings indicate CF.<sup>18</sup>

**Figure 33-6.** Classic radiographic findings of meconium ileus are seen on this retrograde contrast study. First, a “microcolon of disuse” is seen. The colon is extremely small and unused. Second, inspissated pellets (filling defects) of meconium are seen in the more proximal small bowel. Third, note there is a small bowel obstruction as the contrast material has not reached the markedly dilated loops of small bowel.

Neonates with meconium ileus who fail to respond to nonoperative measures may be treated by appendectomy and irrigation with a hyperosmolar contrast medium into the small bowel via the appendiceal stump or small bowel.<sup>93</sup> The appendix (or intestinal biopsy) may be sent for histologic examination. Pathognomonic findings for CF include goblet cell hyperplasia and accumulated secretions within the crypts or lumen.<sup>94</sup>

## Treatment

### Nonoperative Management of Simple Meconium Ileus

Treatment of meconium ileus has evolved over the past 55 years. Neonates should initially be managed as having a newborn intestinal obstruction. Volume resuscitation, gastric decompression, and mechanical respiratory support should be provided as necessary. Correction of any coagulation disorders and empirical broad-spectrum antibiotic coverage complete this initial management. When meconium ileus is suspected or diagnosed, a diagnostic enema or hyperosmolar enema is performed initially to exclude other causes of neonatal intestinal obstruction. Many newborns with meconium ileus can be managed nonoperatively with hyperosmolar enema washouts (Table 33-1).

**Table 33-1** Commonly Used Contrast Materials for Meconium Ileus Patients

	Gastrografin (Bracco)	Conray 43 (Mallinckrodt)	Omnipaque 240 (GE Healthcare)	Omnipaque 300 (GE Healthcare)
Chemical Structure	Ionic	Ionic	Iohexol	Iohexol
Anion	Diatrizoate	Iothalamate	Nonionic	Nonionic
Cation	Meglumine sodium	Meglumine	None	None
% Salt Concentration	6610	43	24	30
% Iodine Concentration	37	20.2	24	30
Iodine + (mg I/mL)	370	20.2	240	300
Viscosity + 25° C (cps)		≈3	5.8	11.8
Viscosity + 25° C (cps)	8.4	≈2	3.4	6.3
Osmolality (mOsm/kg H <sub>2</sub> O)	1940	≈100	520	672

On instillation, fluid is drawn into the intestinal lumen, hydrating and softening the meconium mass. Both transient osmotic diarrhea and diuresis follow. Thus, adequate resuscitation and hydration anticipating these fluid losses is important. Additionally, they should receive appropriate electrolyte repletion and maintenance of normothermia. These enemas are contraindicated in patients with complicated meconium ileus. The hypertonic enema must be performed under fluoroscopic control. Close surgical supervision, from the initial evaluation and throughout the hospital course, is mandatory, and the patient should be prepared for immediate operation should complications develop.<sup>89</sup>

Under fluoroscopic control, a 25% to 50% dilution of the hyperosmolar enema is slowly infused at low hydrostatic pressure through a catheter inserted into the rectum. Balloon inflation should be avoided to minimize the risk of rectal perforation. Usually there is rapid passage of meconium “pellets” followed by semiliquid meconium, which continues in the ensuing 24 to 48 hours. On completion of the enema, the catheter is withdrawn and an abdominal radiograph is obtained to evaluate for perforation. The infant is then returned to the neonatal care unit for intensive monitoring and fluid resuscitation. Warm saline enemas containing 1% *N*-acetylcysteine (Mucomyst; Apothecan, Princeton, NJ) may be given to help complete the meconium evacuation.<sup>77</sup> Radiographs should be taken in 8 to 12 hours, or as clinically indicated, to confirm evacuation of the obstruction and to exclude late perforation. If evacuation is incomplete, or if the first attempt at hyperosmolar enema evacuation does not reflux contrast medium into dilated bowel, a second enema may be necessary. However, if progressive distention, signs of peritonitis, or clinical deterioration occurs, surgical exploration is indicated. After two failed attempts at nonoperative hyperosmolar washout, operative intervention is needed.

After successful evacuation and resuscitation, 5 mL of a 10% *N*-acetylcysteine solution may be administered every 6 hours through a nasogastric tube to liquefy upper gastrointestinal secretions. Feedings, with supplemental pancreatic enzymes for those infants confirmed with CF, may be initiated when signs of obstruction have subsided.<sup>95</sup> The success rate of babies with uncomplicated

meconium ileus treated with hyperosmolar enemas ranges between 63% and 83%.<sup>96</sup>

Several potential complications exist with the use of hyperosmolar enemas in treating meconium ileus. The risk of rectal perforation can be avoided by careful placement of the catheter under fluoroscopic guidance and not inflating the balloon-tipped catheter. A 23% perforation rate has been demonstrated in patients when inflated balloon catheters were used.<sup>97</sup> Early perforation, occurring during the administration of the enema, is usually apparent under fluoroscopy. The risk of perforation increases with repeated enemas.<sup>98</sup> Late perforation, occurring between 12 and 48 hours after the enema, can occur. Potential causes for late perforation include severe bowel distention by fluid osmotically drawn into the intestine or by direct injury to the bowel mucosa by the contrast medium.<sup>98</sup> The former appears to be the etiology in experimental models.<sup>99,100</sup> Delayed perforation associated with extensive bowel necrosis has been reported.<sup>101,102</sup> The pathogenesis of intestinal perforation associated with necrotizing enterocolitis is believed to be the ischemia produced by intestinal distention.<sup>101</sup> Hypovolemic shock is also a risk when delivering hypertonic enemas. Ischemia caused by overdistention is worsened by hypoperfusion caused by hypovolemia due to inadequate fluid resuscitation. Adequate fluid resuscitation (150 mL/kg/day, minimum) with anticipation of fluid losses due to osmotic diarrhea and diuresis is mandatory and should be initiated at the time of the enema.<sup>101</sup>

## Operative Management

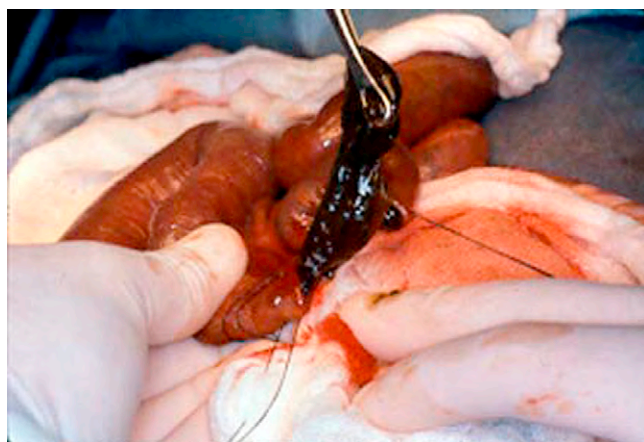

### SIMPLE MECONIUM ILEUS

The indications for operative management of simple meconium ileus are inadequate meconium evacuation or a complication of the contrast enema (e.g., perforation). Failure of nonoperative treatment with hyperosmolar enemas may result from the technical inability to advance the enema column for a sufficient distance into the ileum or from an unsuspected, associated intestinal atresia. If the enema fails to promote passage of meconium within 24 to 48 hours, or two attempts at washout are unsuccessful, an operative approach is indicated.

Before the widespread acceptance of enemas and an initial nonoperative approach, several operative strategies predominated as initial therapy.<sup>50</sup> Many of these techniques involved the use of proximal and distal stomas. This approach provided for decompression of the dilated proximal intestine and provided access for intestinal irrigation.

In 1948, the first successful operative management of five infants with meconium ileus by intraoperative meconium disimpaction with saline via a tube enterostomy coupled with a limited small bowel resection was reported.<sup>103</sup> Enterotomy and intraoperative saline irrigation for mechanical separation of the pellets from the bowel wall and evacuation of the meconium continues to be the mainstay of operative therapy for simple meconium ileus.

With either operative approach, manual evacuation of the inspissated meconium can be aided by intraoperative instillation of 2% or 4% *N*-acetylcysteine or 50% hyperosmolar solutions. A purse-string suture is placed in the antimesenteric wall of the small bowel proximal to the obstruction, and a red rubber catheter is inserted through a small incision within the purse-string. This is followed by gentle instillation of the solution into the terminal ileum. Often the thick tenacious meconium must be removed directly through the enterotomy (Fig. 33-7), while the dissolved meconium and the pellets can be either removed directly or milked into the colon. A similar technique was reported in 1989 in which an appendectomy was performed and a cecostomy catheter was placed through the appendiceal stump to irrigate and evacuate impacted meconium.<sup>93</sup> With either technique, the surgeon must take care to avoid exposure of the meconium to the peritoneal cavity. Once the meconium is cleared, the enterotomy or appendiceal stump can be closed. In some situations, an indwelling intestinal catheter or a T-tube may be left in the enterotomy for the purpose of postoperative bowel irrigation, decompression, pancreatic enzyme instillation, and/or feeding.<sup>104</sup> The T-tube or enterostomy tube should be left at the junction of the proximal dilated bowel and collapsed distal ileum. The

**Figure 33-7.** At operation, the meconium in a neonate with cystic fibrosis is very thick and tenacious.

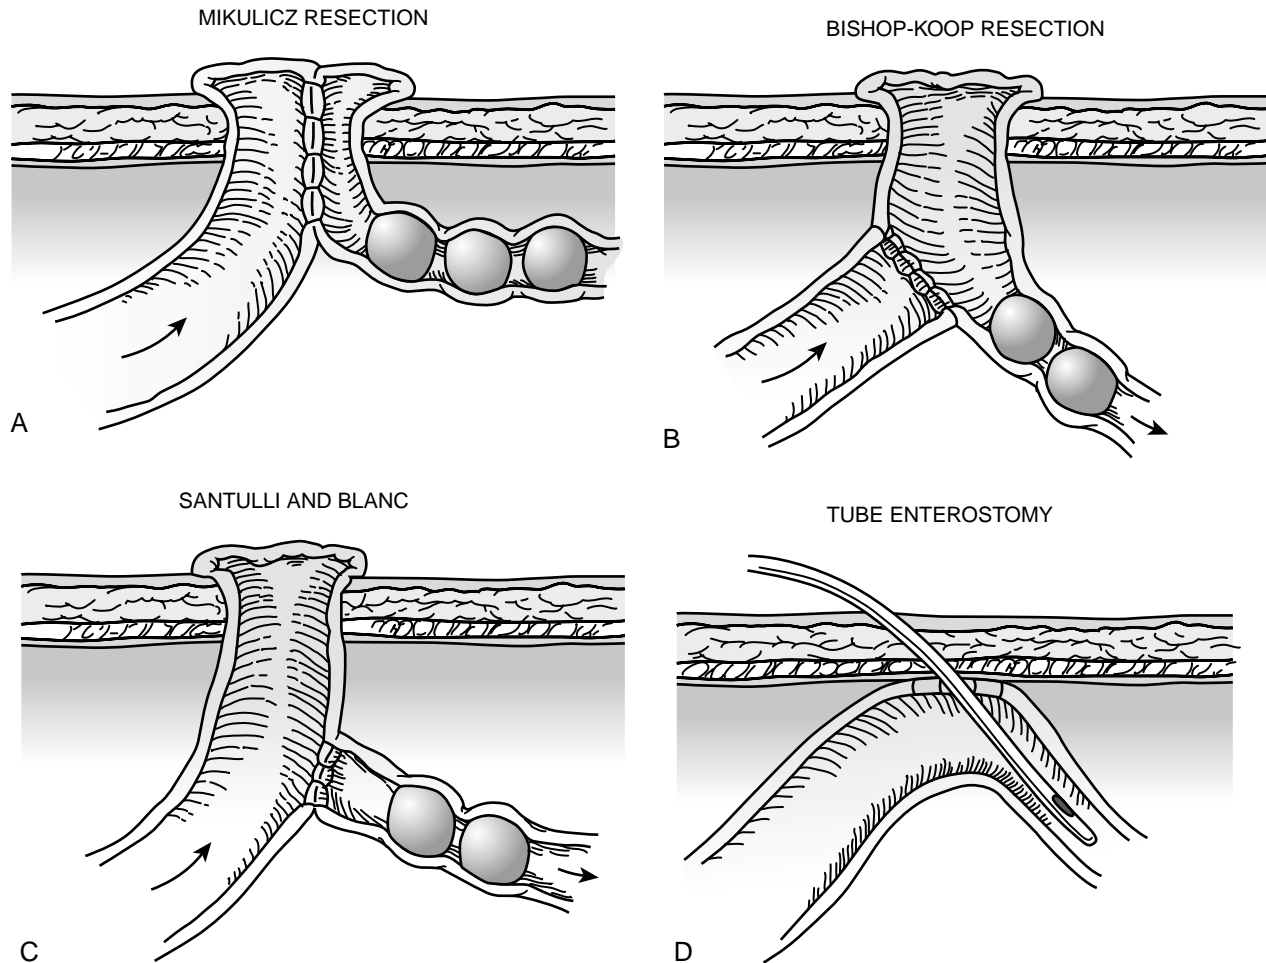

irrigations are begun in the early postoperative period. After successful clearance of meconium, the tubes are removed and the enterocutaneous fistula is allowed to close spontaneously.<sup>69,74,77,93,105-108</sup>

Resection with primary anastomosis was first described in 1962.<sup>108</sup> Anastomotic leakage complicated early attempts with this approach. Since then improved results have been reported.<sup>109,110</sup> An alternative to this approach was small bowel resection with creation of a stoma and eventual closure of the stoma with an end-to-end anastomosis. Successful outcome after resection with primary anastomosis depends on adequate resection of compromised bowel, complete proximal and distal evacuation of meconium, and preservation of adequate blood supply to the anastomosis.

Alternative surgical techniques involve resection, anastomosis, and temporary enterostomy through which postoperative irrigations may be delivered (Fig. 33-8). The Mikulicz double-barreled enterostomy has three distinct advantages. First, operative and anesthesia times are reduced because complete evacuation of inspissated meconium is not necessary. Second, an intra-abdominal anastomosis is averted, avoiding the risk of anastomotic leakage. Third, the bowel is opened after complete closure of the abdominal wound, thereby reducing the risk of intraperitoneal contamination. Solubilizing agents are administered postoperatively through both the proximal and distal limbs of the stoma as well as per rectum or via a nasogastric tube.<sup>86,106</sup> As classically described, a spur-crushing Mikulicz clamp may be applied to the two limbs to create continuity for distal flow of intestinal fluids. The clamp-induced anastomosis may spontaneously close after relief of the distal obstruction (inspissated meconium). Disadvantages of this and other procedures employing resection and stoma(s) are potential postoperative fluid losses through high volume stomas, bowel shortening by resection, and the need for a second procedure to re-establish intestinal continuity.

A distal chimney enterostomy (the Bishop-Koop procedure) involves resection with anastomosis between the end of the proximal segment and the side of the distal segment of bowel approximately 4 cm from the opening of the distal segment. The distal end is brought out as the ileostomy.<sup>105</sup> This technique allows for normal gastrointestinal transit while providing a means for management of the distal obstruction through the ileostomy should it occur. The reverse of the distal chimney enterostomy is the Santulli and Blanc proximal enterostomy. After resection, the end of the distal limb is anastomosed to the side of the proximal limb. The end of the proximal limb is brought out as the enterostomy.<sup>74,111</sup> With this arrangement, proximal irrigation and decompression are enhanced and it is not necessary to evacuate the proximal small bowel at the time of surgery. Like the distal chimney enterostomy, catheter access to the distal limb is achieved through the stoma, thus providing a means of irrigating the distal bowel. The apparent disadvantage of this technique is the presence of a high-output stoma and the inherent risk of dehydration and electrolyte derangement.

**Figure 33-8.** There are a number of options for surgical management of a neonate with meconium ileus. Options for creation of an ileostomy include the double-barrel ileostomy (Mikulicz enterostomy) (A), the Bishop-Koop ileostomy (B), and the Santulli ileostomy (C). Both the Bishop-Koop and Santulli ileostomies require an intra-abdominal anastomosis. Another option is to place a red rubber catheter into the uninvolved proximal small bowel for postoperative irrigations (D).

Care must be taken to replenish fluids, electrolytes, and nutrients in accordance with the stoma output. Re-instillation of stoma output from the proximal to the distal limb is often performed via the indwelling catheter.<sup>74,86</sup>

### COMPLICATED MECONIUM ILEUS

An operation is almost always indicated in cases of complicated meconium ileus. One exception is a rare in-utero spontaneously sealed perforation with intact intestinal continuity and extraluminal intraperitoneal calcified meconium.<sup>73</sup> Additional findings seen later in life include calcified meconium identified in a patent processus vaginalis during herniorrhaphy or incidentally on an abdominal radiograph. Indications for operation include peritonitis, persistent intestinal obstruction, an enlarging abdominal mass, and ongoing sepsis. Surgical management includes early diagnosis, debridement of necrotic material, pseudocyst resection, diverting stoma(s), antibiotics, and meticulous postoperative care.<sup>76</sup> Creation of an ostomy is the fastest and safest course, alleviating concern over bowel discrepancy, anastomotic breakdown, and return of bowel

activity. Decortication of the cyst wall is recommended, if possible.

Whereas meconium peritonitis is best managed in this fashion, both segmental volvulus and intestinal atresia in stable patients without peritoneal contamination may be managed with resection, irrigation of the bowel to remove inspissated contents, and an end-to-end or end-to-oblique anastomosis depending on the size of the intestine. The goal of operative management is the relief of intestinal obstruction and the preservation of maximal intestinal length.

### Postoperative Management

The initial postoperative management involves ongoing resuscitation. Maintenance fluids and replacement of insensible fluid losses, as well as gastrointestinal losses (nasogastric suction and ileostomy) must be carefully monitored. Instillation of 2% or 4% *N*-acetylcysteine via a nasogastric tube or ileostomy will help solubilize residual meconium. In the patient with fetal or neonatal bowel obstruction, CF must be suspected, and diagnostic tests should be performed

as soon as possible. Stomas placed in the course of surgical management should be closed as soon as possible (4 to 6 weeks) to help avoid prolonged problems with fluid, electrolyte, nutritional losses, and cholestatic jaundice.

### Nutritional Management

With relief of the obstruction and resumption of bowel function, infants with uncomplicated meconium ileus and CF may be given breast milk or infant formula, along with supplemental pancreatic enzymes and vitamins.<sup>112,113</sup> Caution must be used when prescribing enteric enzyme medication to patients with meconium ileus and CF. Treatment failures and complications, such as fibrosing colonopathy from excessive enzyme doses<sup>112</sup> and meconium ileus equivalent, or distal intestinal obstruction syndrome (DIOS),<sup>47</sup> from inadequate enzyme therapy or generic substitutions for proprietary medications have been reported.<sup>114-116</sup> Those with a complicated surgical course will require either continuous enteral feeds or total parenteral nutrition (TPN). Dilation of the small bowel by the obstructing meconium may lead to mucosal damage that could contribute to poor peristalsis or malabsorption. In patients with complicated meconium ileus or in those with significant loss of intestinal length, we recommend beginning feeding with predigested, diluted formula at low continuous volumes. If this is well tolerated, the strength may be increased followed by the volume, while observing for signs of feeding intolerance (i.e., abdominal distention, heme-positive stools, and/or emesis). Once enteral feedings are begun, pancreatic enzymes must be given (even with predigested formula) starting at 2000 to 4000 lipase units per 120 mL of full-strength formula. Capsules containing enteric-coated microspheres can be opened and the contents mixed with formula or applesauce in older infants. The microcapsules should not be crushed because this will expose the enzymes to the acid of the stomach where they will be destroyed. Uncrushed pancreatic enzymes should be given, even with medium-chain triglyceride/oil-containing formulas.<sup>117</sup>
